These methodologies need domain-specific pattern dictionaries that must be built for each different kind of information. However, none of these methods can be directly applied to generic information. Thus we decide to bypass these two obstacles: our approach is based on the utilization of an existing electronic dictionary, in order to expand the data in a document to equivalent forms extracted from that dictionary.

Our method deals with the identification of semantic contents in documents through a lexical, syntactic and semantic analysis. It then becomes possible to enrich words and multi-word expressions in a document with synonyms, synonymous expressions, semantic information etc. extracted from the dictionary.

2. Problems and Prospects

As for a lot of methodologies developed for natural language processing, the results of a method of information extraction are evaluated by two measures: precision and recall. Precision is the ratio of correctly extracted items to the number of items both correctly and erroneously extracted from the text; noise is the ratio of the faulty extracted items to all the achieved extractions. Recall is the ratio of correctly extracted items to the number of items actually present in the text. The problem consists in improving both precision and recall.

2.1. Recall improvement

A usual technique to improve the recall consists of enriching a text with a list of synonyms or near-synonyms for each word of that text. For example, all the synonyms of "climb" would be added to the document, even though some of those meanings have a remote semantic connection to the text. By this kind of enrichment, all the ways to express the same token (but not the same meaning) are taken into account.

This type of enrichment can be extended to synonymous expressions with a robust parser: syntactic dependencies and their arguments (the tokens belonging to the selected expression) are enlarged to dependencies that are generated out of the corresponding synonymous expressions.

[1] We use the term "structured text" to refer to what the database community calls semi-structured text; "semi-structured text" is ungrammatical and often telegraphic text that does not follow any rigid format; "free text" is simply grammatical text (Soderland, 1999).

The recall is usually optimised to the detriment of the precision with those techniques, since most words within a set of synonyms are themselves polysemous and are seldom equivalent for each of their meanings. Thus, a simply adding of all those polysemous synonyms in a document introduces meaning inconsistencies. Noise may stem from these inconsistencies.

2.2. Reduction of noise – Precision improvement

We notice that improving the recall using synonyms may often increase the noise. Although identified in the domain of IE, this problem is not yet solved and it has a negative influence on the system effectiveness. Our purpose is to use the linguistic context of the polysemous tokens to identify their meanings and select contextual synonyms or synonymous expressions. This approach should improve the precision in comparison with adding all the synonyms.

Sentences in the text:

La température **grimpe**.
(The temperature is climbing.)

Corresponding set of synonyms:

escalader	*monter*
(to climb)	*(to go up)*
sauter	*augmenter*
(to jump)	*(to increase)*
se hisser sur	
(to heave oneself up onto)	

Sentences resulting from the enrichment:

La temperature escalade.
La temperature ***monte****.*
La temperature saute.
La temperature ***augmente****.*
La temperature se hisse sur (???).

Figure 1: Enrichment by a list of synonyms.

For example, the dictionary [2] entry for the word *grimper* contains a set of 5 synonyms. If we use these synonyms to enrich the original text, we obtain five variations of the original sentence. Only the second and the fourth of the enriching variations are accurate in this context. The meteorological context associated with the word *température* in the dictionary should correctly discriminate the synonyms in this context: in the dictionary, each synonym of a lemma is associated with a meaning of this lemma and with the typical linguistic context of the lemma in this sense.

Consequently, we decided to use the linguistic context of the words that can be enriched to discriminate which synonyms should be used and which should not. The synonyms are stored in the dictionary according to the sense of each lemma. So, the task amounts to performing a lexical semantic disambiguation of the text and using synonymous expressions in the selected meanings to enrich the document.

3. Enrichment method by WSD

3.1. Our experience in WSD

We previously have developed a range of tools and techniques to perform Word Sense Disambiguation (WSD), for French and English. The basic idea is to use a dictionary as a tagged corpus in order to extract semantic disambiguation rules, (Brun et al., 2002; Brun, 2000; Brun and Segond, 2001; Dini et al., 1998; Dini et al., 2000). Since electronic dictionaries exist for many languages and they encode fine-grained reliable sense distinctions, be they monolingual or bilingual, we decided to take advantage of this detailed information in order to extract a semantic disambiguation rule database [3]. The disambiguation rules associate each word with a sense number taking the context into account. For bilingual dictionaries the sense number is associated with a translation, for monolingual dictionaries with a definition. WSD is therefore performed according to sense distinctions of a given dictionary. The linguistic rules have been created using functional dependencies provided by an incremental shallow parser (IFSP, (Ait-Mokhtar and Chanod, 1997)), semantic tags from an ontology (45 classes from WordNet (Feldbaum, 1998) for English) as well as information encoded in SGML tags of dictionaries. This method comprises two stages, rule extraction and rule application.

- Rule extraction process: for each entry of the dictionary, and then for each sense of the entry, examples are parsed with the IFSP shallow parser. The shallow parsing task includes tokenization, morphological analysis, tagging, chunking, extraction of functional dependencies, such as subject and object (SUBJ(X, Y), DOBJ (X, Y)), etc. For instance, parsing the dictionary example attached to one particular sense $\mathbf{S}_i$ of *drift* :

  1)The country is drifting towards recession.

  Gives as output the following chunks and dependencies :

  [SC [NP The country NP]/SUBJ :v is drifting SC] [PP towards recession PP] SUBJ(country, drift) VMOD-OBJ(drift, towards, recession)

  Using both the output of the shallow parser and the sense numbering from the dictionary we extract the following semantic disambiguation rule: When the ambiguous word "drift" has *country* as subject and/or *toward recession* as modifier, it can be disambiguated with its sense $\mathbf{S}_i$. We repeat this process as all dictionary example phrases in order to extract the word level rules, so called because they match the lexical context.

[2] The dictionary we use is a French electronic one (Dubois and Dubois-Charlier, 1997). We will give a more detailed information about it later.

[3] The English dictionary contained 39 755 entries and 74 858 senses, ie a polysemy of 1.88; the French dictionary contained 38 944 entries and 69 432 senses, ie a polysemy of 1.78

Finally, for each rule already built, we use semantic classes from an ontology in order to generalize the scope of the rules. In the above example the subject "country" is replaced in the semantic disambiguation rule by its ambiguity class. We call ambiguity class of a word, the set of WordNet tags associated with it. Each word level rule generates an associated class level rule, so called because it matches the semantic context: when the ambiguous word "drift" has a word belonging to the WordNet ambiguity class *noun.location* and *noun.group* as subject and/or a word belonging to the WordNet ambiguity class *noun.shape*, *noun.act*, and *noun.state* as modifier, it disambiguates with its sense $\mathbf{S}_i$. Once all entries are processed, we can use the disambiguation rule database to disambiguates new unseen texts. For French, semantic classes (69 distinctive characteristics) provided by the *AlethDic* dictionary (Gsi-Erli, 1994) have been used with the same methodology.

- Rule application process: The rule applier matches rules of the semantic database against new unseen input text using a preference strategy in order to disambiguate words on the fly. Suppose we want to disambiguate the word drift, in the sentence:

  2) In November 1938, after Kristallnacht, the world drifted towards military conflict.

  The dependencies extracted by the shallow parser, which might lead to a disambiguation, i.e., which involve *drift*, are:

  SUBJ(world, drift)
  VMODOBJ(drift, towards, conflict)

  The next step tries to match these dependencies with one or more rules in the semantic disambiguation database. First, the system tries to match lexical rules, which are more precise. If there is no match, then the system tries the semantic rules, using a distance calculus between rules and semantic context of the word in the text [4]. In this particular case, the two rules previously extracted match the semantic context of *drift*, because *world* and *country* shares semantic classes according to WordNet, as well as *conflict* and *recession*.

The methodology attempts to avoid the data acquisition bottleneck observed in WSD techniques. Thanks to this methodology, we built all-words (within the limits of the used dictionary) unsupervised Word Sense Disambiguator for French (precision: 65%, recall: 35%) and English (precision: 79%, recall: 34%).

3.2. Xerox Incremental Parser (XIP)

IFSP, which was used in the first experiments on semantic disambiguation at Xerox, has been implemented with transducers. Transducers proved to be an interesting formalism to implement quickly an efficient dependency parser, as long as syntactic rules would only be based on POS. The difficulty of using more refined information, such as syntactic features, drove us to implement a specific platform that would keep the same strategies of parsing as in IFSP, but would no longer rely on transducers.

This new platform (Ait-Mokhtar et al., 2001; Roux, 1999) comprises different sorts of rules that chunk and extract dependencies from a sequence of linguistics tokens, which is usually but not necessarily a sentence. The grammar of French that has been developed computes a large number of dependencies such as *Subject, Object, Oblique, NN* etc. These dependencies are used in specific rules, the disambiguation rules, to detect the syntactic and semantic information surrounding a given word in order to yield a list of words that are synonyms according to that context. Thus, a disambiguation rule manipulates together a list of semantic features originating from dictionaries, and a list of dependencies that have been computed so far. The result is a list of contextual synonyms.

If (Dependency$_0$(t, t^0) & ...& Dependency$_n$(t,t^k) & ... attribute$_p$(t^j)=v^u)

synonym(t) = s^0,...,s^n.

where

t^0,...,t^n is a list of token

s^0,...,s^n a list of synonyms.

Example:

- La température grimpe.
  (the temperature is climbing)
- La température augmente.
  (the temperature is rising)
- L'alpiniste grimpe le mont Ventoux.
  (the alpinist climbs the mount Ventoux)
- ???L'alpiniste augmente le mont Ventoux.
  (???the alpinist raises the mount Ventoux)

Figure 2: Application of a disambiguation rule for enrichment.

The contextual synonymy between *grimper* and *augmenter* can be defined with the following rule. The feature *MTO* is one of the semantic features that are associated with the entries of the Dubois dictionary. This feature is associated with each word that is connected to meteorology, such as *chaleur, froid, température* (heat, cold, température).

if (Subject(*grimper*, X) AND feature(X, *domain*)=MTO) synonym(*grimper*) = *augmenter*.

This rule applies on the above first example, *La température grimpe*, but fails to apply on the third sentence, *L'alpiniste grimpe le mont Ventoux*, since the subject does not bear the MTO feature.

[4] The first parameter of this metric is the intersection of the rule classes and the context classes; the second one is the union of the rule classes and the context classes. Distance equals the ratio of intersection to union.

3.3. Which WSD for which enrichment?

3.3.1. A very rich dictionary information

The new robust parser offers a flexible formalism and the possibility to handle semantic or other features. In addition to this parser, the semantic disambiguation now uses a monolingual French dictionary (Dubois and Dubois-Charlier, 1997). This dictionary contains many kind of information in the lexical field as well as in the syntactic or the semantic one. From the 115 229 entries of this dictionary, we can only use the 38 965 ones that are covered by the morphological analyser. These entries represent 68 588 senses, ie a polysemy of 1.76.

We build lexico-syntactic WSD rules using the methodology presented above (cf. section 3.1.): examples of the dictionary are parsed; extracted syntactic relations and their arguments are used to create the rules. We also make the most of the domain indication (171 different domains) to generalize the example rules (see later for details) – as previously done using WordNet for the English WSD and by AlethDic for the French one (Brun et al., 2002).

We use the specificity of the dictionary to improve the disambiguation task as far as possible in order to maximize the enrichment of the documents. The information of this dictionary is divided into several fields: domain, example, morphological variations, derived or root words, synonyms, POS, meaning, estimate of use frequency in the common language; in the verbal part of the dictionary only, syntactico-semantic class and subcategorization patterns of the arguments of the verb. Resulting WSD rules are spread over three levels reflecting the abstraction register of the dictionary fields.

3.3.2. Disambiguation rules at various levels

We build a disambiguation rule database at three levels: rules at word level (23 986), rules at domain level (22 790) and rules at syntactico-semantic level (40 736).

Word level rules use lexical information from the examples. They correspond to the basic rules in the previous system, which use constraints on words and syntactic relations. These dependencies are extracted from the illustrative examples from the dictionary.

L'avion de la société **décrit** un large cercle avant de (…)
*(The company's plane **describes** a wide circle before (…))*
SUBJECT(décrire,avion)
OBJECT(décrire,cercle)

Example in the dictionary for the entry "décrire":
L'avion décrit un cercle.
(The plane describes a circle.)
SUBJECT(décrire,avion)
OBJECT(décrire,cercle)

Figure 3: WSD at word level.

Rules at domain level are generalized from word level rules: instead of using the words of the examples as arguments of the syntactic relations in the rules, we replace them by the domains they belong to. These rules correspond to the class level rules in the previous system, but an improvement in comparison with them is that in some cases, we can discriminate the right domain if the argument is polysemous. This is mainly due to the internal consistency of the dictionary that enables the correspondences of domain across different arguments of a dependency. The consistency should help to reduce the noise.

L'escadrille décrit son approche vers l'aéroport où (…)
(The squadron describes its approach to the airport where (…))
SUBJECT(décrire,escadrille[dom:AER])
OBJECT(décrire,approche[dom:LOC])

Example in the dictionary for the entry "décrire":
L'avion décrit un cercle.
(The plane describes a circle.)
SUBJECT(décrire,avion[dom:AER])
OBJECT(décrire,cercle[dom:LOC])

Figure 4: WSD at domain level.

We don't rule out the possibility of using other lexico-semantic resources to generalize or expand this kind of rules, as we did previously using French EuroWordNet or AlethDic. These lexicons present the advantage of a hierarchical structure that doesn't exist for the domain field in the Dubois dictionary. Nevertheless, we will encounter the problem of the mapping of the various resources used by the system to avoid inconsistencies between them, as shown in (Ide and Véronis, 1990; **?**; Brun et al., 2002).

The third level of the rules currently in use in the semantic disambiguator is the syntactico-semantic one. The abstraction level of these rules is even higher than in the domain level. They are built from a syntactic pattern of subcategorization that indicates the typical syntactic construction of the current entry in its current meaning. Although the distinction between the arguments is very general – they are differentiated from human, animal and inanimate – our examination of the verbal dictionary indicates that, for 30% of the polysemous entries, this kind of rules is sufficient to choose the appropriate meaning.

3.4. Enrichment at various levels

WSD is not an end in itself. In our system, it is a means to select appropriate information in the dictionary to enrich a document. The quality and the variety of this enrichment vary according to the quality and the richness of the information in the dictionary. The variety of information allows several kind of enrichment.

For the specific task of information extraction, an index of the documents whose information is likely to be extracted is built. It allows the classification of all the linguistic realities extracted from text analysis. These realities are listed according to the XIP-formalism: syntactic relations,

L'escadrille décrit son approche vers l'aéroport where (...)
(The squadron describes its approach to the airport where(...))
SUBJECT(décrire,escadrille[dom:AER])
OBJECT(décrire,approche[dom:LOC])

Subcategorisation for the entry "décrire":
Transitive verb;
Subject inanimate.
SUBJECT(décrire,?[subcat:inanimate]) & OBJECT(décrire,?)

Figure 5: WSD at lexico-semantic level.

arguments, and features attached to the arguments. The enrichment is done inside the index because dependencies can be added without affecting the original document.

3.4.1. Lexical level

Replacing a word by its contextual synonyms is the easiest way to perform enrichment. This method of recall improvement is very common in IE, but in our system, the enrichment is targeted according to the context thanks to the semantic disambiguation. This process often reduces the noise. The enrichment is achieved by copying the dependencies containing the disambiguated word and by replacing this word by one of its synonyms.

La température grimpe.
(The temperature is climbing.)

Original index:
SUBJECT(grimper,température)

Set of targeted synonyms:
monter, augmenter.

Enriched index:
SUBJECT(grimper,température)
SUBJECT(monter,température)
SUBJECT(augmenter,température)

Figure 6: Enrichment at lexical level.

3.4.2. Lexico-syntactic level

The lexico-syntactic level of enrichment is more complex to achieve. The task consists in replacing a word by a multi-word expression (more than 14 000 synonyms are multi-word expressions in our dictionary) or in replacing a multi-word expression by a word, taking into account the words (lexical) and the dependencies between them (syntactic):

- Replacing a word by a multi-word expression (see figure 7):
  - Parse the multi-word expression to obtain dependencies;
  - Match the corresponding dependencies in the text;
  - Instantiate the missing arguments with the text arguments.
- Replacing a multi-word expression by a word:
  - Identify the POS of the word;
  - Select dependencies implying one and only one word of the multi-word expression;
  - Eliminate dependency where this word has a different POS;
  - Replace this word with its synonym in the remaining dependencies.

Le spécialiste a édité un manuscrit très abîmé.
(The specialist published a very damaged manuscript.)

Original index:
SUBJECT(éditer,spécialiste)
OBJECT(éditer,manuscrit)

Targeted synonymous expression:
établir l'édition critique de

Extracted dependencies from the expression:
SUBJECT(établir,?)
OBJECT(établir,édition)
EPITHET(édition,critique)
PP(édition,de,?)

Enriched index:
SUBJECT(éditer,spécialiste)
OBJECT(éditer,manuscrit)
SUBJECT(établir,spécialiste)
OBJECT(établir,édition)
EPITHET(édition,critique)
PP(édition,de,manuscrit)

Figure 7: Enrichment at lexico-syntactic level.

Since our work is based on the Dubois dictionary – whose entries are single words – most of the enrichment is one-to-one word. When a multi-word expression appears in the synonyms list, a single word has to be replaced by a multi-word expression, and the inverse process can be achieved if necessary. The complex case of replacing a multi-word expression by another multi-word expression could arise, but we never encounter this situation. The replacement of a multi-word expression by another is not yet implemented because of the complexity of the process. Nevertheless, the system relies on relations and arguments that are easy to handle, very simple and modular. These characteristics should allow us to bypass the inherent complexity of these structures.

3.4.3. A semantic level example

Syntactico-semantic fields in the dictionary allow a third enrichment level. The syntactico-semantic class structure contains very useful information that makes it possible to link verbs that are semantically related but lexically and syntactically very different. It might be interesting to semantically link *vendre* ("to sell", class D2a) and *acheter* ("to buy", class D2c) even though their respective actors are inverted. For example, *le marchand vend un produit au client* (the trader sells a product to the customer) bears the same meaning as *le client achète un produit au marchand* (the customer buys a product from the trader). The semantic class gives a general meaning of the verb(D2, meaning *donner, obtenir*, to give, to obtain), while the syntactic pattern (a for *vendre*: *fournir qc qn*, to supply so with sth, transitive with a oblique compliment, c for *acheter*: *prendre qc qn*, to take sth to so, transitive with a oblique compliment) yields the semantic realization.

Le papa offre un cadeau à sa fille.
(The father is giving a present to his daughter.)

Original index:
SUBJECT(offrir,papa)
OBJECT(offrir,cadeau)
OBLIQUE(offrir,fille)

offrir 01: D2a (to give sth to sb)
D2a corresponds to D2e (receive, obtain sth from sb).
recevoir 01: D2e

Enriched index:
SUBJECT(offrir,papa)
OBJECT(offrir,cadeau)
OBLIQUE(offrir,fille)
SUBJECT(recevoir,fille)
OBJECT(recevoir,cadeau)
????(recevoir,de,papa)

Figure 8: Enrichment at semantic level.

In a same perspective, a syntactico-semantic class constitutes another synonym set. Since this set is too general and too imprecise, it cannot be used to enrich a document. Still, it can be used as a last resort to enrich the query side when other methods have failed. We will not use this set as enrichment, but only to match a query by the class if the enrichment fails.

4. Evaluation

Though the method presented in this article is based on previous works, the use of other tools and lexical resource may have extended the potential of WSD rules. In particular, it is possible that the number of domains increase precision, and the use of subcategorization patterns may ensure more general rules to increase recall.

The partial evaluation we performed concerns 604 disambiguations in a corpus of 82 sentences from the French newspaper *Le Monde*. Precision in WSD is ratio of correct disambiguations to all disambiguations performed; recall is ratio of correct disambiguations to all possible disambiguations in the corpus. We distinguish the mistakes due to the method and the ones linked to our analysis tools in order to identify what we have to improve in order to increase the performance. These results are promising since both precision and recall are better than in the previous system.

Tokenization mistakes	44	7.28%
Tagging mistakes	19	3.15%
Parsing mistakes	9	1.49%
WSD mistakes	84	13.91%
Precision	**448**	**74.17%**
Recall		**43.61**%

Table 1: WSD method evaluation.

We note some remarks about this evaluation:

1. The lexicon used to perform tokenization has been modified in order to include additional information from the dictionary. We noticed during this evaluation some problems of coverage;

2. For this first prototype, we do not yet establish a strategy for cases in which multiple rules match. If more than one rule can be applied to the context, the sense is randomly chosen among the ones suggested by the matching rules [5];

3. Conversely, we do not yet try a strategy using the domain of disambiguated words as a general context to choose the corresponding meaning of a word to disambigate.

During the evaluation, we also notice that when a result was correct, the suggested synonymous expressions were always correct for the disambiguated word in this context. Our method for an optimized enrichment is validated.

5. Conclusion

In this paper, we present an original method for processing documents, preparing the text for information extraction. The goal of this processing is to expand each concept by the largest list of contextualy synonymous expressions in order to match a request corresponding to this concept.

Therefore, we implement an enrichment methodology applied to words and multi-word expressions. In order to perform the enrichment task, we have decided to use WSD to contextually identify the appropriate meaning of the expressions to expand. Inconsistent enrichment by synonyms is currently known as a major cause of noise in Information Extraction systems. Our strategy lets the system target the enriching synonymous expressions according to the semantic context. Moreover, this enrichment is achieved not

[5] This random choice is only performed for this evaluation and not in a IE perspective, since noise is better than silence in this field.

only with single synonymous words, but also with multi-word expressions that might be more complex than simple synonyms.

The WSD task and the resulting enrichment stage are achieved using syntactic dependencies extracted by a robust parser: the WSD is performed using lexico-semantic rules that indicate the preferred meaning according to the context. The linguistic information extracted from the analysis of the documents is indexed for the IE task. This index also stores additional new dependencies stemming from the enrichment process.

The utilization of a unique, all-purpose dictionary to achieve WSD and enrichment ensures the consistency of the methodology. Nevertheless, the information quality and richness of the dictionary might determine the system effectiveness.

The evaluation validates the quality of our method, which allows a great deal of lexical enrichment with less noise than is introduced by other enrichment methods. We have also indicated some ways our method could be expanded and our analysis tools could be improved. Our next step will be to test the effect of the enrichment in an IE task.

The method is designed to achieve a generic IE task, and the tools and resources are developed to process text data at a lexical level as well as at a syntactic or semantic level.

Abstract

This paper presents an automatic method for resolving the lexical ambiguity of nouns in any free-flowing text. The method exploits the noun taxonomy present in the WordNet and also the relative position of nouns in the given text, to construct semantic sets from the text. The semantic set has been defined as a collection of senses of words in given text that are related through the WordNet. Two different concepts of semantic distance between words have been explored and used for disambiguation. Hand-tagging of text and training are not required by the method presented in this paper. The method has been tested against SemCor, the tagged version of the Brown corpus and compared with previous unsupervised WSD algorithms. The method is supported by good empirical results.

1 Introduction

Any language uses words with multiple meanings. Before Information Retrieval or Semantic analysis of texts, it is essential to determine the true senses of those words. The problem of determining the right sense of words, in a context, is called *Word Sense Disambiguation* (WSD).

The typical approaches to the problem of WSD can be classified into 3 types: (1) *Supervised*, (2) *Unsupervised* and (3) *Cross-Lingual*.

Supervised Methods require resources like semantically annotated corpora to train the WSD system, and lexical resource like WordNet which provides the sense numbers using which the annotations are made. These algorithms, like the ones considered in [1], [2] and [3] use the corpora like Grolier's encyclopedia [1] or private sense-tagged data-sets [2]. However, the semantically annotated corpora are Laborious to construct and expensive, since tagging is done manually or at most semi-automatically.

Unsupervised Methods consider the statistically relevant co-occurance of individual keywords as classes and generate a class based model to predict which will be the most likely class to follow a particular keyword. The class is treated as an equivalent of sense. Unsupervised WSD methods can be further classified into two types, viz. WSD that makes use of the information provided by machine readable dictionaries: this is the case with the work reported by [10], [14], [4], [12] and [11]. And WSD that uses information gathered from raw corpora (unsupervised training methods); [1] and [13] presented unsupervised WSD methods using raw corpora.

From a multilingual point of view, word sense disambiguation is nothing more than determining the appropriate *translation* of a word or lexical item. Thus, translation presupposes word sense disambiguation. Word translation only requires only that the words should be expressing the same meaning. However, it is not necessary to know the exact meaning of the words. See [7] for further details.

2 WordNet

WordNet[9] is an online lexical reference system whose design is inspired by current psycholinguistic theories of human lexical memory. English nouns, verbs, adjectives and adverbs are organized into synonym sets, each representing one underlying lexical concept. Different relations link the synonym sets. WordNet was developed by the Cognitive Science Laboratory at Princeton University.

The WordNet consists of synsets arranged in semantic relationships with one another, through *hypernymy, hyponymy, holonymy, meronymy, synonymy* and *antonymy* relationships. In our discussion, we use WordNet as the only lexical resource and all the *senses* are with respect to the WordNet.

3 Semantic Set

Below is a sample text of 100 words, from the *Brown Corpus*, with some nouns underlined.

In the WordNet sub-graph in figure 2, the relationship between these nouns is shown. The words marked in ellipses are words that actually occur in the text.

The Fulton_County_Grand_Jury said Friday an investigation of Atlanta 's recent primary_election produced no *evidence* that any irregularities took_place. The jury further said in *term* end presentments that the City_Executive_Committee which had over-all charge of the election deserves the praise and thanks of the City_of_Atlanta for the manner in which the election was conducted The September-October *term* jury had been charged by Fulton Superior_Court_Judge_Durwood_Pye to investigate reports of possible irregularities in the hard-fought primary which was won by Mayor-nominate_Ivan_Allen_Jr ..... It recommended that Fulton legislators act to have these laws studied and revised to the end of modernizing and improving them. The grand_jury commented on a number of other *topics* among them the Atlanta and Fulton_County purchasing_departments which it said are well operated and follow generally accepted practices which inure to the best interest of both governments However the jury said it believes these two offices should be combined to achieve greater efficiency and reduce the cost of administration ... Implementation of Georgia 's automobile title *law* was also recommended by the outgoing jury It urged that the next Legislature provide enabling funds and re-set the effective date so_that an orderly implementation of the *law* may be effected. ... This is one of the major items in the Fulton_County general assistance *program* the jury said but the State_Welfare_Department has seen_fit to distribute these funds through the welfare departments of all the counties in the state with the exception of Fulton_County which receives none of_this money The jurors said they realize a proportionate distribution of these funds might disable this *program* in our less populous counties. The jurors said Failure to do this will continue to place a disproportionate *burden* on Fulton taxpayers.

Figure 1: Sample text from SemCor, br-a01 with the word *program* (word number 93) in consideration

The number in the brackets, by the side of the word, is its WordNet sense number. The numbers mentioned in the square brackets are the textual positions. For example, the word *law* appears in textual positions 66 and 72. The arrows going up-down show the *hyponymy* relations. Thus, 2 hyponyms of *sense number 1* of *cognition* are shown.

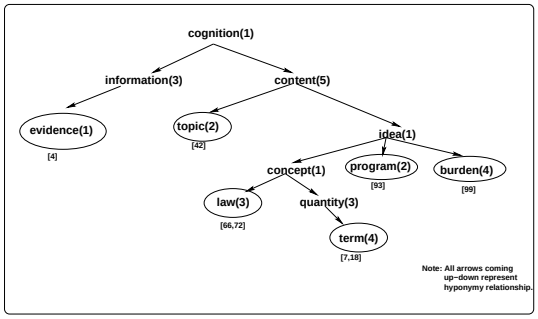

Figure 2: An extract of the WordNet graph, corresponding to the nouns underlined in figure 1

In the same way, one can consider the *holonymy*, *meronymy*, *synonymy* and *antonymy* relationships from the WordNet to capture all the nouns in a given piece of text. Consider the resultant WordNet subgraph. Also, suppose that distances are measured over edges, with every edge of unit distance and the distances are additive. Consider all the words that occur in the graph, within a distance of 4 from the 2^{nd} sense of the word *program*. We call the set of word-senses, within a fixed distance from the chosen synset as the *semantic set* corresponding to that synset. Fig. 3 is an example. The notations and the definitions are given in section 4.

program<80,2,<0,0,0,0,0,0>>, portion<95,1,<0,3,1,0,1,0>>, policy<58,2,<0,2,0,0,0,0>>, term<7,4,<0,3,1,0,0,0>>, topic<42,2,<0,1,2,0,0,0>>, law<66,1,<0,3,1,0,0,0>>, end<8,3,<0,4,0,1,0,0>>, term<18,4,<0,3,1,0,0,0>>, end<8,4,<0,1,0,1,0,1>>, practice<45,5,<0,1,3,0,0,0>>, manner<14,3,<0,4,1,0,0,0>>, law<66,3,<0,2,1,0,0,0>>, end<39,3,<0,4,0,1,0,0>>, end<39,4,<0,1,0,1,0,1>>, law<72,1,<0,3,1,0,0,0>>, burden<99,4,<0,1,1,0,0,0>>, city<59,1,<0,2,3,0,0,0>>, law<72,3,<0,2,1,0,0,0>>, city<31,1,<0,2,3,0,0,0>>, city<56,1,<0,2,3,0,0,0>>, evidence<4,1,<0,2,3,0,0,0>>

Figure 3: Semantic set corresponding to sense number 2 of the word *program*

4 Terminology

We want to find the correct senses of the words in a text T. Let W be a window in T having n nouns,

(w_1, w_2, w_3, ...w_n). For every w_i its s_i senses are σ_{i_1},.....$\sigma_{i_{s_i}}$. Let P_i be the position of w_i in the text.

Semantic Graph

Let G be that minimal sub-graph of the WordNet, which includes all the noun-senses σ_{i_k}, $1 \leq k \leq s_i$ and $1 \leq i \leq n$, from T. We call G, the *Semantic Graph* for the text T.

Let σ_{i_p} and σ_{j_q} be two noun-senses in the sub-graph G. Consider the shortest path from σ_{i_p} to σ_{j_q}. Let $\eta_1(\sigma_{i_p}, \sigma_{j_q})$, $\eta_2(\sigma_{i_p}, \sigma_{j_q})$, $\eta_3(\sigma_{i_p}, \sigma_{j_q})$, $\eta_4(\sigma_{i_p}, \sigma_{j_q})$, $\eta_5(\sigma_{i_p}, \sigma_{j_q})$ and $\eta_6(\sigma_{i_p}, \sigma_{j_{q_6}})$ respectively be the number of *hyponymy*, *hypernymy*, *meronymy*, *holonymy*, *synonymy* and *antonymy* arcs on this path.

Semantic vector

The *semantic vector* between two noun senses σ_{i_p} and σ_{j_q} in the graph G is the sequence

$< \eta_1(\sigma_{i_p}, \sigma_{j_q}),$ ..... $\eta_4(\sigma_{i_p}, \sigma_{j_q}),$ $\eta_5(\sigma_{i_p}, \sigma_{j_q}),$ $\eta_6(\sigma_{i_p}, \sigma_{j_q}) >$,

where the $\eta_i(\sigma_i, \sigma_{j_q})$'s are as given in previous definition. We denote the semantic vector by $N(\sigma_{i_p}, \sigma_{j_q})$.

Semantic distance

The concept of semantic distance has been explored in [15]. Broadly, two concepts of semantic distance have been mentioned there. They are *semantic similarity* and *semantic relatedness*. In this paper, we talk of semantic relatedness, as explored in [16]. But the measures of semantic distance that we adopt are little variants of what has been proposed by [16]. The first measure of the *semantic distance* of a noun-sense σ_{j_q} from σ_{i_p} in G corresponds to the minimum number of arcs that *must* be traversed in order to reach σ_{j_q} from σ_{i_p}.

From the fact that *hypernymy*, *hyponymy* and *meronymy*, *holonymy* are complementary, and that *synonymy* and *antonymy* are *symmetric*, it follows that the semantic distance is *commutative*.

The second measure of semantic distance will be given in section 5.2.

Semantic form

Recall the definition that P_i is the position of w_i in the text. The expression, $w_j < P_j, q, < N(\sigma_{i_p}, \sigma_{j_q} >>$ is called the *semantic form* for σ_{j_q} *with respect to* σ_{i_p}. We will denote it by $F(\sigma_{i_p}, \sigma_{j_q})$.

Semantic set

Consider every noun-sense σ_{j_q} in G, within a maximum semantic distance of R from σ_{i_p}. The collection of all the semantic forms $F(\sigma_{i_p}, \sigma_{j_q})$ is called the *semantic set* S_{i_p} for σ_{i_p}, with radius R. σ_{i_p} is called the *reference noun-sense* for S_{i_p}.

A semantic set S_{i_p} is of the form given in equation 1.

$$S_{i_p} = F(\sigma_{i_p}, \sigma_{i_p}), F(\sigma_{i_p}, \sigma_{i_{1_{p_1}}}) .... F(\sigma_{i_p}, \sigma_{i_{k_{p_k}}}) \quad (1)$$

where k is the length of the semantic set. For word w_i we have s_i semantic sets S_{i_1}, S_{i_2} , ... $S_{i_{s_i}}$. Also, for the word sense σ_{i_p} we define the position vector $\overline{P_{i_p}}$ and $\overline{M_{i_p}}$ as in equations 2 and 3.

$$\overline{P_{i_p}} =< P_{i_1} ... P_{i_k} > \quad (2)$$

$$\overline{M_{i_p}} =< N(\sigma_{i_p}, \sigma_{i_{1_{p_1}}}), ... N(\sigma_{i_p}, \sigma_{i_{k_{p_k}}}) > \quad (3)$$

An Example

Consider again the figure 1 which shows a sample from the text br-a01 of SemCor. The wordsenses of the underlined nouns in the text, form a semantic graph, part of which has been depicted in figure 2. For instance consider the word *program* which has position number 93 in br-a01 and *burden* which has position number 99 in br-a01. IN figure 2, it is shown that sense number 4 of *burden* and sense number 2 of *program* have the same hypernym - the sense number 1 of *idea*. Thus, the semantic distance between *program(2)* and *burden(4)* is 2. The semantic vector from *program(2)* to *burden(4)*, keeping *program(2)* as the reference word is $< \eta_1(\sigma_{93_2}, \sigma_{99_4})$,.. $\eta_6(\sigma_{93_2}, \sigma_{99_4}) >$=<1,1,0,0,0,0>

The distances traversed along the different relation arcs, in the figure 2 from *program(2)* to *burden(4)* are as given in the table 1.

The semantic form $F(\sigma_{93_2}, \sigma_{99_4})$ is given as *burden<99,4,<1,1,0,0,0,0>>*. σ_{99_4} is within a semantic distance of 4 from σ_{93_2}. The collection of all $F(\sigma_{93_2}, \sigma_{j_q}), 1 \leq q \leq s_j \forall$ words $w_j, j \neq i$ in the text T such that, σ_{j_q} is within a semantic distance 4 from σ_{93_2} is called the semantic set for σ_{93_2}, $S(\sigma_{93_2})$. This semantic set is given in figure 3.

5 The Approach

The problem of finding the appropriate sense for w_i can be transformed to the problem of choosing the corresponding appropriate semantic set for w_i. This means we intend to find a measure function $M(S_{i_p}) =$

Table 1: The distance along the different relation arcs, between *program(2)* and *buden(4)* as depicted in 2

Relation	Notation for dist.	Distance
hyponymy	$\eta_1(\sigma_{93_2}, \sigma_{99_4})$	1
hypenymy	$\eta_2(\sigma_{93_2}, \sigma_{99_4})$	1
meronymy	$\eta_3(\sigma_{93_2}, \sigma_{99_4})$	0
holonymy	$\eta_4(\sigma_{93_2}, \sigma_{99_4})$	0
synonymy	$\eta_5(\sigma_{93_2}, \sigma_{99_4})$	0
antonymy	$\eta_6(\sigma_{93_2}, \sigma_{99_4})$	0

m_{i_p} such that $\text{argmax}_{1 \le p \le s_i} M(S_{i_p})$ gives the correct sense for the word w_i.

The idea is that, a word-sense in the text indicates the presence of other word-senses in the piece of text in such a way that **semantically close word senses should also appear textually close**. Therefore, a word-sense in the text is affected by another word-sense in the text in two ways. First is that, *as the semantic distance between them increases, the influence should decrease*. Secondly, *as the textual distance between them increases, the influence should decrease.*

Intuitively, the first factor plays a predominant role in determining the sense of the word under consideration. This follows from the fact that **slight variation in textual position of a word-sense should not influence the sense of the passage as such. But a slight variation in semantic distance should considerably alter the sense of the passage.**

Based on these two observations, we state the hypothesis in section 5.1

5.1 Simple Manhattan measure

Hypothesis

The measure $M(S_{i_p})$ is of the form $M(\overline{P_{i_p}}, \overline{M_{i_p}})$. The contribution of each word σ_{i_j} in the semantic set to the score $M(S_{i_p})$ decreases exponentially its the semantic distance from w_i and decreases inversely with its textual distance from w_i.

Semantic distance (defined in section 4) can be restated as the *Manhattan distance*, $H(\sigma_{i_p}, \sigma_{j_q})$ in equation 4. Note that this measure, in contrast to the measure of semantic distance as given in [16], does not reduce the distance if the path connecting the two concepts changes 'direction too often'. (*e.g* of such a change is when the path connecting the two synsets, changes from say hypernymy to meronymy relation).

$$H(\sigma_{i_p}, \sigma_{j_q}) = \Sigma_{m=1}^{6} \eta_m(\sigma_i, \sigma_{j_q}) \tag{4}$$

According to the hypothesis mentioned above, the expression for the measure function is as given in equation 5.

$$M(\overline{P_{i_p}}, \overline{M_{i_p}}) = \Sigma_{F(\sigma_{i_p}, \sigma_{j_q}) \in S(\sigma_{i_p})} \frac{1}{|P_{j_q} - P_i|} \times e^{-H(\sigma_{i_p}, \sigma_{j_q})} \tag{5}$$

For a word w_i, the appropriate sense number is p and the second most appropriate sense number is $\overline{p}$ iff the conditions given in equations (6) and (7) are satisfied.

$$p = \underset{0 \le j \le s_i}{\text{argmax}} M(S_{i_j}) \tag{6}$$

$$\overline{p} = \underset{0 \le j \le s, j \ne k}{\text{argmax}} M(S_{i_j}) \tag{7}$$

5.2 Eucledian measure

Instead of using the *Manhattan distance*, one can use the *Eucledian distance* . The intuition is given in the figure 4

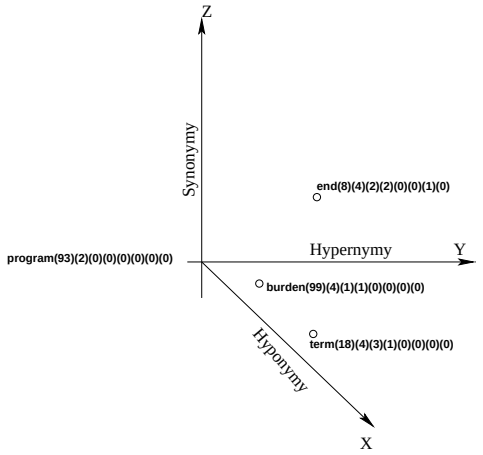

Figure 4: 3-D Graph showing the relative positions of three words with respect the the word *program*

We can look upon the words as being arranged in a six dimensional space, with each space corresponding to one of the 6 relations (*hypernymy etc*). The figure 4 for instance, shows the word-senses *end*(4), *burden*(4) and *term*(4), with respect to the word-sense *program*(2) in 3-D space of *hypernymy, hyponymy* and *synonymy.*

Instead of using the distance measure as in equation 4, we can use the measure $H(\sigma_{i_p}, \sigma_{j_q})$ as in equation 8. Again, this meaure of distance is different from that sugested in [16], because, instead of considering

change of direction along the path, we consider each of the 6 WordNet relations to be along orthogonal directions.

$$H(\sigma_{i_p}, \sigma_{j_q}) = \sqrt{\Sigma_{m=1}^{6}(\eta_m(\sigma_i, \sigma_{j_q})^2)} \quad (8)$$

The appropriate sense for the word w_i can be found as before, using equation 5 and 6. In the measure in equation 8, we give uniform weight-age to all the six relations - *hypernyms* etc. One can instead, give more weight-age to the *hypernymy* and *synonymy* relations as compared to the other relations (say, by taking cubes instead of squares), since, they determine the context of a passage of text, to a greater extent. This gives us the equations 9 and 10 for $H(\sigma_{i_p}, \sigma_{j_q})$.

$$E(\sigma_{i_p}, \sigma_{j_q}) = (\eta_2(\sigma_{i_p}, \sigma_{j_q})^3) + (\eta_5(\sigma_{i_p}, \sigma_{j_q})^3) \quad (9)$$

$$H(\sigma_{i_p}, \sigma_{j_q}) = \sqrt{\Sigma_{m=1,m\neq 2,5}^{6}(\eta_m(\sigma_i, \sigma_{j_q})^2) + E(\sigma_{i_p}, \sigma_{j_q})} \quad (10)$$

Again, one can employ equations 5 and 6 to find the appropriate sense for w_i.

Mutual Reinforcement

We may note that **a word w which has a unique sense in WordNet, helps disambiguate other words related to it**. That is, if word w_j has only one WordNet sense, we would like to give special attention to this information, in all the sets that contain σ_{j_1}. For instance, if the p^{th} semantic set for w_i, i.e S_{i_p} has the word w_j, with w_j having only onse sense in the WordNet, giving more weightage to w_j, sense number 1, will add additional emphasis on the p^{th} sense of w_i.

Moreover, we would like that this effect on σ_{i_p} be reflected on all the sets that contain σ_{i_p}.in turn. To ensure that this happens, we make the following changes to equation 5. Initially, we set the score for each semantic set to 1. Next, within the semantic sets for a word, we normalise the scores. Not that sets corresponding to unambiguous word senses (i.e word senses for the words having just one WordNet sense) will have a score of 1 initially. Then we find the new measure for each semantic set using equations 11 and 12:

$$I(\sigma_{i_p}, \sigma_{j_q}) = M(S_{j_q}) \times \frac{1}{|P_{j_q} - P_i|} \times e^{-H(\sigma_{i_p}, \sigma_{j_q})} \quad (11)$$

$$M(\overline{P_{i_p}}, \overline{M_{i_p}}) = \Sigma_{F(\sigma_{i_p}, \sigma_{j_q}) \in S(\sigma_{i_p})} I(\sigma_{i_p}, \sigma_{j_q}) \quad (12)$$

After updating all set measures for w_i using equation 12, we normalise the measures for the sets correspionding to w_i using equation 13.

$$M(S_{i_p}) = M(\overline{P_{i_p}}, \overline{M_{i_p}}) = \frac{M(S_{i_p})}{\Sigma_{r=1}^{s_i} M(S_{i_r})} \quad (13)$$

Note that in the equation 12 we have scaled the entry for each term σ_{j_q} in the set S_{i_p}, by the measure $M(S_{j_q})$ for the corresponding set S_{j_q}. This means that, if in a particular iteration, sense number q of w_j is found to be more probable than the other senses of w_j, then it's contribution to the scores of other sets is more than the other senses of w_j.

The pseudocode is summarised in figures 5 (INITIALISATION) and 6 (MUTUAL REINFORCEMENT).

1. **INTIALISATION**

2. Incrementally construct semantic chains S_{i_p}, $1 \leq p \leq i_s$, for each of the i_s WordNet senses of σ_i, $1 \leq i \leq n$.

3. for all $1 \leq i \leq n$ do

   (a) for all $1 \leq p \leq s_i$ do

      i. $M(S_{i_p}) = \frac{1}{s_i}$ /* Note that we have combined 2 steps into 1; setting $M(S_{ip})$ to 1 and then normalising */

Figure 5: The INITIALISATION Pseudocode for the method

6 Experiments and results

Experiments were performed over nouns in Brown corpus and checked against SemCor for correctness. As an example case, consider the 93^{rd} noun, *program* in the text in figure 1. It is tagged with sense number 2 in SemCor. Figure 7 shows the 8 semantic sets for the word *program*.

Using equations 4 and 5, we get the scores for the different sets as indicated by the bold number to the right of each set in the figure. *The scores stabilse after around 10 iterations.* We find highest score for the

1. do till the scores stabilise
   (a) **MUTUAL REINFORCEMENT**
   (b) for all $1 \leq i \leq n$ do
      i.
      ii. for all $1 \leq p \leq s_i$ do
         A. $H(\sigma_{i_p}, \sigma_{j_q}) = \Sigma_{m=1}^{6} \eta_m(\sigma_i, \sigma_{j_q})$ /*This could be replaced by the Eucledian measure.*/
         B. $M(\overline{P_{i_p}}, \overline{N_{i_p}}) = \Sigma_{F(\sigma_{i_p}, \sigma_{j_q}) \in S(\sigma_{i_p})} M(S_{j_q}) \times \frac{1}{|P_{j_q} - P_i|} \times e^{-H(\sigma_{i_p}, \sigma_{j_q})}$
   (c) **NORMALISATION**
   (d) for all $1 \leq i \leq n$ do
      i. for all $1 \leq p \leq s_i$ do
         A. $M(S_{i_p}) = M(\overline{P_{i_p}}, \overline{N_{i_p}}) = \frac{M(S_{i_p})}{\Sigma_{r=1}^{s_i} M(S_{ir})}$

Figure 6: The MUTUAL REINFORCEMENT Pseudocode for the method

Figure 7: Example of 8 semantic sets for the word *program*

second set - thus indicating *sense number 2*. Thus, as per our expectation, the algorithm correctly disambiguated the word *program*. On the other hand, using equations 8 and 5, we get the scores as the underlined number, to the right of each set, in the figure 7. As far as the *Eucledian distance* was concerned, it did not make a big difference, whether we used the measure as suggested in equation 8 or 10. The experiments were carried out on the fist 100 nouns for each of 10 documents from the *Brown corpus*. 2 tests were done - (1) comparing the top ranked sense p and (2) comparing the 2 top ranked senses, p and $\overline{p}$ derived using equation 6. The results for 5 of them are tabulated below.

The average *precision* obtained using the *Eucledian measure* was $3-4\%$ lower than that obtained using

Table 2: Results with top sense for each of 10 *brown corpus* documents

Text	Coverage (%)	Precision (%)	Recall (%)
a01	99	70	69.3
a02	98	69	67.6
a11	96	63	60.5
a12	95	65.0	61.8

Table 3: Results with top 2 senses for each of 10 *brown corpus* documents

Text	Coverage (%)	Precision (%)	Recall (%)
a01	99	83.8	83.0
a02	98	75.5	74.0
a11	96	79.2	76.0
a12	95	74.7	71.0

the *Manhattan measure*. The comparison of our algorithm was done with [4], one of the best known *Unsupervised* WSD algorithms.The comparison was performed on the entire text of *br-a01*. The results were as mentioned in table 4

Table 4: Comparison with [4]

	Aigrre		Our algo	
	precision	recall	precision	recall
br-a01	66.4	58.8	76.9	68.2
br-a02	-	-	70.9	68.8
br-b13	-	-	77.8	75.5
br-c04	-	-	67.3	64.10

The window size $|W| = n$, for all the above tests was chosen as 100. Changing it to 150 produced improvement by $5-7\%$.

7 Conclusions

The algorithm discussed in this paper is unsupervised. Currently, it is designed only for disambiguating nouns. All it needs is WordNet, an extensively used lexical database. It can disambiguate any free running text, provided that the *part of speech tags* are provided. The idea behind the algorithm is theoretically well supported. It has many special features compared to previous unsupervised algorithms. Even though a window of words is used for disambiguation, all the nouns in the window are not considered with equal importance for disambiguating a word in the

text - the importance decreases with increasing distance in the text as well as with increasing *Manhattan* or *Eucledian* distance in the WordNet. Also note that the same word, occurring in different parts of the window is disambiguated in a different way - it considers separately, the multiple occurrences of same word in the same window.

With slight modification, this algorithm can be used for disambiguating *verbs*, *adjectives* in any text. The corresponding *verb* and *adjective* taxonomies in the WordNet can be used for these purposes - in a most similar way.

The algorithm can be improved by choosing a different measure function or choosing different measures of semantic distance, than the two mentioned in this paper. Also, consideration of collocation of words and verb-noun collocations, should give additional clues for disambiguation.

Abstract

We developed a method for generating a sense-disambiguated association thesaurus, in which word senses are distinguished according to the related words, from a bilingual comparable corpus. The method aligns pairs of related words translingually by looking up a bilingual dictionary. To overcome both the problem of ambiguity in the translingual alignment of pairs of related words and that of disparity of topical coverage between corpora of different languages, we devised an algorithm for calculating the correlation between the senses of a polysemous word and its related words iteratively according to the set of words related to both the polysemous word and each of the related words. A preliminary experiment using Wall Street Journal and Nihon Keizai Shimbun corpora demonstrated that the method produces a sense-disambiguated association thesaurus successfully. We expect the sense-disambiguated association thesaurus will play essential roles in information retrieval and filtering. Namely, it enables word sense disambiguation of documents and queries as well as effective query expansion. It also functions as an effective user interface for translingual information retrieval.

1 Introduction

An association thesaurus, that is, a collection of pairs of related words, plays an essential role in information retrieval. Query expansion using a corpus-dependent association thesaurus improves recall and/or precision (Jing and Croft 1994; Schuetze and Pedersen 1994; Mandala et al. 1999). Navigation in an association thesaurus allows users to efficiently explore information through a large text corpus even when their information needs are vague (Kaji et al. 2000).

Association thesauri have the advantage of being possibly generated from corpora automatically. However, they have a drawback that they cannot distinguish between the senses of a polysemous word; namely, although each word that is related to a polysemous word is usually relevant to a specific sense of the polysemous word, the association thesauri list all related words regardless of sense. Query expansion using words irrelevant to the sense of user's interest decreases the precision of retrieval. A mixed list of related words relevant to different senses of a polysemous word prevents users from navigating smoothly in the association thesaurus.

In order to solve this problem, we propose a method for generating a sense-disambiguated association thesaurus, in which the senses of a polysemous word are distinguished. More specifically, the words related to a polysemous word are classified according to the sense of the polysemous word to which they are relevant.

2 Approach

The high cost of sense-tagging a corpus prohibits us from collecting pairs of related "senses" directly from a corpus. Accordingly, we adopt a strategy to extract pairs of related "words" from a corpus and then transform each of them to a pair of related senses. This transformation is done through translingual alignment of pairs of related words, as shown in Figure 1. The underlying assumptions are:

(1) The senses of a polysemous word in a language are lexicalized differently in another language (Resnik and Yarowsky 2000).
(2) Translations of words that are related in one language are also related in the other language (Rapp 1995).

According to the first assumption, we define each sense of a polysemous word x of the first language by a synonym set consisting of x itself and one or more of its translations $y_1, y_2, \ldots$ into the second language. The synonym set is similar to that in WordNet (Miller 1990) except that it is bilingual, not monolingual. Examples of some sets are given below.

{tank, タンク<*TANKU*>, 水槽<*SUISO*>, 槽<*SO*>}

{tank, 戦車<*SENSHA*>}

These synonym sets define the "container" sense and the "military vehicle" sense of "tank" respectively.

According to the second assumption, our method aligns first-language pairs of related words with second-language pairs of related words via a bilingual dictionary. An alignment of a first-language pair of a polysemous word and its related word with its counterpart in the second language is transformed into a pair of a sense of the polysemous word and a clue. A word related to the polysemous word is called a clue, because it helps to determine the sense of the polysemous word. For example, the alignment of (tank, gasoline) with (タンク<*TANKU*>, ガソリン<*GASORIN*>) results in a sense-clue pair ({tank, タンク<*TANKU*>, 水槽<*SUISO*>, 槽<*SO*>}, gasoline), and the alignment of (tank, soldier) with (戦車<*SENSHA*>, 兵士<*HEISHI*>) results in a sense-clue pair ({tank, 戦車<*SENSHA*>}, soldier).

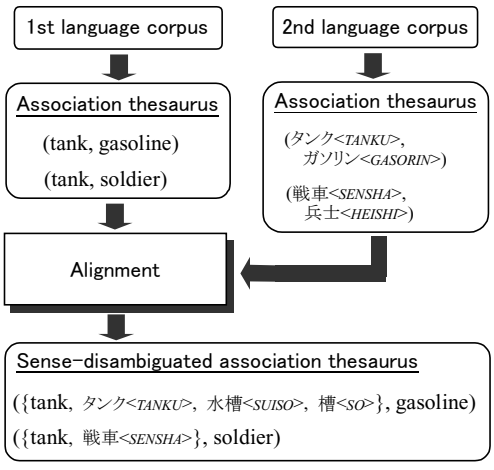

Figure 1: Proposed framework for producing a sense-disambiguated association thesaurus

3 Proposed Method

3.1 Problems and solution

In the framework of aligning pairs of related words translingually, we encounter two major problems: the ambiguity in alignment of pairs of related words, and the disparity of topical coverage between the corpora of the two languages. The following subsections discuss how to overcome these problems.

3.1.1 Coping with ambiguity in alignment

Matching of pairs of related words via a bilingual dictionary often suggests that a pair in one language can be aligned with two or more pairs in the other language (Dagan and Itai 1994; Kikui 1998). To cope with this ambiguity, we evaluate the plausibility of alignments according to the following two assumptions.

(a) Correct alignments are those with pairs of strongly related words.
(b) Correct alignments are accompanied by a lot of common related words that can be aligned with each other.

Then, according to the plausibility of alignments, we calculate the correlation between the senses of a polysemous word and the clues, i.e., words related to the polysemous word.

To precisely estimate the plausibility of alignments according to assumption (b), we should use the correlation between senses and clues. Therefore, we developed an algorithm for calculating the correlation between senses and clues iteratively (see Subsection 3.2.2 for details).

3.1.2 Coping with disparity between corpora

Matching of pairs of related words via a bilingual dictionary often results in a number of pairs not being aligned with any pair. One reason for this is the disparity of topical coverage between the corpora of two languages; another reason is the insufficient coverage of the bilingual dictionary.

To make it possible to acquire the correlations between senses and a clue, even from a first-language pair of related words that cannot be aligned with any second-language pair of related words, we introduce a "wild card" pair. The wild-card pair is a virtual pair related to every word of the second language and implies every sense of the polysemous word of the first language. When a pair cannot be aligned with any other pair, we align it with the wild-card pair compulsorily. We apply the iterative algorithm mentioned in Subsection 3.1.1 to all alignments including alignments with the wild-card pair. Although an alignment with the wild-card pair produces no distinction among the senses of the polysemous word in the first iteration, it produces distinction after the second iteration (An example is given in Section 3.3).

3.2 Algorithm

Our method consists of two steps: translingual alignment of pairs of related words and iterative calculation of correlation between senses and clues. The following subsections give a detailed description of these steps.

3.2.1 Alignment of pairs of related words

An association thesaurus is a collection of pairs of related words with a measure of association between them. In this section, R_X and R_Y denote association thesauri of the first and second languages, respectively. We use mutual information, which is calculated according to co-occurrence statistics, as a measure of association; $MI(x,x')$ denotes the mutual information value of a pair of related words (x,x') ($\in R_X$), and $MI(y,y')$ denotes that of a pair of related words (y,y') ($\in R_Y$), respectively. It should be noted that the measure of association is not limited to the mutual information.

Alignments of pairs of related words between R_X and R_Y, each of which is accompanied by a set of common related words, are extracted through the following procedure.

(1) Extraction of possible alignments

First, for each polysemous word x of the first language, we extract the clue set $X(x)$, which is defined as the set of words related to x, i.e.,

$$X(x)=\{x' \mid (x,x') \in R_X\}.$$

Henceforth, we denote the j-th clue of x as $x'(j)$. Then, for each pair of x and $x'(j)$ ($\in X(x)$), we extract the counterpart set $Y(x, x'(j))$, which is defined as the set of second-language pairs with which the first-language pair $(x, x'(j))$ is possibly aligned, i.e.,

$$Y(x, x'(j))=\{ (y, y') \mid (y, y') \in R_Y, (x, y) \in D, (x'(j), y') \in D\}.$$

Where D denotes a bilingual dictionary, i.e., a collection of pairs consisting of a first-language word and a second-language word that are translations of each other.

(2) Extraction of sets of common related words

(a) In case the counterpart set $Y(x, x'(j))$ is nonempty, for each alignment of $(x, x'(j))$ with (y, y') ($\in Y(x, x'(j))$), we extract a set of common related words $Z((x, x'(j)), (y, y'))$, which is defined as a set of first-language words related to the first-language pair $(x, x'(j))$ and with at least one translation related to the second-language pair (y, y'), i. e.,

$$Z((x, x'(j)), (y, y'))=\{x'' \mid (x, x'') \in R_X, (x'(j), x'') \in R_X\} \cap \{x'' \mid \exists y'' (x'', y'') \in D, (y, y'') \in R_Y, (y', y'') \in R_Y\}.$$

(b) In case the counterpart set $Y(x, x'(j))$ is empty, or the set of common related words $Z((x, x'(j)), (y, y'))$ extracted in the step (a) is empty for all counterparts (y, y') ($\in Y(x, x'(j))$), we align the first-language pair $(x, x'(j))$ with the wild-card pair (y_0, y_0') and construct a set of common related words as follows:

$$Z((x, x'(j)), (y_0, y_0'))=\{x'' \mid (x, x'') \in R_X, (x'(j), x'') \in R_X\}.$$

3.2.2 Calculation of correlation between senses and clues

We define the correlation between each sense of a polysemous word and a clue as the mutual information between them multiplied by the maximum plausibility of alignments that imply the sense. That is,

$$C_n(S(i),x'(j)) = MI(x,x'(j)) \cdot \frac{\max_{y(\in S(i)\cup\{y_0\}),y'} \left(MI(y,y') \cdot \sum_{x'' \in Z((x,x'(j)),(y,y'))} C_{n-1}(S(i),x'') \right)}{\max_k \left\{ \max_{y(\in S(k)\cup\{y_0\}),y'} \left(MI(y,y') \cdot \sum_{x'' \in Z((x,x'(j)),(y,y'))} C_{n-1}(S(k),x'') \right) \right\}},$$

where n denotes the iteration number, and $S(i)$ denotes the i-th sense of the polysemous word x, precisely, the synonym set that defines the i-th sense of x.

The numerator of the second term in the above formula is the maximum of plausibility of alignments that imply the sense, and the denominator is introduced to normalize the plausibility of alignments. The first term of the plausibility of alignment, the mutual information of the second-language pair of related words, corresponds to assumption (a) in Subsection 3.1.1. We assign an arbitrary value larger than zero to the mutual

Alignment	Set of common related words	Sense(s) implied
((tank, troop), (水槽<*SUISO*>, 群れ<*MURE*>))	{air, area, fire, government}	{tank, タンク<*TANKU*>, 水槽 <*SUISO*>, 槽<*SO*>}
((tank, troop), (槽<*SO*>, 多数<*TASU*>))	{area, army, control, force}	
((tank, troop), (戦車<*SENSHA*>, 群<*GUN*>))	{area, army, battle, commander, force, government}	{tank, 戦車<*SENSHA*>}
((tank, troop), (戦車<*SENSHA*>, 多数<*TASU*>))	{Serb, area, army, battle, force, government}	
((tank, troop), (戦車<*SENSHA*>, 隊<*TAI*>))	{Russia, Serb, air, area, army, battle, commander, defense, fight, fire, force, government, helicopter, soldier}	
((tank, gallon), wild card)	{Ford, Institute, car, explosion, fuel, gas, gasoline, leak, natural-gas, oil, pump, toilet, treaty, truck, vehicle, water}	{tank, タンク<*TANKU*>, 水槽 <*SUISO*>, 槽<*SO*>}, {tank, 戦車<*SENSHA*>}

(a) Alignments and accompanying sets of common related words

information of the wild-card pair (y_0, y_0'). Note that the value of the mutual information of the wild-card pair does not have an effect on the results. The second term of the plausibility of alignment, the sum of the correlations between the sense and the common related words, corresponds to assumption (b) in Subsection 3.1.1.

We set the initial values of the correlations between senses and clues as follows:

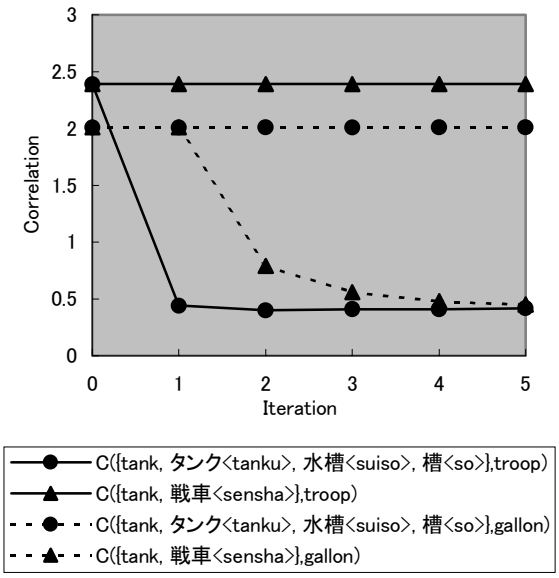
$$C_0(S(i), x'(j)) = MI(x, x'(j)).$$

In the present implementation, we iterate the calculation five times, which makes the correlation values converge. The iteration results in a correlation matrix between the senses of the polysemous word x and the clues. We do not determine the only sense that each clue suggests, but leave using the sense-vs.-clue correlation matrix to application systems.

3.3 Example of calculation

An example of calculating sense-vs.-clue correlations for an English polysemous word "tank" is shown in Figure 2. An English pair of related words (tank, troop) is aligned with five Japanese pairs of related words (水槽<*SUISO*>, 群れ<*MURE*>), (槽<*SO*>, 多数<*TASU*>), (戦車<*SENSHA*>, 群<*GUN*>), (戦車 <*SENSHA*>, 多数<*TASU*>), and (戦車<*SENSHA*>, 隊<*TAI*>). The five sets of common related words that accompany these alignments are shown in Figure 2(a). On the contrary, another English pair of related words (tank, gallon) cannot be aligned with any Japanese pair of related words and, therefore, is aligned with the wild-card pair. The set of common related words that accompanies the alignment of (tank, gallon) with the wild-card pair is also shown in Figure 2(a).

Figure 2(b) shows how the correlation values between the senses of "tank" and the two clues "troop" and "gallon" converge. The correlations with irrelevant senses approach certain small values as the iteration proceeds, while the correlations with relevant senses are kept constant. Note that the correlation value between {tank, タンク<*TANKU*>, 水槽 <*SUISO*>, 槽<*SO*>} and "gallon" and that between {tank, 戦車 <*SENSHA*>} and "gallon", both of which are based on the alignment with the wild-card pair, begin to diverge after the second iteration.



(b) Convergence of correlations

Figure 2: Example of calculating sense-vs.-clue correlations

4 Experiment

4.1 Experimental method

We conducted an experiment to study the feasibility of our method. In this experiment, the first and second languages were English and Japanese, respectively.

First, input data were prepared as follows.

(i) Association thesauri

An English association thesaurus was generated from a Wall Street Journal corpus (July, 1994 to Dec., 1995; 189 Mbytes), and a Japanese association thesaurus was generated from a Nihon Keizai Shimbun corpus (Dec., 1993 to Nov., 1994; 275 Mbytes). The procedure used is outlined as follows (Kaji et al. 2000). Mutual information was calculated for each pair of words according to the frequency of co-occurrence in a window, and pairs of words having a mutual information value larger than a threshold were selected. The words were restricted to nouns and unknown words, which are probably nouns. The size of the window was set to 25 words excluding function words, and the threshold of mutual information value was set to 0.

(ii) Test words

60 English polysemous nouns, whose different senses appear in newspapers, were selected as the test words, and their senses were defined by using their translations into Japanese. The frequencies of the test words in the corpus ranged from 39,140 ("share", the third noun in descending order of frequency) to 106 ("appreciation", the 2,914th noun).

The number of senses defined per test word ranged from 2 to 8, and the average was 3.4.

(iii) Bilingual dictionary

An English-Japanese noun dictionary was compiled from the EDR (Japan Electronic Dictionary Research Institute) English-to-Japanese and Japanese-to-English dictionaries. The resulting dictionary included 269,000 English nouns and 276,000 Japanese nouns.

Then, a sense-vs.-clue correlation matrix was produced for each test word by the method described in Section 3. Finally, the clues were classified according to their correlation with the senses. Namely, the sense having the largest correlation value was selected for each clue on the assumption that a clue is relevant to only one sense (Yarowsky 1993). Although this assumption is not always true, we did so because it is most important to distinguish the most relevant sense from the others.

4.2 Experimental results

Table 1(a) is a classified list of clues obtained for a test word "tank", and Table 1(b) is that obtained for another test word "intelligence". In these lists, clues are sorted in descending order of a score, which is defined as the minimum difference between the correlation with the sense and those with the other senses, i.e.,

$$Score(c) = \min_{S' \neq S} \left[C_5(S,c) - C_5(S',c) \right],$$

where *Score(c)* denotes the score of a clue *c* in the list corresponding to a sense *S*. The score indicates the capability of the clue distinguishing the most relevant sense from the others.

Note that Table 1 lists the top 50 clues for each sense. The total number of clues obtained for each sense of "tank" was as follows:

{tank, タンク<*TANKU*>, 水槽<*SUISO*>, 槽<*SO*>}: 86

{tank, 戦車<*SENSHA*>}: 89

As for "intelligence", two senses were defined: the "ability to learn" sense and the "information" sense. The total number of clues obtained for each sense was as follows:

{intelligence, 知能<*CHINO*>, 知性<*CHISEI*>}: 64

{intelligence, 情報<*JOHO*>, 諜報<*CHOHO*>}: 153

The experiment demonstrated the effectiveness of our method. At the same time, it revealed a few problems. First, when it happens that the second-language association thesaurus includes one or more counterparts of a first-language pair of related words but all of them are incorrect ones, the method causes an error. A sense-clue pair ({tank, タンク<*TANK*>, 水槽<*SUISO*>, 槽<*SO*>}, Poland) included in Table 1(a) is an example. The Japanese association thesaurus included an incorrect counterpart of (tank, Poland), i.e., (水槽<*SUISO*>, 波<*NAMI*>), but it did not include any correct counterpart of (tank, Poland), e.g., (戦車<*SENSHA*>, ポーランド<*PORANDO*>). Consequently, (tank, Poland) was aligned only with (水槽<*SUISO*>, 波<*NAMI*>), which resulted in the incorrect sense-clue pair.

Second, the experimental results show that it is difficult to distinguish a generic or non-topical sense from the other senses. An example is given below. Three senses of "measure" were defined: the "amount, size, weight, etc." sense, the "action taken to gain a certain end" sense, and the "law" sense. The number of clues obtained for each sense was as follows:

{measure, 量<*RYO*>, 尺度<*SHAKUDO*>, 指数<*SHISU*>}: 39

{measure, 対策<*TAISAKU*>, 手段<*SHUDAN*>, 処置<*SHOCHI*>}: 1

{measure, 法案<*HOAN*>, 議案<*GIAN*>, 法令<*HOREI*>}: 93

The method failed to obtain effective clues for selecting the second sense, which is extremely generic, although "measure" in this sense occurred frequently in the corpus.

5 Future Extensions

5.1 From sense-vs.-clue correlation to sense-vs.-sense correlation

The sense-vs.-clue correlation matrix is an intermediate form of sense-disambiguated association thesaurus. It should be transformed further into a sense-vs.-sense correlation matrix. This transformation can be done straightforwardly.

Let's take a pair of related words (tank, troop) as an example. The sense-vs.-clue correlation matrix produced for a polysemous word "tank", which is denoted as *M*(tank), includes the following pairs of a sense and a clue.

({tank, タンク<*TANKU*>, 水槽<*SUISO*>, 槽<*SO*>}, troop)

({tank, 戦車<*SENSHA*>}, troop)

Likewise, the sense-vs.-clue correlation matrix produced for another polysemous word "troop", which is denoted as *M*(troop), includes the following pairs of a sense and a clue.

({troop, 群れ<*MURE*>, 群<*GUN*>, 多数<*TASU*>}, tank)

({troop, 軍隊<*GUNTAI*>, 隊<*TAI*>, 部隊<*BUTAI*>}, tank)

So a pair of senses is produced by combining two pairs of a sense and a clue, one from *M*(tank) and the other from *M*(troop). The correlation value of the pair of senses is defined as the minimum of the correlation values of the combined pairs of a sense and a clue. For example,

C({tank, 戦車<*SENSHA*>}, {troop, 軍隊<*GUNTAI*>, 隊<*TAI*>, 部隊<*BUTAI*>}) = min [*C*({tank, 戦車<*SENSHA*>}, troop), *C*({troop, 軍隊<*GUNTAI*>, 隊<*TAI*>, 部隊<*BUTAI*>}, tank)].

5.2 Use of syntactic co-occurrence

We have conducted another experiment to evaluate word sense disambiguation using the sense-vs.-clue correlation matrix, which will be reported in detail at another opportunity. Although the overall results have been promising, our method has its limitations.

The present method deals with only nouns, and it extracts clues for word sense disambiguation according to co-occurrence in a window. However, it is obvious that doing this is not suitable for all polysemous words. Syntactic co-occurrence is more useful for disambiguating some sorts of polysemous words (Lin 1997). It is an important and interesting research issue to extend our method so that it can extract clues according to syntactic co-occurrence. This extended method does not replace the present method; however, we should combine both methods or use the one suitable for each polysemous word.

The framework of our method is compatible with syntactic co-occurrence. Basically, we only have to incorporate a parser into the association thesaurus generator. A parser of the first language is indispensable, but a parser of the second language is not. As for the second language, we may use co-occurrence in a small-sized window instead of syntactic co-occurrence.

Table 1: Excerpt from the produced sense-disambiguated association thesaurus

6.1 Usefulness of sense-disambiguated thesaurus

The usefulness of the sense-disambiguated association thesaurus for information retrieval and filtering is discussed below. First, when it is shared by a system and users, the sense-disambiguated association thesaurus enables users to input

unambiguous queries. The system does not need to sense-disambiguate queries, since they are already disambiguated.

Second, the sense-disambiguated association thesaurus definitely improves the performance of query expansion. Because it enables a query to be expanded with related words relevant to the sense of user's interest, not with related words regardless of sense.

Third, the sense-disambiguated association thesaurus can be effectively used to sense-disambiguate documents. The sense of a polysemous word in a document is determined by comparing the context with the clues of each sense.

Finally, the sense-disambiguated association thesaurus, in which a sense is defined by a set of bilingual synonyms, functions as a user interface for translingual information retrieval. A user, who may not understand the second language, recognizes senses via the clues of the first language, and the system obtains second-language translation(s) from the synonym set specified by the user.

6.2 Word sense disambiguation and bilingual corpora

Word sense disambiguation using bilingual corpora has an advantage in that it enables unsupervised learning. However, the previous methods, which align instances of words (Brown et al. 1991), require a parallel corpus and, therefore, are applicable to limited domains. On the other hand, our new method requires a comparable corpus. The comparability required by the new method is very weak: any combination of corpora of different languages in the same domain, e.g., Wall Street Journal and Nihon Keizai Shimbun, is acceptable as a comparable corpus. Thus the new method has an advantage over the previous methods in being applicable to many domains.

Word sense disambiguation using bilingual corpora has a limitation because the senses of a first-language polysemous word are not always lexicalized differently in the second language. Second-language translations that preserve the ambiguity cause erroneous disambiguation. To avoid this problem, we eliminate translations that preserve the ambiguity from the synonym sets defining senses.

An example is given below.

{title, 肩書き<*KATAGAKI*>, 称号<*SHOGO*>, ~~タイトル<*TAITORU*>~~, 敬称<*KEISHO*>}

{title, 題名<*DAIMEI*>, 題目<*DAIMOKU*>, 表題<*HYODAI*>, 書名<*SHOMEI*>, ~~タイトル<*TAITORU*>~~}

{title, ~~タイトル<*TAITORU*>~~, 選手権<*SENSHUKEN*>}

These synonym sets define three senses of "title", the "person's rank or profession" sense, the "name of a book or play" sense, and the "championship" sense. A Japanese translation "タイトル<*TAITORU*>", which represents all these senses, is eliminated from all these synonym sets.

The method of eliminating ambiguous translations is effective as far as we can find alternative translations. However, it is not always the case. An essential approach to solving this problem is to use two or more second languages (Resnik and Yarowsky 2000).

7 Conclusion

Sense-disambiguated association thesauri, in which word senses are distinguished according to the related words, were proposed. It is produced through aligning pairs of related words between association thesauri of different languages. To overcome both the problem of ambiguity in the translingual alignment of pairs of related words and that of disparity of topical coverage between the association thesauri of different languages, an iterative algorithm for calculating the correlation between the senses of a polysemous word and its related words according to the set of words related to both the polysemous word and each of the related words was developed. An experiment using English and Japanese association thesauri, both of which were generated from newspaper article corpora, demonstrated that the algorithm produces a sense-disambiguated association thesaurus successfully. The usefulness of the sense-disambiguated association thesauri for information retrieval and filtering was also discussed.

Designing Text Filtering Rules: Interaction between General and Specific Lexical Resources

Antonio Balvet

antonio.balvet@u-paris10.fr

Abstract

In this paper, we present a modular linguistic wizard for information retrieval applications based on explicit rules. We focus on the main features of the present version of the linguistic wizard: extracting rough verb subcategorization frames from existing corpora and querying a large coverage, corpus-independent semantic network (i.e. Memodata's Dictionnaire Intégral). We also provide performance evaluation measures computed on the basis of a rules-based text filtering system, in order to quantify the gain achieved by making use of the linguistic wizard. The performance evaluation figures are therefore based on a manual run and a "random" run, which provide, respectively, the maximum and minimum quality bounds for a system filtering texts through explicit rules.

1. Introduction

How to provide the right information to the right person at the right time ? This question has become all the more crucial in automatic Information Retrieval (IR) systems, which have to deal with ever-increasing volumes of data. The question at hand, which is, in fact, about relevancy, also applies to the field of Information Filtering (IF). Automatic IF systems, let them be statistics-based or rules-based, are rapidly confronted to the issue of enhancing their initial performance.

In this paper, we show how to integrate both corpus-driven and corpus-independent resources in order to provide more relevant information to the final user.

We first give a historical background of the field of IF, from H.P. Luhn's initial specifications to the current TREC[1] definition. Then, we justify our approach to IF, which is based on explicit categorization rules. In the following section, we present the main features of a LInguistic wiZARD and the gain which can be attained by integrating the LIZARD into the text categorization process, compared to a manual approach.

1.1. From Selective Dissemination of Information to Text Filtering

Providing relevant information is a standard requirement for information systems, let them be human or computer-assisted. This requirement was formally stated in (Luhn, 1958), in the initial framework of public libraries. Luhn was one of the first authors to specify the task which was later to be known as "Information Filtering". The then called "Selective Dissemination of Information" (SDI) activity specified every aspect of a process aimed at fulfilling a full-scale information service, from profiles (information needs) to social filtering (collaborative filtering).

1.2. Filtering Texts: a TREC Definition

The TREC international evaluation conferences, sponsored mainly by the United States' federal government, have taken Luhn's initial specifications to their farthest point, providing the field of Information Retrieval (IR) with standard evaluation procedures as well as standardized tasks and data (gigabytes of text corpora).

1.2.1. Text Filtering as a "Push" Activity

Within the general framework of IR, the IF task was first formalized in 1995. The IF "track", as specified in (Lewis, 1995), is defined as belonging to the range of "push" activities, as opposed to "pull" ones. This means IF is a task where queries (profiles) are stable while the textual data are dynamic (high update rate).

1.2.2. A Binary Selection Decision

The TREC conferences also defined IF as implementing a "binary text classification". The emphasis laid on the binary (YES/NO) aspect of the selection decision distinguishes IF from other push activities such as routing[2], where texts are classified according to a relevance rate computed mainly on the basis of the occurrence probability of a given set of terms (continuous selection decision).

We state that the TREC definition of IF implies an approach to the problem of automatic text classification based on explicit rules, while the routing definition implies a machine-learning, or even statistics-based, one, as explicit rules directly implement binary pattern-matching.

2. Categorizing Text with Rules

2.1. Why Use Rules ?

2.1.1. Explicit *vs.* Implicit Categorization Rules

Machine-learning approaches rely on large amounts of learning material and on the fine-tuning of the often time and space-consuming learning algorithms used. These characteristics make the machine-learning approaches suitable to the classification of stable data repositories, and for activities that do not require -even close to- real-time processing. That is to say that these approaches are particularly well suited to *pull* activities, where data are stable and queries are transient.

[1] Text REtrieval Conference, see (Harman, 1993).

[2] See (Robertson & Hull, 2001) for an overview of the filtering track's subtask (adaptive and batch filtering, routing) specifications.

These approaches are also well adapted to the evaluation procedures defined in the TREC conferences, which are based on a two-stage process[3] for defining reference corpora. The first phase collects all the evaluated systems' outputs, for precedent editions of the evaluation conference[4], from which a portion is extracted, proof-read by human assessors in the second phase[5]. This portion of the original collection is considered as the reference (test) corpus for all evaluated systems.

2.1.2. Real-Scale Data and Explicit Rules

Real-world IF does not fit well in the frame of the TREC conferences, though. As will be seen later in the paper, the available data in actual applications (both "learning" and "testing" corpora) are sometimes quite scarce, amounting to the maximum to megabytes rather than gigabytes of text, thus ruling out *de facto* data-intensive approaches. Furthermore, most of the relevant text units have very low occurrence rates[6], to such extent that detecting these "low signals" appears fundamental to the task of filtering documents. This constitutes yet another indirect justification for the use of symbolic rules, inherently independent from occurrence rates.

2.2. What Rules to Use ?

2.2.1. Keywords-Based Pattern-Matching

In the field of rules-based IF systems, keyword-based pattern-matching approaches are the most common ones. Most of the keyword-based systems are but instances of the renown "grep" command found on Unix-like systems. In keywords-based systems, filters are constituted of search strings, and profiles are Boolean operations on individual filters (NOT, AND, OR). Matching, thus filtering, is limited to exact match of a given string.

2.2.2. Regular Expressions-Based Pattern-Matching

Regular expressions-based IF systems are more flexible than keywords-based ones, in the sense that wildcards (+ and * operators), Boolean (&, |, !) and range (e.g. [a-z]) operators allow for extended search patterns[7]. Those basic features are the building blocks for efficient IF systems. Nevertheless, regular expressions-based IF systems are limited by their syntax, which naïve users are not always willing to master.

[3] See (Voorhees & Harman, 2001) for more details.

[4] This procedure is known as the "pooling method".

[5] The pooling method appears common to all text-related tasks, even the filtering track. Given that most of the evaluated systems rely on implicit categorization rules, this evaluation procedure clearly disfavors alternative approaches, such as explicit rules-based ones.

[6] Named entities (e.g. person/products/company names) register very low occurrence rates compared to other text units; in some cases, non-ambiguous persons/products/companies are only mentioned once.

[7] For example, the following search pattern retrieves all conjugated forms of the French verb "manger": mang*, together with "mangue", "mangeoire" etc..

Neither isolated keywords nor regular expressions appear appropriate for filtering texts: the cost of developing text categorization rules based solely on those basic elements appears overwhelmingly high. Therefore, once stated the necessity of using explicit rules for filtering texts, we need to investigate alternative explicit rules.

3. Local Grammars as Text Filtering Rules

In this section, we introduce corpus-processing oriented symbolic rules: "local grammars" as defined in (Gross, 1975). We show how these local grammars can be used for specific tasks such as text filtering, following the approaches introduced in (Grefenstette, 1996) and (Roche, 1993), who use cascades of Finite State Transducers (FST) for Natural Language Processing-related tasks, in an iterative fashion[8].

3.1. The Local Grammars Approach

Alongside the chomskyan "classical" paradigm for Natural Language Processing (NLP), alternative approaches exist, focusing more on the phrase than on the sentence level, even though pursuing the same goal of arriving at a complete description of human natural language.
Harris's "link grammar"[9] and Gross's "local grammars" are instances of such alternative approaches.

3.1.1. Describing Complex Lexical Units

We focus on the concept of local grammars, such as illustrated in the work of the LAboratoire d'Automatique Documentaire et Linguistique (LADL), and implemented through the Intex platform[10].
Local grammars rely heavily on a distributional analysis of a given corpus. They describe linguistic constituents which are closer to idiomatic phrases than to general sentences, which other distributionalist authors such as B. Habert have named "complex lexical units". Most of the time, local grammars capture very contextual properties of lexical items. Thus, the local grammars approach appears very productive for specialized domains/fields of expertise and terminology-oriented tasks.
The Intex system is based on local grammars, expressed as Finite-State Transducers (FST), which are used as a formalism, as a parsing technique and as a data structure for linguistic knowledge representation. Preprocessing rules (sentence boundaries detection, input normalization), tagging dictionaries (simple and compound words, frozen expressions, named entities etc.) and parsing rules are thus represented as FSTs. This has the effect of ensuring optimal consistency in both data and processes, together with processing efficiency (speed) and extensibility[11]. Moreover, Intex comes with standard large-coverage lexical resources for French: simple and compound words dictionaries, lexicon-

[8] Information processed in earlier stages constrain subsequent analyses. See (Abney, 1996) for other applications such as parsing.

[9] Introduced in (Harris, 1968) and developed ever since.

[10] See (Silberztein, 1993).

[11] Extending/revising a set of local grammars boils down to editing symbolic rules, expressed in a graphical format for better readability (see Figure 1).

grammar tables for frozen expressions, and specialized local grammars (occupational nouns, toponyms, dates, roman numerals etc.).
Figure 1 below shows an example of a very simple local grammar, used to describe, parse and translate roman to modern numerals (transducer output). This very simple local grammar allows for parsing and transformation of input strings: the pattern to match is described in the boxes (e.g. I, II, IX …), the output of the transformation is written in bold (e.g. 1, 2, 9 …).

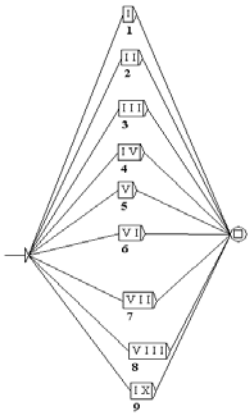

Figure 1: a local grammar used to parse and transform roman numerals into modern numerals

The Intex system also allows for multiple embedding of local grammars, ensuring sufficient computational power for the most common cases by extending FSTs to Augmented Transition Networks.

3.1.2. Describing "Topical Signatures" as local grammars

Our approach to text filtering aims at:

- isolating typical complex lexical units of a given domain/field of expertise, which we call "topical signatures", through a distributional analysis of reference corpora, close to terminological studies in its philosophy,
- describing those expressions as a set of local grammars,
- use this set of local grammars in the process of text categorization.

Typical expressions are thus mainly taken from reference corpora, nevertheless we also make use of thesaurus-like resources in order to provide better coverage for our topical signatures. The approach described here is close to Riloff's[12] in its philosophy, except that topical signatures range from single (e.g. non-ambiguous person names) to complex units (typical phrases such as "monter au capital de"), rather than word pairs exclusively.

3.2. Profiles and Filters as Local Grammars

Filtering textual information involves at least two objects: the user's personal information need, which will be referred to as a "profile", and the individual filters matching relevant parts of documents.
In a rules-based approach, a profile is a conjunction/disjunction or negation of existing filters. In our approach, both filters and profiles can be expressed as local grammars: profiles are conjunctions/disjunctions or negations of existing local grammars matching textual sequences considered relevant by experts of the field.
For example, in order to automatically retrieve relevant documents about the "Mad Cow Disease" epidemics, local grammars for detecting phrases stating the following facts could be designed: typical symptoms have been found on animals, animals have been put down in order to prevent contagion, then perform a Boolean conjunction (AND) operation on those filters in order to implement a "Mad Cow Disease" profile.
Translating filters and profiles into local grammars is consistent with the Intex system's convention. Nevertheless, it implies rendering users' knowledge of the field explicit, which is an inherent source of limitation in coverage of the problem. In some cases, finding categorization rules based on textual cues would even seem awkward, as users rely on implicit, rather than explicit, knowledge and synthetic, rather than analytic, categorization strategies. In those cases, messages are understood in a global fashion and users rely more on their experience of the field than on the actual textual cues contained in the messages. Therefore, the local grammars approach is inherently limited in coverage, even though it complies fully with the TREC specifications[13].

3.3. Problems with Designing Local Grammars by Hand

3.3.1. Experience from a Functional Prototype

A functional prototype of an information filtering system based on local grammars has been designed at a French corporate research laboratory[14]. The prototype, connected to the Agence France Press (AFP) newswire, has demonstrated the feasibility and usability of a rules-based approach to text categorization, together with processing efficiency on French news extracts (ranging from 1 to 10 Kbytes): average processing time (input normalization, filtering and routing) was estimated to 30 seconds per document, which is inferior to the AFP newswire update frequency (1 document per minute).
Nevertheless, the prototype has also shown the necessity to semi-automatically expand user-designed filters, as users cannot explicitly predict future utterances related to a particular domain/area of expertise. In other words, the operational prototype lacked "linguistic calculus" features.

3.3.2. Managing "Flat" Local Grammars

In day-to-day practice, users are quickly confronted to resources management issues due to the proliferation of very specialized (context-dependent) local grammars.

[12] See (Riloff, 1994), where the author presents a strategy focused on extracting non-ambiguous pairs of words from text corpora for "portable" text classification systems.

[13] Our experience of the field has shown us that the TREC specifications for the text filtering task do not account for the complex cognitive (categorization) operations involved in human text filtering.

[14] See (Balvet *et al*., 2001) for more details.

Moreover man-made local grammars are often too restrictive: for example, common phrase alternations (passive/active voice, nominalization etc.) are not available as a standard resource, therefore users usually develop very rough and imperfect grammars for such alternations. Semantic expansion is not implemented in the Intex platform either. Thus, users are rapidly confronted to the problem of expanding their local grammars in a semi-automatic fashion for better coverage and reusability.

4. LIZARD, Main Features

In this section, we introduce the concept of expanded local grammars, and the tools available for French in order to achieve a kind of semi-automatic query expansion on user defined local grammars used as filters, through the LIZARD system.

LIZARD is a tool we have designed, allowing the integration of heterogeneous lexical resources. It was built using the Open Agent Architecture, which provides efficient agent and remote-access capability to heterogeneous systems: OAA allows the creation of Java/C/C++ and Prolog-based agents. The current version of the LInguistic wiZARD is still in alpha status, providing minimal expansion of local grammars: inclusion of synonyms and hyper/hyponyms of terms found in the user's local grammars is suggested, by querying a Memodata agent. Extension to semantically related verbs, together with their preference selection frames extracted from the reference corpora is made available by querying a verb selection preference database.

Syntactic variants are also made available through the following transformations, implemented via local grammars: passive/active form, nominalization with support-verb (e.g. augmenter son capital → procéder à l'augmentation de son capital), and multiple insertions (adjectives, adverbs, phrases etc.).

4.1. Overview of the Global Architecture

4.1.1. A System-Oriented Application

The figure below presents the general system-oriented architecture of the linguistic wizard. Each box in the system diagram represents a processing module. Each module offers standard linguistic and corpus-related facilities, based on existing components, following a "component off-the-shelf" philosophy: every module is thought as a service, therefore each particular component can be replaced by another equivalent component[15].

The Intex module's services are all FST-related text operations (text normalization, pattern-matching, local grammars editing).

The Memodata module's services are all semantics-related operations (retrieving semantically/morphologically related words and phrases, comparing pairs of words or phrases).

[15] For example, the Intex module can be replaced by AT&T's FSM package.

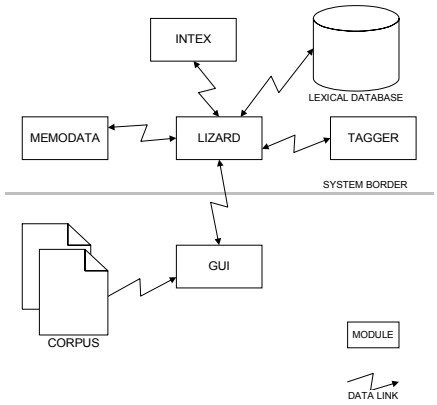

Figure 2: system-oriented architecture of the LIZARD

Communication paths (queries and responses) are represented by broken arrows. The gray line represents the "visible" limits of the whole LIZARD system: the only module accessible by the end-user is the Graphical User Interface (GUI).

The output of the system is a lexical database of domain-dependent typical expressions, which we call "topical signatures".

4.1.2. An Agents-Based System

Developing an agents-based system on top of the modular application shown in Figure 2 was rendered possible by the integration of Stanford Research Institute's Open Agent Architecture (OAA). Within this framework, turning a software component into an autonomous agent is rather straightforward: each module provides services and all agents communicate in a "blackboard" fashion via a central supervising agent called "Supervisor". The Supervisor centralizes all requests from all declared agents and routes them to the appropriate service-rendering agents.

Designing an agent-based NLP system allows the system to operate in a distributed (client/server) fashion over a network (intra/internet), so that memory-intensive applications, such as Memodata's Dictionnaire Intégral, can be run on a dedicated server.

4.2. Rough Verb Subcategorization Frames Extraction

The LIZARD system implements an interactive distributional analysis of reference corpora, in order to extract rough subcategorization frames for relevant verbal entries. For this task, the reference corpora need to be unambiguously tagged and lemmatized, so that only one tag per individual word remains. A first customizable generalization phase deletes most of the Adjectives, all the Adverbs, numbers and punctuation signs. This first phase only keeps those parts of speech generally considered informationally relevant, such as Nouns (part-of-speech information only), Determiners, Verbs (infinitive form), Prepositions and Pronouns.

A second generalization phase provides general subcategorization frames such as: V-Det-N, V-Prep-Det-N etc. Those frames form the core of the domain's set of topical signatures. Once the subcategorization frames have been extracted and validated by the user, all

selected topical signatures candidates are transformed in order to conform to the lexicon-grammar format[16], which the Intex system translates into local grammars[17].

4.3. Querying a Semantic Network

4.3.1. Integrating the Dictionnaire Intégral

Memodata's Dictionnaire Intégral (DI), a corpus-independent semantic network, is presented in detail in (Dutoit, 2000), therefore we only mention the features used by the LIZARD system. The DI comes with a Java API, allowing easy integration in existing systems. This API gives access to common word functions such as synonymy, hyper/hyponymy, morphological relatedness etc. It also gives access to less common features, such as phrase and sentence functions. Those functions are essential to our system, in that they allow easy retrieval of semantically related phrases, not just words. Those functions also allow rough semantic evaluation of two phrases based on a proximity algorithm developed by D. Dutoit.

4.3.2. Expanding Core Topical Signatures

The candidate topical signatures extracted from reference corpora in the previous phase are expanded by querying the DI for related words and phrases: hyper/hyponyms[18], morphologically related words[19] and related phrases are interactively integrated into the existing core topical signatures[20]. The general philosophy is to compensate lack of coverage of hand-designed local grammars by integrating common (extracted from the DI) as well as specific knowledge (extracted from reference corpora) into local grammars intended to be used for automatic text categorization tasks.

5. Performance Evaluation

In the following evaluation, we compare the performance of three text filtering systems[21], following an evaluation procedure aiming at emphasizing the gain attainable by integrating the LIZARD in a rules-based text filtering system.

The first one, the "manual" system, uses hand-designed local grammars[22] and sets the upper bound in quality for the evaluation runs.

The second one, the "computer-assisted" system, is based on the LIZARD and allows us to evaluate our local grammars expansion approach.

The third one, the "random" system, uses random filtering rules and simulates a black-box, automatic text categorization system. This system sets the lower bound for the evaluation runs: we expect our system to perform at least better in quality than the random system.

5.1. The Corpus

5.1.1. A Financial News Corpus

The corpus comes from a private company, Firstinvest, providing targeted financial news to its customers. The financial news extracts are routed by human operators to the appropriate clients in a binary fashion. Thus, the corpus constitutes a reference for an automatic IF system: the situation described matches the TREC definition for the document filtering track.

The reference corpus is organized as follows: 2.6 Mo of French financial news extracts in ASCII format, 19 topics (from Internet-related news to profit warning, rumors and interviews). We focus on topic 19, "corporate transactions", describing scenarios of companies buying or selling parts of their capital.

The performance evaluation measures we used (see below) are based on the number of matches **and** the number of incorrectly retrieved documents (i.e. negative examples) registered for the tested system. As the entire corpus has reached us completely sorted, providing us only with positive examples for each topic, we needed to provide a set of negative examples (noise). Therefore, 50 news extracts (66 Kbytes) of noise corpus, assigned to other topics than the one tested here, were extracted manually from the whole corpus for evaluation purposes.

5.1.2. Learning and Test Corpus

Topic 19 totals 303 documents, which we segment in two parts: 2/3 for the learning corpus (200 documents) and 1/3 (103 documents) for the test corpus. For each evaluation run, standard precision and recall rates (P/R, see below) were computed based on the comparison between each system's output and the reference corpus from Firstinvest.

As the reader will undoubtedly notice, these figures are very far from those of evaluation conferences such as TREC, even though they correspond to real-life data. In fact, the reference data we describe can not be compared to the reference corpora provided by TREC editions: the documents were sorted entirely by hand, they represent but a fraction, in size, of the TREC test suites, and they match an actual information need from users ready to pay for the service provided by Firstinvest.

5.2. Setting the Upper and Lower Bounds to Evaluate the LIZARD Approach

5.2.1. The Manual Run

S. Bizouard designed a set of local grammars for an information extraction (IE) system evaluation experiment undertaken at Thales RT. Following E. Riloff, we assert that IF and IE are complementary activities. Thus, IE local grammars can be used as IF profiles. Therefore, we took S. Bizouard's hand-designed local grammars as a reference for the manual run. Those

---

[16] Syntactic and semantic information, associated to a lexical entry, are expressed as a set of binary features (+/-). Lexicon-grammar tables also include lexical parameters such as the form of a typical complement.

[17] See (Silberztein, 1999) for more details on the lexicon-grammar feature of the Intex system.

[18] Specifics and generics in Memodata's terminology.

[19] For example: "achat" (Noun) which is morphologically related to "acheter" (Verb).

[20] The current version of the LIZARD does not make use of the semantic net navigation customization features, implemented in the DI, yet.

[21] Performing a form of "batch" filtering according to the definition of (Robertson & Hull, 2001).

[22] See (Bizouard, 2001) for more details.

resources were designed following the topical signature approach described above.
Precision and recall of S. Bizouard's grammars do not equal the theoretical 100%, even though they are the result of considerable effort[23]. Our hypothesis is that this apparent lack of coverage is mainly due to implicit knowledge used by experts of the field in classifying texts, which explicit approaches such as the one described in this paper can not capture. The apparent lack of coverage of the hand-designed local grammars also appears due to a lack of proper selection preference constraining: some rules remain too "open" by failing to provide a closed list of possible complements for some very common verbs[24].
Our implicit hypothesis is that manually-designed resources tend to rate high in precision, but low on recall, so the manual run will give the higher precision bound.

5.2.2. The LIZARD Run

The computer-assisted run shows the impact of the integration of both corpus-driven and corpus-independent resources on a text categorization task. In other words, the computer-assisted run implements a query expansion approach based on explicit resources (verb subcategorization frames, semantically related words ...).
The implicit hypothesis is that the natural low recall rates tendency of the manual approach can be compensated by elements (parameters) taken both from existing specialized corpora and general purpose semantic nets (i.e. Memodata's Dictionnaire Intégral).

5.2.3. The "Random" Run

This run is based on a fully automatic text filtering system, which randomly selects documents, independently from their content. The random run shows what can be achieved by a text filtering system which decision selection rules are hidden (black-box system). The implicit hypothesis is that the random run will set the lower bound for both recall and precision (around 50%), in other words, the minimal recall and precision rates expected from the computer-assisted system.

5.3. Figures

RUN	Matches	Noise
Manual	76	9
LIZARD	103	13
Random[25]	53.2	24.8

Figure 3: performance table for each run

These figures were computed on the test (103 documents) and noise corpus (50 documents). As the table shows, the LIZARD system retrieves all the relevant documents. Moreover, it only is responsible for about 1/3 additional noise (compared to the manual run).
The figures presented below give the standard precision/recall rates for each run[26]. As the figures show, the LIZARD system performs very good in recall (100%) and compares equally to the manual run in precision, despite of its "noise" rate being slightly higher.

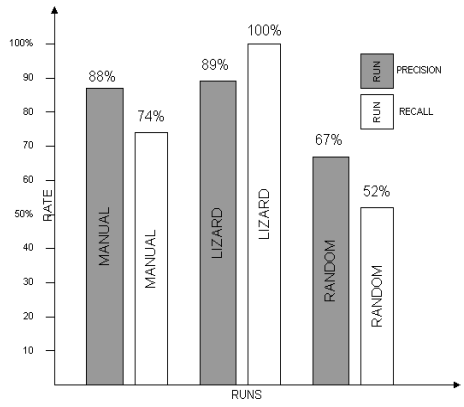

Figure 4: precision/recall rates of three text filtering approaches

5.3.1. Discussion of Figures

The figures presented above show the performance of three types of text filtering systems:

- a system relying exclusively on manually-designed categorization rules, centered on topical signatures,
- a system based on computer-assisted categorization rules (topical signatures), integrating mainly subcategorization frames extracted from the learning corpus, and suggestions from a thesaurus agent,
- a system relying on unknown categorization rules, which appear to be random.

The figures appear consistent with the implicit hypotheses: the "manual" system rates high in precision (88%) but rather low in recall (74%). The manual run validates our "topical signatures" approach, it also shows that explicit approaches fail at capturing part of the knowledge used by experts in a text categorization task.
The "random" system rates moderately in recall (around 50%: 52% in average over 10 runs) and rates rather well in precision (67%). This would appear surprising, should one not bear in mind the essential property of random processes, together with the binary nature of the selection decision evaluated here. In other words, faced with 2 possibilities (select/discard), the random system performs exactly as expected, as it would have for a coin-flipping output prediction simulation: it gives around 50% correct answers[27]. Still, the "rules" used in the decision selection process can not be traced back,

[23] Approximately 3 man-months.
[24] E.g. complements for the verb "céder" are not specified, while it can be found in phrases such as "céder sa filiale" but also in "céder à ses avances" which is not related to topic19.
[25] The rates for the random system were averaged over 10 runs, given the random nature of the system tested.
[26] Precision = Nb. of matches / Nb. of responses,
Recall = Nb. of matches / Total of expected responses.
[27] Respectively, incorrect.

while tracing and debugging capabilities are inherent to symbolic approaches. In other words, the "random" system would appear to perform surprisingly well in regard to its cost[28] if not for its opaque way of categorizing text, its fickle selection decision[29] and its "black box" nature. The random system also shows the relative efficiency of our approach: in the classical evaluation framework described, relying on external evidence (recall and precision rates), almost 50% of the problem are covered without any "intelligence" whatsoever.

Finally, the figures computed for the LIZARD run show the substantial gain attainable by integrating both common and specific knowledge in the text categorization process. The LIZARD approach thus provides the field of information filtering with a seemingly viable and efficient approach, even though complementary experiments should take place in order to evaluate more precisely the gain of the local grammars expansion approach.

5.4. Conclusion and Perspectives

In this paper, we have shown how the field of Information Retrieval, i.e. Information Filtering, could benefit from a symbolic approach to text classification tasks such as "batch filtering". Moreover, we have shown that real-life data, consisting of a corpus of short specialized texts (financial news), did not fit well in the frame of the international TREC evaluation conferences, providing gigabytes of textual data and evaluation procedures that favor data-intensive (machine-learning) approaches. Therefore, in order to evaluate the approach described, we have presented a procedure which compares our system's performance to a manual and a random one, rather than figures based on the official "utility" measures for text filtering systems' evaluation.

We have tried to show how the integration of hybrid resources - corpus-driven (specialized) and corpus independent (general) ones - in the design process of automatic categorization rules expressed as Finite-State Transducers could yield better results than rules designed solely by hand. The figures presented show the performance of LIZARD, a system based on interactively expanded symbolic rules for automatic text filtering, which rates high in recall and compares equally well in precision to a manual approach.

The experiments described in this paper have also shown us that even though human operators' expertise is crucial to the IF activity, it is not less prone to subjectivity than other categorization tasks. Therefore, any attempt to compare the performance of a given IF system to a human reference should take into consideration the problem of the inherent subjectivity attached to the IF/categorization task. In other words, we plan to follow qualitative (glass-box) evaluation procedures in the future, rather than purely quantitative (black-box) ones.

[28] Easy implementation, low space/memory load.

[29] The retrieved document set varies with every run.

Lexically-Based Terminology Structuring: a Feasibility Study

Natalia Grabar, Pierre Zweigenbaum

DIAM — STIM/DSI, Assistance Publique – Hôpitaux de Paris
& Département de Biomathématiques, Université Paris 6
{ngr,pz}@biomath.jussieu.fr

Abstract

Terminology structuring has been the subject of much work in the context of terms extracted from corpora: given a set of terms, obtained from an existing resource or extracted from a corpus, identifying hierarchical (or other types of) relations between these terms. The present work aims at assessing the feasibility of such structuring by studying it on an existing, hierarchically structured terminology. For the evaluation of the results, we measure recall and precision metrics, taking two different views on the task: relation recovery and term placement. Our overall goal is to test various structuring methods proposed in the literature and to check how they fare on this task. The specific goal in the present phase of our work, which we report here, is focussed on lexical methods that match terms on the basis on their content words, taking morphological variants into account. We describe experiments performed on the French version of the US National Library of Medicine MeSH thesaurus. This method proposes correct term placement for up to 26% of the MeSH concepts, and its precision can reach 58%.

1. Background

Terminology structuring, *i.e.*, organizing a set of terms through semantic relations, is one of the difficult issues that have to be addressed when building terminological resources. These relations include subsumption or hyperonymy (the *is-a* relation), meronymy (*part-of* and its variants), as well as other, diverse relations, sometimes called 'transversal' (*e.g.*, *cause*, or the general *see also*).

Various methods have been proposed to discover relations between terms (see (Jacquemin and Bourigault, 2002) for a review). We divide them into *internal* and *external* methods, in the same way as (McDonald, 1993) for proper names. Internal methods look at the constituency of terms, and compare terms based on the words they contain. Term matching can rely directly on raw word forms (Bodenreider et al., 2001), on morphological variants (Jacquemin and Tzoukermann, 1999), on syntactic structure (Bourigault, 1994; Jacquemin and Tzoukermann, 1999) or on semantic variants (synonyms, hyperonyms, etc.) (Hamon et al., 1998). External methods take advantage of the context in which terms occur: they examine the behavior of terms in corpora. Distributional methods group terms that occur in similar contexts (Grefenstette, 1994). The detection of appropriate syntactic patterns of cooccurrence is another method to uncover relations between terms in corpora (Hearst, 1992; Séguéla and Aussenac, 1999).

The present work aims at assessing the feasibility of such structuring by studying it on an existing, hierarchically structured terminology. Ignoring this existing structure and starting from the set of its terms, we attempt to discover hierarchical term to term links and compare them with the preexisting relations.

Our aim consists in testing various structuring methods proposed in the literature and checking how they fare on this task. The specific goal in the present phase of our work, which we report here, is focussed on lexical methods that match terms on the basis on their content words, taking morphological variants into account.

After the presentation of the data we used in our experiments, we present methods for generating hierarchical links between terms through the study of lexical inclusion and for evaluating their quality with appropriate recall and precision metrics. We then detail and discuss the results obtained in this evaluation.

2. Material

In this experiment we used an existing hierarchically structured thesaurus, a 'stop word' list, and morphological knowledge.

2.1. The MeSH biomedical thesaurus

The Medical Subject Headings (MeSH, MeS (2001)) is one of the main international medical terminologies (see, *e.g.*, Cimino (1996) for a presentation of medical terminologies).

It is a thesaurus specifically designed for information retrieval in the biomedical domain. It is used to index the international biomedical literature in the Medline bibliographic database. The French version of the MeSH (INS, 2000) contains a translation of these terms (19,638 terms) plus synonyms. It happens to be written in unaccented, uppercase letters.

As many other medical terminologies, the MeSH has a hierarchical structure: 'narrower' concepts (children) are related to 'broader' concepts (parents). The MeSH specifically displays a rich, polyhierarchical structure: each concept may have several parents. In total, the MeSH contains 26,094 direct child-to-parent links and (under transitive closure) 95,815 direct or indirect child-to-ancestor links.

2.2. Stop word list

The aim of using a 'stop word' list is to remove from term comparison very frequent words which are considered not to be content-bearing, hence 'non-significant' for terminology structuring.

The stop word list used in this experiment is a short one (15 word forms). It contains the few grammatical words which occur frequently in MeSH terms, articles and prepositions:

au, aux, d', de, des, du, en, et, l', la, le, les, ses, un, une

2.3. Morphological knowledge

Previous work has acknowledged morphology as an important area of medical language processing and medical information indexing (Pacak et al., 1980; Wingert et al., 1989; Grabar et al., 2002) and of term variant extraction (Jacquemin and Tzoukermann, 1999). In this work, we apply morphological knowledge to the terminology structuring task.

Three types of morphological relations are classically considered:

- *Inflection* produces the various forms of a same word such as plural, feminine or the multiple forms of a verb according to person, tense, etc.: *intervention – interventions*, *acid – acids*. The parts of speech of a lemma and its inflected forms are the same. Reducing an inflected form to its lemma is called lemmatization.

- *Derivation* is used to obtain, *e.g.*, the adjectival form of a noun (noun *aorta* ↔ adjective *aortic*, verb *intervene* ↔ noun *intervention*, adjective*human* ↔ adverb *humanely*). Derivation often deals with words of different parts of speech. Reducing a derived word to its base word is called stemming.

- *Compounding* combines several radicals, here often of greek or latin origin, to obtain complex words (*e.g.*, *aorta* + *coronary* yields *aortocoronary*).

The morphological knowledge we used consists of {*lemma*, *derived or inflected form*} pairs of word forms where the first is the 'normalized' form and the second a 'variant' form. The general principle is that both forms of such a pair have similar meaning.

In this work we rely on inflectional knowledge and derivations that do not change word meaning. We have left compounding aside for the time being, since the words it relates may have distant meanings.

2.3.1. Inflectional knowledge

For inflection, we have two lexicons of such word pairs. The first one is based on a general lexicon (ABU, `abu.cnam.fr/DICO`) which we have augmented with pairs obtained from medical corpora processed through a tagger/lemmatizer (in cardiology, hematology, intensive care, and drug monographs): it totals 219,759 pairs (where the inflected form is different from the lemma). The second lexicon is the result of applying rules acquired in previous work (Zweigenbaum et al., 2001) from two other medical terminologies (ICD-10 and SNOMED) to the vocabulary in the MeSH, ICD-10 and SNOMED (total: 2,889 pairs).

2.3.2. Derivational knowledge

For derivation, we also used resources from (Zweigenbaum et al., 2001) which, once combined with inflection pairs, result in 4,517 pairs.

These morphological resources will still need to be improved; but we believe that the results should not vary much from what is present here.

3. Methods

The present work induces hierarchical relations between terms when the constituent words of one term lexically include those of the second term (section 3.1.). We evaluate these relations by comparing them with the pre-existing relations, computing precision and recall both for links and concepts (section 3.2.).

3.1. Lexical Inclusion

The method we use here for inducing of hierarchical relations between terms is basically a test of *lexical inclusion*: we check whether a term P (*parent*) is 'included' in another term C (*child*). We assume that this type of inclusion is a clue of a hierarchical relation between terms, as in the following example: *acides gras* / *acides gras indispensables* (*fatty acids* / *fatty acids, essential*).

To detect this type of relation, we test whether all the content words of P occur in C. We test this on segmented terms with a gradually increasing normalization on word forms:

- basic normalization: conversion to lower case, removal of punctuation, of numbers and of 'stop words' (introduced in section 2.2.);

- normalization with morphological ressources (see section 2.3.): lemmatization (with the two alternative inflectional lexicons) and stemming with a derivational lexicon.

Terms are indexed by their words to speed up the computation of term inclusion over all term pairs of the whole MeSH thesaurus. When these normalizations are applied, terms are indexed by their normalized words: we assume that P is lexically included in C iff all normalized words in P occur in C.

3.2. Evaluation

We evaluated the results obtained with this approach by comparing them with the original structure in the MeSH. We considered two methods to evaluate this terminology structuring task:

- the first method is interested in the number of links found, and compares these links with those originally present in the MeSH thesaurus: do we obtain all the links that pre-exist in the MeSH?

- the second method considers the positioning of individual MeSH concepts (terms) in the hierarchical structure of the thesaurus: can we place each concept in at least one suitable position in the emerging hierarchy?

For both methods, we compute recall and precision metrics. The recall metric allows us to analyze the completeness of the results and to know whether all the expected links are induced and concepts positioned. The precision metric evaluates the correctness of induced results.

The recall and precision measures computed here have two versions:

- strict (only the links to direct parents of a given concept are considered satisfactory), and
- tolerant (a link to any ancestor is considered as correct).

We also tested a mixed scheme: the weight given to each link depends on the distance between the two concepts related with this link in the original hierarchical structure of the MeSH: the more distant these concepts, the lower the weight the induced link obtains. However, since the mixed scheme results are not very different from the tolerant one, we do not present them here.

The lexical inclusion methods and the evaluation procedure were implemented as Perl5 scripts.

4. Results

4.1. Lexical inclusions obtained

The method described in section 3.1. has been applied to the flat list of 19,638 terms ('main headings') of the MeSH thesaurus. The gradualy increasing normalizations we applied to this list of terms allow us to induce an increasing number of hierarchical links between these terms.

In table 1 we show quantitative results for the relations induced with the analysis of lexical inclusions and obtained with each type of morphological normalization tested. The first column introduces the types of normalization. The *raw* results were obtained with no morphological normalization. The *lem-gen* results were obtained with application of inflection pairs compiled from a general lexicon, and *lem-med* results with inflectional pairs acquired from medical terminologies (see section 2.3.1.). The *lem-stem-med* results correspond to the normalization done with derivational pairs (see section 2.3.2.). The basic normalization (conversion to lower case, removal of punctuation, numbers and stop words) is performed in all cases. The second column presents the number of links induced with each of the normalization methods tested. The third column recalls the number of hierarchical relations in the MeSH.

Type of normalization	Number of links	Reference
raw	9,189	95,815
lem-gen	12,963	95,815
lem-med	11,627	95,815
lem-stem-med	15,942	95,815

Table 1: Quantification of induced relations berween analyzed terms.

In table 2 we present the same type of information for the placement of terms. The second column contains the number of terms which have been linked with our methods. This number corresponds to the number of concepts that can be linked in the 'structured' terminology we induced. The third column recalls the number of linked terms in the MeSH hierarchy.

As expected, the number of links induced between terms increases when applying inflectional normalization and even more with derivational normalization. Inflectional knowledge compiled from the general lexicon (*lem-gen*) allows to link more terms than that only obtained from specialized terminologies (*lem-med*): 12,963 *vs* 11,627 links. But for the positionining of terms, we obtain better covering of terms when using specialized morphological knowledge (*lem-med*) than when using morphological knowledge from general lexicon (*lem-gen*): 10,949 *vs* 10,261 terms.

Type of normalization	Number of terms	Reference
raw	9,126	19,638
lem-gen	10,261	19,638
lem-med	10,949	19,638
lem-stem-med	11,752	19,638

Table 2: Quantification of positioned terms.

Lemmatization can be ambiguous when an inflected form can be obtained from several lemmas (*e.g.*, *souris* $\rightarrow$ *souris/N* (*mouse*) and *sourire/V* (*to smile*)). In that case, we have adopted a brute force approach which merges the two corresponding morphological families and chooses one lemma as unique representative for both.

Table 3 shows examples of lexically included terms which we obtained with this method. For each type of normalization, it shown pairs *parent* / *child* corresponding to direct, then indirect relations in the original MeSH structure.

4.2. Evaluation of these lexical inclusions

In section 3.2. we presented the methods designed to evaluate the structuring results we obtain with a lexical inclusion analysis of terms. These methods allow us to evaluate recall and precision metrics for both relations between terms and term positioning. In all the cases we take into account the nature of induced links (direct or indirect ones) by testing both strict and tolerant variants. The correctness of induced results is computed by comparing these results with the original MeSH structure.

Table 4 shows the evaluation results for the links, and table 5 for concept (term) placement.

The second column in table 4 contains the number of direct and indirect correct links; the third column shows the number of incorrect links (links which do not exist in the MeSH). The *Recall, direct* column presents the recall R_d of the direct links found d (weighted by the number of direct links $D = 26,094$ in the MeSH – see section 2.1.); the *Recall, all* column presents the recall R_a of all the links (weighted by the total number of links $D + I = 95,815$ in the MeSH):

$$R_d = \frac{d}{D}; R_a = \frac{d+i}{D+I}$$

The last column of this table presents the evaluation of the precision metric, taking into account both strict and tolerant appoaches; if d is the number of direct links found, i the number of indirect links found, and n the number of non-MeSH links found, strict precision P_s and tolerant precision P_t are:

$$P_s = \frac{d}{d+i+n}; P_t = \frac{d+i}{d+i+n}$$

Type of normalization	Parent P	Child C
raw $_{direct}$	accouchement	accouchement provoque
	delivery	*labor, induced*
raw $_{indirect}$	acides gras	acides gras indispensables
	fatty acids	*fatty acids, essential*
lem-gen $_{direct}$	intervention chirurgicale	interventions chirurgicales obstetricales
	surgical procedures, operative	*obstetric surgical procedures*
lem-gen $_{indirect}$	intervention chirurgicale	interventions chirurgicales voies biliaires
	surgical procedures, operative	*biliary tract surgical procedures*
lem-med $_{direct}$	agents adrenergiques	inhibiteurs captage agent adrenergique
	adrenergic agents	*adrenergic uptake inhibitors*
lem-med $_{indirect}$	chromosomes humains	chromosome humain 21
	chromosomes, human	*chromosomes, human, pair 21*
lem-stem-med $_{direct}$	aberration chromosomique, anomalies	aberrations chromosomes sexuels, anomalies
	chromosome abnormalities	*sex chromosome abnormalities*
lem-stem-med $_{indirect}$	eosinophilie	poumon eosinophile
	eosinophilia	*pulmonary eosinophilia*

Table 3: Examples of correct, lexically induced MeSH terms, and their English translations. Indirect means that the MeSH includes a path of length > 1 from the parent to the child.

Normalization	Correct links		Incorrect	Recall (%)		Precision (%)	
	direct	indirect	(non MeSH)	direct	all	strict	tolerant
raw	2688	1266	5235	10.3	4.1	29.3	43.0
lem-gen	3058	1779	6790	11.7	5.0	26.3	41.6
lem-med	3451	2171	7341	13.2	5.9	26.6	43.4
lem-stem-med	3580	2316	10046	13.7	6.2	22.5	37.0

Table 4: Recall and precision of lexically-induced links.

Normalization	Recall: correct advices / # MeSH nodes			Precision: correct advices / # advices		
	strict (%)	tolerant (%)	MeSH nodes	strict (%)	tolerant (%)	nodes linked
raw	10	18	19543	27	52	6969
lem-gen	10	23	19543	24	55	8078
lem-med	10	26	19543	24	58	8644
lem-stem-med	9	26	19543	18	55	9398

Table 5: Recall and precision of lexically-induced node placement advices.

The recall of links increases when applying more complete morphological knowledge (inflection then derivation). And, not surprisingly, we notice that the recall of relations between terms obtained with morphological knowledge acquired from medical terminologies (*lem-med*, *lem-stem-med*) is higher (13.2 and 13.7%) than the recall corresponding to the use of the morphological knowledge compiled from the general lexicon (*lem-gen*, 11.7%).

The evolution of precision is opposite: injection of more extensive morphological knowledge (derivation *vs* inflection) leads to taking more 'risks' for generating links between terms: *raw* results precision is 29.3% *vs* 22.5% for *lem-stem-med* precision.

When accepting both direct and indirect links (tolerant approach), the precision measure obtained is higher than when only direct links are considered (strict approach). For instance, with raw normalization, the tolerant approach gives a precision of 43.0% and the strict approach 29.3%. For the *lem-stem-med* normalization the tolerant precision is 37.0% and the strict precision is 22.5%.

Depending on the normalization and the weighting scheme, up to 29.3% of the links found are correct, and up to 13.7% of the direct MeSH links are found by lexical inclusion.

Up to 26% of the concepts are correctly placed under their ancestors; and the term positioning advices are correct in up to 58% of the cases.

5. Discussion

We presented in this paper an experiment of terminology structuring. We tested here some 'internal' methods for this task, which consist in the analysis of the lexical inclusions of terms. We consider that a term P is lexically included in a term C iff all words of P occur in C, and that this is a clue of its being a parent (ancestor) of C. To help this analysis we apply normalizations, both basic and making use of morphological knowledge.

Whereas raw lexical inclusion detects directly attainable relations between terms by matching identical words in these terms, lemmatization adds flexibility with inflectional variants. Morphological stemming allows to link terms which contain words that are graphically different but have a very close meaning. This allows to obtain hierarchical dependencies between terms that are more based on the 'meanings' of these terms. These semantic similarities are detected through the morphological analysis we apply.

To assess the induced results we compare them with the original structure of the MeSH. We evaluate both the induced links and the placed terms. Depending on the normalization and the weighting scheme, up to 29.3% of the links found are correct, and up to 13.7% of the direct MeSH links are found by lexical inclusion. Up to 26% of the terms are correctly placed under their ancestors; and the placement advices are correct in up to 58% of the cases.

The only expected and evaluated type of relation is the hierarchical one, as exists in the MeSH thesaurus. But we assume that the methods applied also allow to induce other types of relations, and maybe other hierarchical relations, which are not in the original MeSH hierarchy. Some 'new' relations can be found, for instance, in the incorrect ('extra'-) relations we induced. These additional relations have to be analysed in a detailed way to better evaluate the results obtained with these simple methods.

In summary, lexical inclusion caters for a non-negligible number of the hierarchical concept organization in the MeSH thesaurus; and the use of morphological knowledge, mainly for lemmatization, significantly increases this proportion. As could have been hypothesized, trying to place a concept at one position in the hierarchy is more successful than finding all the links from this concept to its parents in a polyhierarchical terminology.

A simple analysis of lexical inclusions shows that in many cases a hierarchical dependency between (medical) terms can be detected and allows to obtain an important number of hierarchical relations between these terms. This information is useful when dealing with the terminology structuring task.

To detect and evaluate more relations between terms, other methods for terminology structuring may be applied, such as those presented in section 1. We plan to test them in the same context as the morphological experiments presented here.

Query Expansion by a Contextual Use of Classes of Nouns

Gaël de Chalendar and Brigitte Grau

LIR group – LIMSI (CNRS)

Gael.de.Chalendar@limsi.fr, Brigitte.Grau@limsi.fr

Abstract

We developed a system, SVETLAN', dedicated to the acquisition of classes of semantically close nouns from texts. We aim at constructing a structured lexicon for the general language, that is not for representing a specialized domain. Thus, texts are open-domain newspaper articles. The acquisition is based on a distributional method that groups the nouns that are related to a same verb with a same functional role. However, in order to deal with polysemy, classes are learned in context: they are built from text segments related to a same semantic domain. For that, we use results of ROSA, a system that clusters automatically segmented texts in order to build semantic domain defined by sets of weighted words. We will show how these classes can be used to expand queries, in comparison with an expansion realized by using WordNet.

1. Introduction

Information Retrieval systems often require semantic knowledge to improve their results. However, one can ask, "what type of semantics?". According to the application, it may differ. It can be only synonymous, or semantically close words, or words belonging to a same domain, either specific or general. One conclusion is that it is necessary to be able to bring together words with close signification. Moreover this gathering has to be done in a well defined context in order to take into account multiple meanings of words. For example, in the context of nuclear plants, one confronted to the sentences: *"… started to replace the fuel rods…"*, *"… started to replace the combustible of the reactor…"* and *"… to replace the films and the batteries of the camera… "*, should join together the words *combustible* and *rods* but should put aside the word *film*.

We are interested in robust applications aimed to cope with every domain, opposed to domain specialized systems. Those systems often use preexistent knowledge to find synonyms or related words but it remains difficult to select the right information. For instance, the noun *care* has 6 registered meanings in WordNet 1.6 (Fellbaum, 1998). If we are interested in medicine practice, we do not want to retrieve documents that use the word *care* with its 4th sense ("*a cause to feeling concerned*"), but maybe only those that use it with its first sense: "*the work of caring for […] someone […]*".

Our conclusion after these statements is that a general ontology or classification seeking for universality is an utopia and principally because of the word polysemy. So, the terminological aspect of general language has to be modeled by multiple overlapping classifications. The question we have to ask is then: "how can these classifications be acquired". We make three hypotheses. Firstly, at least a part of the semantic knowledge is encoded in the texts. Secondly, a part of this text-encoded knowledge can be automatically extracted and lastly, this extraction will be feasible only if semantics is considered in fine-grained contexts.

Work has been done during previous decades on general language but the encoding was mainly manual, as for scripts of Schank (Schank, 1982) that were defined for storing semantico-pragmatic representations of everyday situations. It has been proved very difficult to extend the scripts beyond the first few ones. Another example of manually encoded semantic knowledge is CYC (Lenat, 1986) that is supposed to be a universal semantic knowledge base. In reality, CYC has to be manually tuned in each application it is used in.

On the contrary, various methods have been used with success to acquire semantic knowledge on specialized domains: cooccurrences statistics (Zernik, 1991), distributional approaches following Harris ideas (Harris, 1968), classification techniques (Agarwal, 1995), linguistic indices (Roark & Charniak, 1998), etc. Our interrogation was on the possibility of adapting these successful techniques to general language. Our proposition is to determine automatically thematic domains and to apply a classical distributional method on texts belonging to a same domain. This approach allows our system to form classes of semantically close words.

The idea behind the distributional method is that the usage of a verb is directed by its sub-categorization frame. This frame specifies for example that the subject of the verb should be an instance of a particular concept. The set of real objects referred to by the words that are subjects of the verb in a particular domain represent this concept by extension. Thus, a description of this extension is the set of words used to refer to these objects. These sets of words are the semantic classes made by our system, SVETLAN' (Chalendar & Grau, 2000).

We will show how these classes can be used to expand queries, in comparison with an expansion realized by using WordNet.

2. Overview of the system

Input data of SVETLAN' (see Fig. 1) are semantic domains with the thematic units (TUs) that have given birth to them. Domains are sets of weighted words, relevant to represent a same specific topic. These domains are automatically learned by ROSA that aggregates similar thematic units, made of sets of words. TUs are built by a topic segmentation process relying on lexical cohesion. It processes texts such as newspaper articles.

The first step of SVETLAN' consists of a syntactic parsing of the corpus in order to produce the structured thematic units (STUs) corresponding to each TU. STUs are constituted by a set of triplets - a verb, the head noun of a phrase and its syntactic role - extracted from the parser results. The STUs related to a same semantic domain are aggregated altogether to learn a structured domain. Aggregation leads to group nouns playing the same syntactic role with a verb in order to form classes.

As these aggregations are made within STUs belonging to a same domain, classes are context sensitive, which ensures a better homogeneity. A filtering step, based on the weights of the words in their domain allows the system to eliminate nouns from classes when they are not very relevant in this context.

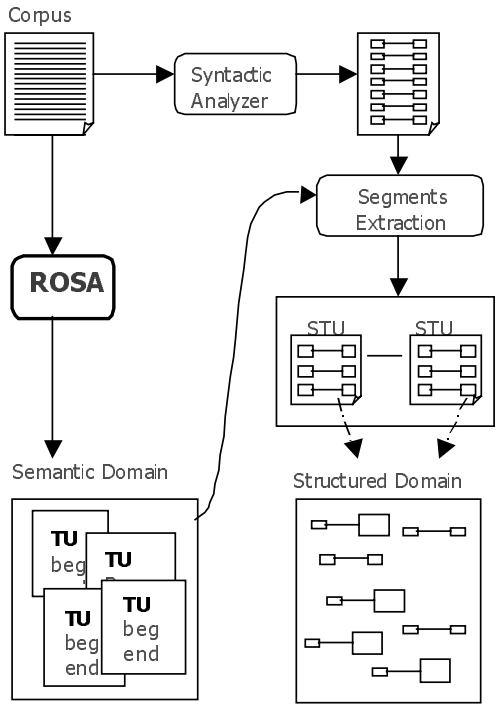

Figure 1: Schemata of Structured Domain learning

3. The ROSA system

We only give here a brief overview of the system that is made of two modules, SEGCOHLEX and SEGAPSITH. It is described more precisely in (Ferret & Grau, 1998). ROSA incrementally builds topic representations, made of weighted words, from discourse segments delimited by SEGCOHLEX (Ferret, 1998). It works without any *a priori* classification or hand-coded pieces of knowledge. Processed texts are typically newspaper articles coming from the *Los Angeles Times*. They are pre-processed to only keep their lemmatized content words (adjectives, single or compound nouns and verbs).

The topic segmentation implemented by SEGCOHLEX is based on a large collocation network, built from 24 months of the *Los Angeles Times* newspaper, where a link between two words aims at capturing semantic and pragmatic relations between them. The strength of such a link is evaluated by the mutual information between its two words. The segmentation process relies on these links for computing a cohesion value for each position of a text. It assumes that a discourse segment is a part of text whose words refer to the same topic, that is, words are strongly linked to each other in the collocation network and yield a high cohesion value. On the contrary, low cohesion values indicate topic shifts. After delimiting segments by an automatic analysis of the cohesion graph, only highly cohesive segments, named thematic units (TUs), are kept to learn topic representations. This segmentation method entails a text to be decomposed in small thematic units, whose size is equivalent to a paragraph. Because discourse segments, even related to the same topic, often develop different points of view of this topic, we enrich the particular description given by a text. We add to the TUs those words of the collocation network that are particularly linked to the words found in the corresponding segment.

Words	occ.	weight
examining judge	58	0.501
police custody	50	0.442
public property	46	0.428
charging	49	0.421
to imprison	45	0.417
court of criminal appeal	47	0.412
receiving stolen goods	42	0.397
to presume	45	0.382
criminal investigation department	42	0.381
fraud	42	0.381

Table 1: The most representative words of a domain about justice

Learning a complete description of a topic consists of merging all successive points of view, i.e. similar TUs, into a single memorized thematic unit, called a semantic domain. Each aggregation of a new TU increases the system's knowledge about one topic by reinforcing recurrent words and adding new ones. Weights on words represent the importance of each word relative to the topic and are computed from the number of occurrences of these words in the TUs (see Table 1 for an example of a domain). This method, implemented in SEGAPSITH, leads to learn specific topic representations as opposed to (Lin, 1997) for example whose method builds general topic descriptions as for economy, sport, etc.

4. Semantic Domain Structuring

Semantic domains are similar to classes formed by (Zernik, 1991). SVETLAN' purpose is then to delimit small classes inside these domains, and to associate them to the verbs they define, as it is made in distributional approaches (Faure & Nedellec, 1998) (Pereira & al., 1993). A class is defined by those nouns which play a same role relative to a same verb and that are supposed to be connected by a strong semantic link. Thus, even if they do not denote a same object, the objects denoted by them play a similar role in the tight context defined by the semantic domain.

4.1. Formation of The Structured Thematic Units

A syntactic parser processes texts in order to find the verbs and their arguments. For English, we used the link grammar (Grinberg & al., 1995). The system extracts all the triplets found by the analyzer, constituted by a verb, a syntactic relation and the head noun of the noun phrase. Relations are subject, direct and indirect objects, the preposition that introduces a prepositional phrase. The link grammar only gives one interpretation of the sentence.

After parsing the texts, SVETLAN' groups the triplets relatively to the delimited thematic units. So, we define a structured thematic unit as a set of <*Verb→syntactic*

relation→Noun> structures, i.e. a syntactic relation instantiated with a verb and a noun. We will refer to these structures as instantiated syntactic relations.

4.2. Aggregation

Structured thematic units related to a same domain are aggregated altogether to form the structured domains. Aggregating a structured thematic unit within a structured domain consists of:

- aggregating the instantiated syntactic relations that contain the same relation and the same verb, i.e. associating a set of words to an argument of a verb;
- adding new instantiated syntactic relations, i.e. adding new verbs with their arguments made of a syntactic relation and the lemmatized form of a noun.

Nouns are not weighted inside a class; they only keep the weight they had in their semantic domain. Thus, the criterion to define a class is that words appear with a same verb, in similar contexts. The similarity of contexts is a lexical similarity computed on the whole domain.

5. Results

Classes are built according to two levels of contextual use of the words: a global similarity of the thematic contexts and a local relevance inside a domain we added to discard irrelevant words. In order to illustrate the effect of topic similarity when building classes, we show in Table 2 a class regrouping all the direct objects found for the verb *to replace* in the whole corpus. We can see that there is no semantic proximity between those nouns. When the class is formed, for the same verb, inside a nuclear domain, the class is then homogeneous. So, even general verbs, as *to replace* (it is possible to replace a lot of things), are relevant criteria to group nouns when their appear in similar thematic units.

to replace	*object*	text, constitution, trousers, combustible, law, dinar, rod, film, circulation, judge, season, device, parliament, battalion, police, president, treaty
to replace	*object*	combustible, rod

Table 2: The effect of the thematic context on the kind of classes

However, classes of nouns contain a lot of words that disturb their homogeneity. These words often belong to parts of the different TUs at the origin of the semantic domain that are not very related to the described topic. They correspond to meanings of words scarcely used in the current context. As these words are weekly weighted in the corresponding domains, the data can be filtered: each noun that possesses a weight lower than a threshold is removed from the class. By this selection, we reinforce learning classes of words according to their contextual use.

to establish	*object*	base, zone
to answer	*to*	document, question, list
~~**to establish**~~	~~*object*~~	~~base, zone~~
to answer	*to*	document, question, ~~list~~

Table 3: Two filtered classes in a domain about nuclear weapons

Table 3 shows two aggregated links obtained without filtering in its upper part and the filtered counterparts in its lower part. The link for the verb '*to establish*' has been completely removed while the link of the verb '*to answer*' with the preposition 'to' has been reduced by the removing of '*list*'.

Table 4 shows some examples of classes obtained by SVETLAN'. Even when verbs are polysemous, which is the case for several verbs in the examples, the domain membership constraint leads the system to build relevant classes. We also can see that the various syntactic relations are relevant criteria to gather semantically linked words.

Domain	Verb	Relation	Class
War	to qualify	Direct Object	president, leader
Food assistance	to take refuge	Into	country, region
Tour de France	to cover	Direct Object	stage, tour
Sport	to face	In	match, final
Economy	to release	Direct Object	million, billion
Festival cinema	to tell	Subject	film-maker, film
Conflict Croatia	to resume	Direct Object	negotiation, discussion
Economy	to reduce	Direct Object	surplus, deficit

Table 4: Examples of noun classes

SVETLAN' originality relies on the constitution of classes given with their context of reference. As a context is explicitly defined by a set of words, it gives indices, when finding a word in a text or a sentence, to choose a class or another, and so to obtain neighbor words. We will show the application of this property when expanding a query.

Verb	Relation	Class
To accuse	Subject	Indictment, prosecutor
	By	Prosecutor, jury
To make	Subject	Prosecutor, indictment
	Direct Object	Jury, prosecutor
To show	Subject	Juror, defendant
	Direct Object	Jury, scheme
To tell	Subject	Magistrate, informant
	Direct Object	Juror, jury
To give	Direct Object	Sentence, prosecutor, trial
	From	Sentence, prosecution
	To	Jury, defendant

Table 5: Example of verbs with classes defining their arguments in a domain about justice

However, the constitution of classes is not the sole result of SVETLAN'. The structuring of semantic domains is another. Instead of bag of words, domains are

now described by verbs associated to classes defining their arguments. This kind of knowledge is a first step towards schema representation of pragmatic knowledge. Such an example is given in Table 5.

6. Experiments

6.1. Corpus Characteristics

We conducted an experiment with a corpus of English newspaper articles composed of 3 months of the "Los Angeles Times" newspaper. We used the following experimental settings: segmentation of the corpus and creation of the thematic memory (i.e. the set of semantic domains); syntactic analysis and syntactic links extraction; structured memory creation (i.e. the set of structured domains); and lastly, an evaluation of the results. We first counted the number of correct classes. A correct class is one that contains words sharing a direct semantic link. For the wrong classes, we counted the number of errors due to parse errors.

For our experiment, we only keep the TUs that lead to build stable domains, i.e. domains grouping at least 10 TUs.

The corpus we worked on is unanalyzed and SGML encoded. Its language level is high with a journalistic style and it tackles various topics. The size of corpus is 7.3 million words.

6.2. Results

The thematic memory created contains 138 stable domains. Table 8 shows results obtained with these domains. Within about 150 classes, about 60% are correct while 7% of wrong classes are due to parse errors.

Number	Correct	Syntactic Parser Errors	Other
149	58 %	7 %	35 %

Table 8: Results on English with a 0.1 threshold

Table 9 shows some examples of the classes contained in a structured domain whose topic is medicine.

Verb	Rel^{on}	Class
To take	Under	Home, residence
To meet	Object	Care, physician
To carry	Object	Virus, antibody
To get	Subject	Treatment, care

Table 9: Examples of classes in a structured domain on English

These examples show two classes with the word care. They instantiate two different kinds of semantic relation: in the class <care, treatment> we see an instrument link between the two terms of the class (a treatment is a means to take care of a patient) and in the class <care, physician>, the link is an agent one (the physician take care of his patients). Meanwhile, in the same structured domain, there were other classes containing the word *care*, some of them carrying the same meaning as care considered as a treatment. So classes do not partition the words of the domains, and they also do not partition the meanings of the words. In a further step, we will study if it is possible and suitable to merge the closest classes.

7. Query Expansion

We were interested in knowing which effects are produced by using different sorts of knowledge in query expansion. Thus, we did some preliminary experiments. Given a query made of words, we tried two kinds of expansion. One kind exploited the acquired classes and the other WordNet. WordNet is a lexical database made by lexicographers. It aims at representing the sense of the bigger part of the lexicon. It is composed of Synsets. A Synset is a set of words that are synonymous. These Synsets are linked by *IS-A* relations. We only did few experiments whose purpose was only to illustrate the interest of having contextual classes compared to a general database which often creates divergences when used as it is.

First, we selected the domain the closest to the query words. Different expansions where computed by adding the words that were belonging to the class of a word of the initial query, and this for each word of the query belonging to a class in the selected domain.

By this way, expansion is done relatively to the query domain of reference. It should be noted that another expansion might be done from a same word from another query, as soon as the other words of the query differ and refer to another context. On the contrary, when expanding with WordNet, the lack of domain knowledge does not allow to select only the right sense.

The queries were sent on Google, that only considers the first 10 words. We chose Google because it is a boolean engine, assuming that when the query contain a lot of words, the retrieved documents are more relevant, as they contain all the words of the query. It is also a way of showing the validity of the acquired classes. If there exists documents containing all the words of the expanded query, the class can be considered coherent. So, in this experiment, we tried to shorten the initial set of documents retrieved by Google.

Initial query : *prosecutor obstruction deliberation jury*
=> 477 documents
SVETLAN' query expansion 1: prosecutor obstruction deliberation jury charge case court trial attorney count
=> 141 answers
SVETLAN' query expansion 2: prosecutor obstruction deliberation jury charge case court trial attorney sentence
=> 222 answers

When using WordNet, we retrieved the different meanings of each word – first, all its synonyms and its hypernyms and second, only the synonyms – and add each of these sets to the initial query. Such a set was considered equivalent to an acquired class. Thus for the same initial query, we obtained the following query expansions.

1 sense of prosecutor (its synonymous and after "=>" its hypernyms)
Sense 1: prosecutor, prosecuting officer, prosecuting attorney
=> lawyer, attorney

Initial query : *prosecutor obstruction deliberation jury*
WordNet expansion 1: prosecutor obstruction deliberation jury, prosecuting officer, prosecuting attorney, lawyer, attorney
=> 65 answers

4 senses of obstruction
Sense 1 :obstruction, impediment, impedimenta
=> structure, construction
Sense 2: obstacle, obstruction
=> hindrance, deterrent, impediment, handicap
Sense 3: obstruction
=> hindrance, interference, interfering
Sense 4: obstruction
=> maneuver, manoeuvre, play

Initial query : *prosecutor obstruction deliberation jury*
WordNet expansion 2: prosecutor obstruction deliberation jury, impediment, impedimenta, structure, construction, obstacle, hindrance, deterrent, handicap, interference, interfering
=> No answer
WordNet expansion 2bis: prosecutor obstruction deliberation jury, impediment, impedimenta, obstacle
=> No answer

5 senses of deliberation
Sense 1: deliberation
=> discussion, give-and-take, word
Sense 2: deliberation, weighing, advisement
=> consideration
Sense 3: calculation, deliberation
=> planning, preparation, provision
Sense 4: slowness, deliberation, deliberateness, unhurriedness
=> pace, rate
Sense 5: deliberation, deliberateness
=> thoughtfulness

Initial query : *prosecutor obstruction deliberation jury*
WordNet expansion 3: prosecutor obstruction deliberation jury, discussion, give-and-take, word, weighing, advisement, consideration, calculation, planning, preparation, provision, slowness, deliberateness, unhurriedness, thoughtfulness
=> No answer
WordNet expansion 3bis: prosecutor obstruction deliberation jury, weighing, advisement, calculation, slowness, deliberateness, unhurriedness
=> No answer

2 senses of jury
Sense 1: jury
=> body
Sense 2: jury, panel
=> committee, commission

Initial query : *prosecutor obstruction deliberation jury*
WordNet expansion 4: prosecutor obstruction deliberation jury, discussion, body, committee, commission
=> 84 answers

We can see that expansions along the WordNet synonyms of polysemous words do not lead to a successful research, as for *deliberation* and *obstruction*. An explanation of this result comes from the fact that SVETLAN's added words are much more related to the query than those added via WordNet. It is due to the contextual construction of the classes and also to the fact that the context is explicitly represented by domains and so can be used to guide the choice of words, contrarily to what happen when using WordNet. WordNet coverage is large but this quality is, in a sense, its shortcoming. Indeed, the generality of its contents makes it difficult to use in real sized applications. It rarely can be used without a lot of manual adaptation.

We are now showing another example, in the sport domain. SVETLAN' added words that all belong to the baseball domain and also lead to reduce the number of retrieved documents.

Initial query: starter hitter batter : 14900 answers
Svetlan'A expansion: starter hitter batter run hit game inning pitch season home
=> 7660 answers

In WordNet, starter and batter are very polysemous words.

5 senses of starter
Sense 1: starter
=> electric motor
Sense 2: starter
=> contestant
Sense 3: starter, dispatcher
=> official
Sense 4: newcomer, fledgling, fledgeling, starter, neophyte, freshman, entrant
=> novice, beginner, tyro, tiro, initiate
Sense 5: crank, starter
=> hand tool

1 sense of hitter
Sense 1: batter, hitter, slugger, batsman
=> ballplayer, baseball player

2 senses of batter
Sense 1: batter, hitter, slugger, batsman
=> ballplayer, baseball player
Sense 2: batter
=> concoction, mixture, intermixture

In such a case, it is not possible to obtain a correct expansion by using only WordNet.

However, one can envisage using SVETLAN' knowledge to select a meaning in WordNet. By combining on one hand sets of semantic closed words, without explicit types of link, and on the other hand sets of words with typed semantic relations that often are no more semantically closed if they are all merged, we could

maybe use the first sets to select contextual meanings in the second sets.

8. Related Works

There is a lot of works dedicated to the formation of classes of words. These classes have very various statuses. They can contain words belonging to the same semantic field or near synonymous, for example.

Automatic systems apply different criteria to group words, but all make use of a context notion or a proximity measure. IMToolset, by Uri Zernik (Zernik, 1991), cluster local contexts of a studied word that is defined by the 10 words surrounding it in the texts. The proximity between words is evaluated by using the mutual information measure, as we do when segmenting the text. The result is groups of words that are similar to our domains but more focused on the sense of a word alone.

Faure and Nedellec (Faure & Nedellec, 1998) with Asium, or Lin (Lin, 1998) apply distributional approaches to learn classes. Asium was designed to build ontology of specialized domains, so there is no need for a context restriction. Its basic classes are clustered to create ontology by the mean of a cooperative learning algorithm. This manual cooperative part is a step analogous to our filtering step. Lin does not apply a contextual selection of the words before regrouping them; he defined a similarity measure between words of a same class to order them according to their similarity degree, This kind of method also lead to build large classes, analogous to our semantic domains.

9. Conclusion and Future Work

The system SVETLAN' we propose, in conjunction with SEGAPSITH and a syntactic parser, extracts classes of words from raw texts and structures domains initially made of bags of words. These classes are created by the gathering of nouns appearing with the same syntactic role after the same verb inside a context. This context is made by the aggregation of text segments referring to similar subjects. Our experiments on different corpus give good enough results, but they also confirm that a great volume of data is necessary in order to extract a large quantity of lexical knowledge by the analysis of syntactic distributions.

In order to show the interest of building small classes inside larger domains, we made some query expansions that comfort the feeling of real proximity between words in the classes and their interest for specializing a query. We are now studying how this expansion can be used in a question-answering system (Ferret et al., 2001) developed in the group that participated to the TREC evaluations. This task is open domain and when the answer is not expressed in the documents with the same words as the question, it requires finding exact synonyms in text sentences. A first step will consist of augmenting our base by applying our system on much more texts, then trying to use WordNet in conjunction with SVETLAN': a synonym in WordNet would be selected if it occurs in a class of SVETLAN' or in classes very close each others. As SVETLAN' classes do not only contain synonyms, the classes are not sufficient in this case, while used along with WordNet it would be a very sure criterion to obtain synonyms in a specified context. We have to verify that it will be applicable on a large scale.

Preface

Aim of the workshop:

The aim of the proposed workshop is to bring together key players in the field of resources and evaluation in order to make a first step towards the creation of a broadly supported Roadmap for Language Resources, i.e. a broadly supported view on the longer, medium and shorter term needs and priorities. This activity should be seen in the context of ELSNET's other roadmapping activities (see http://www.elsnet.org/roadmap.html), which aim at developing a technological roadmap for the whole field of Human Language Technologies.

The purpose of such roadmaps is to give the R&D community an instrument to identify opportunities for concertation of their activities and better exploitation of possible synergies between players all over the world.

Scope of this workshop:

there is no standard model for roadmaps for resources and evaluation available, we will narrow the scope of this roadmapping workshop to a specific sub-area: Multimodal Language Resources and Evaluation. This will make our discussions more focused and concrete, and it will also allow us to exploit the fact that this workshop will take place the As day after the workshop dedicated to Multimodal Resources and Evaluation of Multimodal Systems (MREMS) in general.

Recommended reading (preferably before the workshop):

- ELSNET's First Roadmap Report, edited by Ole Bernsen (http://utrecht.elsnet.org/roadmap/docs/rm-bernsen-v2.pdf),
- ELSNET's Second Roadmap Report, edited by Dorothee Ziegler-Eisele and Andreas Eisele (http://utrecht.elsnet.org/roadmap/docs/rm-eisele-v2.pdf),

Both reports can be found in the annex of the proceedings

Results of the workshop:

The results of the workshop will be published on the ELSNET website at http://www.elsnet.org

April 2002

Abstract

In this paper I want to discuss the problems researchers face in trying to plan and carry out an evaluation study for multimodal systems – particularly in qualifying the purpose of the testing, defining the intended user group for their application, arranging the testing setting and aligning the evaluation plan. It is my intention to show which aspects should be taken into account and which basic standards should be fulfilled. Furthermore, I provide two sections about points to consider in performing the study as well as in the analysis of the received data. Then I describe possible difficulties concerning the evaluation of (multimodal) systems and try to sketch longer term solutions. Finally, I list possible options on how to utilize the results of evaluations studies in further research.

1. Introduction

Multimodal dialog systems should be efficient, easy to handle and comprehensible for intended users – so how should the evaluation of such dialogue systems be designed and carried out in order to accomplish these goals and how can the outcome and the conclusions of the concerned studies be used for further research and development?

How can researchers and developers of dialogue systems answer the needs and preferences of the users, how can they accommodate their special interests and characteristics?

And how can problematic issues researchers and developers face today be tackled and solved? To which extent can experiences made until now help to find solutions for the future?

These questions need to be answered already in the very beginning of the whole development process – before the start of the planning and mental development of the system one has to designate the goals of the system and which functions it serves. At the same time the target group has to be defined – this can on the one hand be a small group of experts and for a special field of application or on the other hand the entire population, depending on the system or object. During the development process these facts must be taken into account in order to produce the most efficient system for the special target group. To this end, it is useful to perform an iterative mode of evaluation which means that for every important phase of development an evaluation study is provided so as to find out about the direction the development of the systems leads to and to make sure that the intended users are able to handle it. Especially as far as multimodal dialogue systems are concerned, evaluation studies are a relevant part of the development and – at the same time – a challenging task. The particular difficulty is to provide methods for logging and analysing two or more different modalities and to test each of them separately as well as combined with the other(s). This means that the developers and researchers receive much data, which require experience and reliable methods to be analysed.

Because of the innovative design and handling of those systems a careful evaluation planning has to be provided.

I wrote this paper from a social scientific point of view – as a different perspective concerning the preparation and the procedure of evaluating a system. Social and empiric science can provide information on methodological issues, questions concerning the analysis of the data, the selection of test subjects, the arrangement of the setting and the formulation of the specific tasks for the test persons.

2. Goal of the paper

The main intention of this paper is to show how important a careful planning and performance of an evaluation study – concerning especially multimodal dialogue systems – is. It should be made clear which features of the testing process are particularly relevant and which problems may appear and which challenges the evaluation of a system, possessing more than one modality for handling, may involve. Furthermore, in this paper important aspects which may appear negligible at the first sight should be mentioned, for example the range of persons who are going to use this system in the future, ergo the intended user group: what are their characteristics, their needs and how can the system serve them? For the designer and the researcher, this means also knowing exactly the functions of the system. Another aspect would be the setting in which the testing should take place: how should it be arranged and which role plays the tester?

A very important part of this paper is the one about how the results of the evaluation research in general and the experiences of each researcher can contribute to the further research done in these fields and consequently to establishing standards for the design and the performance of evaluation studies of multimodal systems.

I also like to state my point of view concerning the present as well as the longer term problems researcher might face in developing and evaluating multimodal dialogue systems, and also how they might be avoided.

3. What is the image of the intended (average) user and how does it affect the development of the evaluation of a system?

As I mentioned before, theoretically the entire population can be the target group of a certain system or object, for instance of information extracting systems like automatic telephone enquiry for train schedules. As far as IT systems are concerned, in the last years it was often assumed implicitly that the circle of intended users is a rather small one (compared to the one of objects of everyday life) and is composed of experts of fields like computer technology and science, managers or other academic job-holders in hierarchical higher positions.

But today such systems should serve everybody. It is the developers´ duty to design the system in such a way that it can also be conceived and used by non-experts. That concerns especially the presentation of the graphical user interface, which the user gets the first impression of before even having tried out how to handle the application.

So if one has in mind that the target group may be as heterogeneous as the general population there is no possibility to postulate any specific knowledge or experience concerning multimodal dialogue systems among all persons. This means that the researcher has to begin at the very start and make the use of the system as easy as possible. That is for sure a very challenging task – and an important one, because the design and the usability of the system are important factors for its acceptance among the intended users. One has to consider that persons of every age group, sex, society position and socialisation background may use this system. The sample the researcher assorts should be representative in so far that each of these parameters is taken into account. One possibility to find out about those features is to provide a user questionnaire.

One option is to search test persons of a certain age, sex and education level. The last parameter is useful to get some information about the position in society they bear. Another way would be to consider income or field of profession, or respectively the job they are working in. It is hard to find out much about the economic or social background of the test persons without violating their privacy. And one must not believe that one statistical feature gives information about a person's standard of living. So this parameter is a rather hard one to obtain. Nevertheless it should be included in the evaluation.

The aspect of age is also an important one, because one may find big differences between younger and older people concerning their competence as well as their experience with modern technological instruments and systems – a phenomenon which does not apply universally. But there may be the tendency that older persons are more sceptical and reserved if not afraid to serve as test persons for evaluations of such systems. They often argue that they need not be taken into account, because they are too old – which is of course a misbelief.

It is common to consider sex as a variable, too, because it is interesting to view possible differences between women and men in handling technological systems and to react to them in the further development of the system.

4. Recommended standards for multimodal dialogue systems

It seems to be of use to establish basic standards that need to be fulfilled in order to provide a system appropriate for a great range of users. This is particularly relevant for multimodal dialogue systems, which provide several ways of handling and therefore require extraordinary user-friendliness. The standards described in this chapter can be seen as provisional and extensible – they should serve as basic points of orientation.

These standards make clear which direction further research should take and on which aspects it should focus, but also which main issues any evaluations study should focus on.

4.1. Easy intelligibility of the functions and applicability of the system

In order to be able to use the system in an efficient way the users have to understand which actions one can perform and which goals one can accomplish with it. That is to say that the instruction manual must be clear and specific. But also the design of the user interface should give a clue to how to use the system.

4.2. Distinct visual design of the graphical user interface

The user interface, i.e. the part of the system the user sees and interacts with, should not be complex, but the various elements should be arranged clearly and distinguishably. Concerning this feature, knowledge from fields like psychology or the specific domain of advertisement could be advantageous, but the cooperation between these fields and the one of IT is not that strong yet.

4.3. Good intelligibility of the commands

The language in which the user communicates with the system is usually a set of commands – either given via speech or via GUI. And vice versa the systems gives commands or poses questions to the user – often in the form of spoken prompts. It is necessary to formulate these in a simple and intelligible way so that the user is able to catch it.

4.4. Good speech recognition

A dialogue system that provides the modality of handling via speech needs to have an excellent speech recognizer. That is a prerequisite for efficiency, which is an overall goal of such systems. This means that it should also work in noisy environment, as the system should be adaptable in awkward situations where the user cannot have regard of a clear articulation. Unfortunately – although there has been much research done in this area – it takes a long time to develop a good recognizer respectively it is hard to find a recognizer appropriate for the functions a system should fulfil

4.5. Efficiency as well as smooth performance of the actions

Multimodal dialogue systems have the special aim to work smoothly even in difficult or stressful situations, for instance if the user needs both hands for other actions. It would be very exhausting for the user to be forced to

repeat the commands or questions a several times because of the slow processing or the long upload time of the system.

4.6. Clear, intelligible output (speech-output as well as output via the GUI)

In order to provide a smooth process and a good information extraction respectively an optimum support the output the system delivers should be correct as well as intelligible.

5. Advantages of multimodal dialogue systems

The advantages listed in this chapter are supposed to supplement or – in part – condition each other. This list should – on the one hand – emphasize the differences between single- and multimodal dialogue systems and – on the other hand – show which anticipations researcher have concerning these kind of systems.

To reach the intended users as well as to make the system interesting for them, one has to emphasize its advantages in achieving a certain goal, possibly by comparing it to other kinds of systems or – in general – ways to reach this goal (for instance using a multimodal dialogue device to extract information about the surroundings instead of a simple map).

One big use of such a multimodal dialogue system is for sure the *flexibility*. The overall goal of the development of multimodal applications is for the users to interact with the system the way they like to – depending on the situation they are in. For example when driving in his car, the user cannot use his hands to operate the system – so there has to be one or more other ways to handle it in order to fulfil the claims of efficiency and usability. In this case, the modality of handling via speech input is an optimum alternative.

The optimum situation would be that every user was free to interact with the system the way the situation requires it – and to alternate the one modality with the other(s) in a spontaneous way. The system should therefore be designed to react and adapt to this user-specific behaviour. This demands – in case of a multimodal dialogue system – an excellent speech recognition as well as a synoptic user interface quick to apprehend.

Beside flexibility higher *efficiency* is another advantage of multimodal dialogue systems – provided that sufficient evaluation studies has been performed in order to find out about how a system needs to be designed to serve the users well. It´s clear that efficiency – at least in part – grows proportionally with flexibility (and the other way round), so these two aspects are connected tightly.

A third advantage which may be of great importance for "everyday users" is the *individuality and personality* a system gets when becoming multimodal, hence being able to be integrated smoothly in ones everyday life and supporting the performance of certain actions.

The great use of multimodal dialogue systems in comparison to other systems is the fact that they combine the advantages of the single modalities they include, this means that the user can profit from the advantages of handling via the GUI as well as via speech. In detail, this would be promptness as far as the modality of speech is concerned – action can be executed far more faster by speaking the commands that by typing them. The other advantage which is already known is the possibility to keep ones hands free for other actions which is, for instance, very important while driving the car. Regarding the modality of handling via the GUI the main advantage lies in the privacy of the commands the user is giving and of the actions the system is executing. While speech can be received by persons around the user, actions like typing are not audible.

Disadvantages of one modality might be eluded by using the other modality – for instance if the speech recognizer does not work properly.

6. Important items in planning and carrying out an evaluation

To evaluate a system one has to know exactly which functions it possesses and who the intended users are (cf. Nielsen 1993: 170). The evaluation study is performed to serve the purpose of finding out more about how the system should be designed in order to answer the needs and interests of the users. As I mentioned in the introduction the best way to carry out an exhaustive evaluation study is to perform several smaller "steps of evaluation". This means that – depending on the development stage of the system – the respective properties, the design and the effect on the users need to be measured.

And for each of these steps some important points must be considered. To receive sufficient and eligible data for the analysis afterwards, the evaluation study needs to be planned carefully, tasks for the test persons to perform must be formulated – which are supposed to accomplish the intentions the researchers have –, methods to log the process of evaluation need to be found as well as methods to capture the impressions and experiences of the test persons. The choice of these instruments depends on which aspects of the tests are important for the developers on the one hand, and – on the other hand – how easily the requested information can be extracted. A good way to find out which methods are appropriate for the evaluation study is to evaluate the logging methods themselves. That is also useful to assure that the methods one uses really measure what they are pretending to measure – hence if they are suitable for what the respective developer wants to find out. A good method for logging the evaluation process is to use instruments like audio recorder, video camera, mouse tracker, screen logger or eye tracker. But one must be aware that receiving too much data out of an evaluation study can be as well a problem as receiving too little.

Not only the methods and the technological equipment are to be considered – the whole setting of the testing process needs to be planned. The role of the tester who stays with the test persons must be defined – mostly he is the one who explains the aim of the testing as well as the specific tasks and who observes the test person during the performance. This raises some questions: How much information should the test person be given in order to not affect the authenticity of the situation and the (possible) impartiality of the user? Should the tester answer questions during the testing? Where should he place himself? To which extent should he adapt himself to the test person (concerning behaviour, speech, …) to provide a more informal setting or how can he prevent himself

from doing so? Are there differences in the performance of the test persons depending on the sex, the age or the credibility of the tester?

As far as the test persons are concerned, should they be given some time to get to know the system better (some minutes without logging or even observing) or should they be tested from the very beginning?

And how should the testing setting look like to provide as much authenticity as possible?

All these questions can become problematic when too little time and know-how is spent on the preparations of the evaluation studies – the difficult issues are explained in detail in chapter 7.

7. Analysis methods

It is important to find appropriate analysis methods as well, for instance annotating schemes to analyse spoken language and synchronize it with actions like mouse movements or clicks. That is a good and rather objective possibility of spotting the problems the users had performing the tasks, but also the points where the test persons apparently used the system in an efficient way, for example – concerning multimodal dialogue systems – combined speech and handling via the GUI. Especially for large numbers of test persons and hence a lot of data such standardized analysing methods are useful. However, the range of good and reliable annotating schemes is not that great. The few that are made use of in empirical studies fall short of easy applicability and efficient programming. Much remains to be done in this field of research. Also the methods themselves need to be tested to find out if they work the way the researcher wants them to. If the methods fail, the whole study needs to be repeated.

However, also the subjective impressions of the test persons are important for the analysis, so one should not surrender a questionnaire, an individual interview or informal talk with the test persons after the testing. These data need to be analysed either quantitatively – in the case of a questionnaire – and presented in statistics or analysed in a qualitative way, that is to collect the test persons' impressions and statements and to detect positive or negative tendencies.

But not in every case all the errors of a system can be detected: one cannot be sure that all the problems could actually be recovered – "one troubling aspect of testing is the uncertainty that remains even after exhaustive testing by multiple methods". [Shneiderman 1998: 125]

8. Problems to be solved concerning the process of developing and testing a new system

There is a range of problems researchers of multimodal dialogue systems have to face during the process of developing and optimizing the system. In some ways, preparing the evaluation study for multimodal dialogue systems does not differ from preparing one for "singlemodal" systems. Just a few aspects are more challenging as far as multimodal systems are concerned.

8.1. Defining the user group and test subjects

First of all, it is difficult to find out about the intended user group: how should the researchers know which persons the system will be used by? And how can they be sure that the users they design the system for are really the ones who will use the system in the end? A step towards finding a solution to this problem would be to carry out a survey among the supposed target group or among the whole population to get a clue about who is interested in the product and may benefit from it.

The range of test persons should be representative for the group of intended users, that is to say that the test subjects should represent the properties of the target group. If the system was designed primarily for elder persons, it is recommended to choose such persons for the evaluation study. In this regard the question must be raised where one should find appropriate test subjects. There are several possibilities:

One may look for persons in public institutions or buildings like schools, universities or on the street. An alternative would be the search for people by an advertisement. Or one may get access to a range of test persons by buying (or exchanging) subjects databases.

8.2. The discrepancy between researcher and user

Another difficulty in the process of developing a (multimodal dialogue) system is the discrepancy between researcher/developer and "normal" user or test subject. The researcher who designs the system is an expert in this field, he/she possesses knowledge and experiences concerning this specific system and knows how to handle it – so one can assume that he/she is the person appropriate for testing the system. That is true – to some extent. The persons, who understand the functions and operations of the system best, may also know how to measure and optimize them. The problem, which may occur, is that the researcher knows the system to well. This means that he/she is not able to put him/herself in the situation of the non-expert user and, therefore, blind out all his/her knowledge. One may argue that just because of these problems evaluation studies are carried out. That is correct. But it is not enough to perform one or more evaluation studies, it has to be guaranteed that the study is performed in a correct way, this means to really find out about the user group and its needs and expectations. The researchers are – in some way – preoccupied. So they do not seem to suit for planning such a study. A possibility to avoid this problem would be to separate the role of the researcher and the one of the evaluation designer strictly. But here another difficulty appears: how can the evaluation designer know enough about the system to understand its functions and features and at the same time know not too much about it in order to stay as objective as possible?

8.3. The evaluation setting

In order to get valid testing results, not only the tasks to fulfill need to be chosen carefully, also the setting where the testing should take place has to be planned regardfully.

The easiest possibility is to perform the tests within an isolated laboratory or at least in the rooms of the company which developed the system. This would mean that the testing situation could be controlled rather easily and that no unexpected disturbances would happen. These apparent advantages entail one negative aspect. Choosing such a testing setting would mean that the authenticity of the situation would be in peril. Especially as far as

applications are concerned which are not designed to be used at home or in a quiet and private place, testing within the circumstances mentioned above would not represent the conditions which the user has to face when using the application in reality. The researcher cannot foresee all the different situations in which the system may be applied but he knows the intended user group and the functions of the application and therefore can assume how it is going to be used.

Portable devices for example are supposed to be applied on the way, for instance on the streets, in public buildings and institutions, while walking or traveling by car, at different events or in likewise noisy environment. The noise must not be underestimated – as well as other factors, for instance when information is required as quick as possible (train departure times for example). A system, which works perfectly within the laboratory setting, might turn out to fail when being used in real surroundings. How should these settings be imitated in the laboratory to gain valid results?

As a matter of course, one must in this case consider the development phase of the system. If there is not an application to be carried around yet it can hardly be tested like if there was. An iterative kind of evaluation study requires several different testing settings.

8.4. Methods

Finding appropriate methods for logging the testing process might be a problem as well. The choice depends on which modalities the system has, as there are several options for each of them to be logged and measured. Most multimodal dialogue systems offer at least the two following modalities: the speech-modality and the handling via the GUI.

In order to log spoken user-output, one could for instance use a simple recorder with a microphone or a camera which could also tape visual impressions like the gesture and the face of the test subject as well as the monitor of the computer or the display of the application device (if it is not too small) – depending on which kind of system is tested. At the same time, the output of the system should also be taped for to liaise the both kinds of output in order to get information about the quality of the speech recognition and the smoothness of the whole process.

It is not as simple to find methods – beside the camera – to trace the operations on the monitor or the display, ergo the handling via the GUI. There exist some software tools like screen logger or key tracker which log the mouse movements or clicks as well as the input via the keyboard or the selection via the menu. Unfortunately, the existing software is either very expensive or only available for companies of specific fields.

In addition, there are other tools to log the process in order to gain more information about the handling of the system – for instance a so-called eye-tracker that logs the eye movements of the user. Through its analysis one may find out about which elements of the GUI are bold and how easy or difficult it is for the user to understand how to operate the system.

The challenging aspect concerning multimodal systems is to connect the methods used for logging the handling of different modalities. One kind of information needs to be related with another. The speech signals must be synchronized with the manual actions, for instance. This intention requires another software or program like an annotation scheme.

8.5. Possible solutions and recommendations for the future

As I said before, it is necessary to involve several persons in the developing and the testing process of the system, as more perspectives are required for an effective evaluation study. Concretely, this means that persons from several fields of research should work together, the tasks should be distributed and the roles the persons occupy within this process should be defined well. The researcher, the developer, the designer, the market research institute, the tester, several university institutes like psychology, sociology and computer science – all of these persons and institutions have competences in their specific fields and can contribute to producing a good working system. Through exchanging experience and know-how, as many difficulties as possible might be avoided.

In my view, this strategy will play an important role in the future, for aspects like user friendliness and acceptance of the system by the users are more and more coming into prominence. It is not any longer the group of IT experts and business people only who need applications of new technologies, but “average persons” from every part of the society.

Nowadays the number of those companies increases which specialize on evaluation studies and tests on usability – a fact that indicates the prominence of these aspects.

While IT companies spent most time on producing new systems and optimising new technologies, the aspect of user friendliness was rather neglected. The big chance to catch up on these experiences is the cooperation with persons of other fields or companies; to get support at finding the right test subjects, equipment and methods.

9. Evaluation outcomes as resources for further research

First of all, the outcome of the evaluation studies serves the improvement and the development of the evaluated system. But the received data are not useless after completing the evaluation process. The lessons one draws out of this testing can be used for other – similar – studies. On the one hand developers get to know the logging and analysing methods better, on the other hand they learn more about this kind of systems in general and how the intended users manage them – this knowledge can be made use of in further research.

To mention the economical aspect, the results of an evaluation study can of course also be used in cooperation with other technological enterprises or research centers with commercial as well as scientific interests; they can be exchanged or sold.

This procedure does not need to be restricted to similar, ergo technological, fields of research – instead the knowledge can also be connected to different fields like psychological or sociological research or the particular field of advertisement, where methods of usability and analyses of effects on consumers and users have long tradition. Knowledge from these disciplines can be used for evaluation studies and – vice versa – the results of these kinds of studies can be made use of in other fields.

10. Conclusions

The challenges in designing evaluation studies for multimodal dialogue systems are plain to perceive: in contrast to dialogue systems using one modality, evaluating multimodal systems demands more than one perspective of testing and hence just as many methods of logging. To use the received data for the improvement of the system and for further research it has to be processed with the support of suitable analysis methods – the particular challenge at this is to find an appropriate method for each modality and each kind of data.

Another aspect is the definition of the purpose as well as the intended users, and as a main task the designing of the user interface and the systems functions in order to meet the interests and needs of the target group.

The field of research of multimodal dialogue systems and applications is relatively new and few standards concerning the design of the user interface or the ways of testing and analysing have been established. But today usability studies are attached more importance than ever – for every kind of system or object, not only in fields of technology. There are – on the contrary – branches that deal frequently with aspects of usability and already gained precious information, for instance (cognitive) psychology. This knowledge can be useful for enterprises or persons who develop such multimodal systems. In my opinion, the cooperation with other companies or even other fields of research and hence the exchange of experiences and know-how is one big chance to improve usability testing, even for very specific applications.

Abstract

Current views of multimodal language resources have not yet sufficiently captured the complex interrelationships within page-based information delivery. This is critical for development of multimodal corpora and language resources suitable for large-scale empirical investigation. Serious attempts to interrogate the nature of multimodal meaning-making in professionally-produced documents, both paper and electronic, require a clear understanding of the organisation of the layers into which meaning is organised. In this paper, we present the first multi-layered XML annotation scheme that meets these requirements, developed using a combination of expertise from computational linguists and designers from various sectors of the publishing industry.

1. Introduction

With current developments and goals involving multimodal documents in the widest sense—i.e., including highly interactive artifacts capable of responding to, and producing information in, input/output modes ranging across verbal, gesture, touch and so on, animated/video content, traditional texts, graphics, and so on—it is perhaps tempting to believe that the organization of 'simpler', more traditional document forms, such as two-dimensional presentations involving textual, graphical and diagrammatic information, has been 'solved'. Attention is then drawn away from the complexities of these document types, such as they are, and are to be picked up as a by-product of dealings with more complex artifacts. In our ongoing work on two-dimensional, non-animated information presentations—e.g., books, information leaflets, traditional websites, newspapers (in both print and online forms), and so on—we have found a wealth of complexity that raises serious doubts about such an approach. One aspect of the problem, and the challenge, can be seen in the large gap that exists between previous corpus encoding initiatives (e.g., TEI and the derived CES) which are text based and more recent proposals for capturing mixed media/mode presentations: Somewhere between these two extremes, much of the highly flexible and meaningful resources of two-dimensional information presentation traditionally and non-technically subsumed under 'layout' and graphic design go missing.

As a consequence of this, we have found it necessary to develop a new annotation scheme for describing the informational relationships employed in the area. Two-dimensional information presentation—whether on the page, screen, or whatever—still represents the overwhelming majority of users' contact with information, and so a revealing and empirically based understanding of the meaning-making resources of this area remains of crucial importance. Previous attempts to provide annotation schemes for setting up corpora for documents of this kind have not succeeded in covering very much of the range of phenomena encountered in natural documents however (Corio and Lapalme, 1998; Bouayad-Agha, 1999; Bouayad-Agha, 2000). In this paper, we describe the goals of our own annotation work, set out the basic levels of annotation we believe are required, describe the technical approach taken, and indicate what we see as the next immediate stages, problems and challenges of follow-up development.

2. Goals

We take the view that language, layout, image, and typography are all purposive forms of communication. Accordingly, in our research project GeM ("Genre and Multimodality", http://www.purl.org/net/gem), we aim to describe and analyse all these elements within a common framework, thereby providing a more complete understanding of meaning-making in visual artefacts. By analysing resources across visual and verbal modes, we can see the purpose of each in contributing to the message and structure of the communicative artefact as a whole.

One particular goal of the research is to formalise and model the role of *genre* in layout and typographical decisions. Through the analysis of sample types of multimodal document, the project aims to develop a theory of visual and textual page layout in electronic and paper documents that includes adequate attention to local and expert knowledge in information design. The model is being implemented in the form of a computer program that allows exploration of both existing and potential layout genres, generating alternative and novel layouts for evaluation by design profes-

sionals.

Our use of the term genre here is similar to Biber's (1989, pp5–6), who in his study of linguistic variation states that 'text categorizations readily distinguished by mature speakers of a language; for example—novels, newspaper articles, editorials, academic articles, public speeches, radio broadcasts, and everyday conversations—categories defined primarily on the basis of external format'. We adhere, too, to Biber's view that these categories of text also reflect distinctions in the author's purpose: the documents look different, and contain different language forms, because they are intended to do different things.

Although there are many attempts to categorise the kinds of language that occur in different genres of texts in linguistics, there are few attempts to extend genre analysis into other aspects of visual meaning: Twyman (1982) and Bernhardt (1985), for example, provide preliminary schemes for categorising documents according to the interrelationships between images and text, while Kress and Van Leeuwen (2001) have now also explicitly begun to relate multimodality and genre. Waller (1987), however, is the only attempt extant, to our knowledge, that has attempted to describe the role of language, document content, practical production context and visual appearance in the formation of document genre within the same framework. Our work draws upon and extends Waller's in several ways, as we shall make clear below.

For this, or any project addressing the communicative strategies involved in two-dimensional visual artefacts, the provision of suitable corpus materials is fundamental. Furthermore, since such materials are not currently available, the development of such a corpus has been adopted as an additional explicit goal of the GeM project. The purpose of the corpus development within GeM is to investigate systematic connections between a rich characterisation of the context of use of multimodal documents and their linguistic, graphical, and layout realisations. Within the GeM project itself, four broad document genres have been selected for initial treatment: traditional paper-based newspapers, online web-based newspaper sites, instructional documents, and wildlife books; in each area we have secured a collection of documents and have established contact with designers either expert in these respective fields or, in several cases, actually responsible for the documents gathered. We focus here on the annotation scheme that we have found necessary for structuring the corpus developed.

3. Basic levels of annotation

Waller (1987, pp178ff) represents the constraints on the typographer in producing a graphical document as emerging from three sources:

- Topic structure: 'typographic effects whose purpose is to display information about the author's argument—the purpose of the discourse';
- Artefact structure: 'those features of a typographic display that result from the physical nature of the document or display and its production technology';
- Access structure: 'those features that serve to make the document usable by readers and the status of its components clear'.

Waller did not produce detailed text analyses based on his model but, grounded as it is in the very practical concerns of document design, his view that document appearance results from satisfying goals at different levels is persuasive. We have particularly taken the force of his point that the physical nature of the document and its method of production play a major role in its appearance. In this way, the 'ideal' layout of information on a page may never occur: it must be 'folded in' to the structures afforded by the artefact, and labelled and arranged according to the structures required for access. Document design is therefore never 'free', in the sense that it is never motivated solely by the dictates of the subject matter. We therefore have required a place for these kinds of constraints in our annotation.

In our revision of Waller's model, we suggest that there is an advantage to be gained in uncollapsing his 'topic structure' into a separation between content and rhetorical presentation. We view content to be the 'raw' data out of which documents are constructed. What Waller describes as 'the author's argument' is not solely or completely dictated by content: many rhetorical presentations are compatible with the same content. In terms more familiar from natural language generation, we separate out the 'what-to-say' from rhetorically structured text plans for expressing that content. Secondly, we take what Waller terms 'artefact structure' to be not a structure in the sense of some set of ideas that are to be incorporated in the document, but rather as a constraint on the combination of all the other elements into a finished form.

The levels we propose as minimally necessary for revealing accounts of the operation of the kinds of visual artifacts being gathered in our corpus are, then, as follows:

- Content structure: the structure of the information to be communicated;
- Rhetorical structure: the rhetorical relationships between content elements; how the content is 'argued';
- Layout structure: the nature, appearance and position of communicative elements on the page;
- Navigation structure: the ways in which the intended mode(s) of consumption of the document is/are supported; and
- Linguistic structure: the structure of the language used to realise the layout elements.

We suggest that document genre is constituted both in terms of levels of description, and in terms of the constraints that operate on the information at each level in the generation of a document. Document design, then, arises out of the necessity to satisfy communicative goals at the five levels presented above, while also addressing a number of potentially competing and/or overlapping constraints:

- Canvas constraints: Constraints arising out of the physical nature of the object being produced: paper or

screen size; fold geometry such as for a leaflet; number of pages available for a particular topic, for example;

- Production constraints: Constraints arising out of the production technology: limit on page numbers, colours, size of included graphics, availability of photographs; for example, and constraints arising from the micro-and macro-economy of time or materials: e.g. deadlines; expense of using colour; necessity of incorporating advertising;

- Consumption constraints: Constraints arising out of the time, place, and manner of acquiring and consuming the document, such as method of selection at purchase point, or web browser sophistication and the changes it will make on downloading; also constraints arising out of the degree to which the document must be easy to read, understand, or otherwise use; fitness in relation to task (read straight through? Quick reference?); assumptions of expertise of reader, for example.

Following Waller (1987), then, we claim that not only is it possible to find systematic correspondences between these layers, but also that those correspondences themselves will depend on specifiable aspects of their context of use. In particular, they will depend on 'canvas constraints' set by the nature of the realizational medium (paper, screen-based browser, palmtop, screen resolution) and 'production constraints' imposed by available technology and design choices (allowable cost, number of pages, available printing or rendering techniques, etc.). A model of multimodal genre must begin by expressing adequately the above five levels of description as well as finding the most appropriate way of satisfying the three sets of constraints.

Our provision of a corpus of multimodal documents serves as the empirical basis for more thorough investigations of this claim. So far our work has identified widespread mismatches between rhetorical purposes and layout structures even among professionally produced documents; this offers a useful basis for constructive critique. We see the collection of extensive corpora of multimodal documents of this kind, annotated according to the levels of description that we have here briefly motivated, as an essential research and direction for the next five years.

4. Technical implementation

As we have seen, the two communication modes of visual and verbal information presentation are the main perspectives to be captured in the GeM annotation scheme. The scheme accordingly identifies textual elements (verbal mode) and layout elements (visual mode) in a multi-layered annotation, and specifies how these elements are grouped into hierarchical structures (primarily: the rhetorical structure for textual elements, the layout structure formed by the layout elements, and a page model formed by an 'area model': see below). The alignment between these intersecting hierarchies is achieved by specification of the 'GeM base'—a list of the basic units out of which the document is constructed. In accordance with the goal of the GeM project, the granularity of the linguistic basic units employed in the annotation is approximately the sentence level—this does not preclude providing correspondences with other levels of granularity that might be required for other purposes of course.

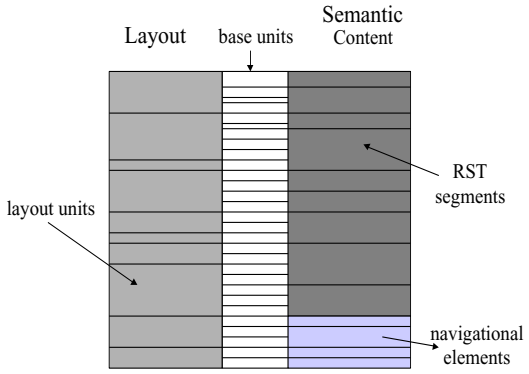

Figure 1: The distribution of base elements to layout, rhetorical and navigational elements

Each layer in the GeM model is represented formally as a structured XML specification, whose precise informational content and form is in turn defined by an appropriate Document Type Description (DTD).[1] The markup for one document then consists generally of the following four inter-related layers:

Name	content
GeM base	base units
RST base	rhetorical structure
Layout base	layout properties and structure
Navigation base	navigation elements and structure

All information apart from that of the base level is expressed in terms of pointers to the relevant units of the base level. This stand-off approach to annotation readily supports the necessary range of non-isomorphic, overlapping hierarchical structures commonly found even in the simplest documents. The relationships of the differing annotation levels to the base level units is depicted graphically in Figure 1. This shows that base units (the central column) provide the basic vocabulary for all other kinds of units and can, further, be cross-classified.

This annotation scheme is being developed further in response to the needs of concrete annotation tasks. Its current state is described in the technical manual available on the GeM website (Henschel, 2002). We describe it further here only in sufficient detail to give an impression of the kinds of annotation information and work involved.

4.1. Basic constituents

The purpose of the base level annotation is to identify the minimal elements which can serve as the common denominator for textual elements as well as for layout elements. Where speech-oriented corpora use the time line as basic reference method, and syntactically oriented corpora use the sequence of characters or words, the GeM annota-

[1] For the DTDs themselves, as well as further information and examples, see the GeM corpus webpages.

tion operates at a less delicate level and uses bigger chunks (mostly sentences and graphical page elements) as the bases of the markup. Everything which can be seen on each page of the document has to be included. How the material on each page is broken up into basic units is given by the following list, each is marked as a base unit:, orthographic sentences, sentence fragments initiating a list, headings, titles, headlines, photos, drawings, diagrams, figures (without caption), captions of photos, drawings, diagrams, tables, text in photos, drawings, diagrams, icons, tables cells, list headers, list items, list labels (itemizers), items in a menu, page numbers, footnotes (without footnote label), footnote labels, running heads, emphasized text, horizontal or vertical lines which function as delimiters between columns or rows, lines, arrows, and polylines which connect other base units.

Everything on a page should belong to one base unit. The base annotation has a flat structure, i.e. it consists of a list of base units.[2] Generally any text portion which is differentiated from its environment by its layout (e.g. typographically, background, border) should be marked as a base unit. The list of base units needs to comprise everything which can be seen on the page/pages of the document. The tag used to mark base units is the <**unit**>. Each base unit has the attribute **id**, which carries an identifying symbol. If the base unit consists of text, the start and end of this text is marked by the <**unit**> tag. Illustrations, however, are not copied into the GeM base. Thus, base units which represent an illustration or another graphical page element are empty XML-elements but can optionally be equipped with an **scr** and/or an **alt** attribute to show, indicate or access the source of an illustration.

4.2. Layout base

The layout base consists of three main parts: (a) layout segmentation – identification of the minimal layout units, (b) realization information – typographical and other layout properties of the basic layout units, and (c) the layout structure information – the grouping of the layout units into more complex layout entities. We explain these three components in more detail below.

In typography, the minimal layout element (in text) is the glyph. In GeM, however, we are primarily concerned with typographical and formatting effects at a more global level for a page; therefore we do not go into such detail, instead considering the paragraph as minimal layout element. That means, a sequence of sentences with the same typographical characteristica which makes up one paragraph is marked as one layout unit. In addition to that we mark all graphically realized elements from the GeM base as layout units. Also highlighted text pieces in sentences, or text pieces within illustrations are marked as layout units. Hence the same list which has been given for the markup of the base units applies here, but with paragraphs instead of orthographic sentences. The tag for a layout unit is <**layout-unit**>. Each layout-unit has the attribute **id**, which carries an identifying symbol, and the attribute **xref** which points to the base units which belong to this layout unit.

The second part of the layout base is the realization. Each layout unit specified in the layout segmentation has a visual realization. The most apparent difference is which mode has been used – the verbal or the visual mode. Following this distinction, the layout base differentiates between two kinds of elements: textual elements and graphical elements marked with the tags <**text**> and <**graphics**> respectively. These two elements have a differing sets of attributes describing their layout properties. The attributes are generally consistent with the layout attributes defined for XSL formatting object and CSS layout models.

Some of the layout units identified in the segmentation part of the layout base can be grouped into larger layout chunks. For instance, the heading and its belonging text form together a larger layout unit, or the cells of a table form the larger layout unit "table". The criterion for grouping layout elements into chunks is that the chunk should consist of elements of the same visual realization (font-family, font-size, ...), or the chunk is differentiated as a whole from its environment *visually* (e.g. by background colour or a surrounding box). In Reichenberger et al. (1995), the authors propose identifying layout chunks by applying a decreasing resolution to the document. The grouping into chunks usually can be applied in several steps, thus forming larger and larger layout chunks out of the basic layout units up to the entire document. Note that one chunk can consist of layout elements of different realizations (text and graphics). The third part of the layout base then serves to represent this hierarchical layout structure. Generally we assume that the layout structure of a document is tree-like with the entire document being the root. Each layout chunk is a node in the tree, and the basic layout units, which have been identified in the segmentation part of the layout base, are the terminal nodes of that tree.

Area model. Each page usually partitions its space into sub-areas. For instance, a page is often designed in three rows – the area for the running head (row-1), the area for the page body (row-2), and the area for the page number (row-3) – which are arranged vertically. The page body space can itself consist of two columns arranged horizontally. These rows/columns need not to be of equal size. For the present, we restrict ourselves to rectangular areas and sub-areas, and allow recursive area subdivision. The partitioning of the space of the entire document is defined in the **area-root**, which structures the document (page) into rectangular subareas in a table-like fashion.[3]

The tag to represent the area root is <**area-root**> The tag to represent the division of a sub-area into smaller rectangles is <**sub-area**>, this shares the attributes of the root but adds a **location** attribute so that subareas are positioned relative to their parent. Locations are indicated with respect to a logical grid defining rows and columns. If, for example, we were considering a page made up of a running

[2] In certain cases, we diverge from the flat structure of the base file. See the technical documentation for further details.

[3] Note that the area-root need not to be a page; if the document to be annotated is a book or brochure, then it can also be the entire book or brochure.

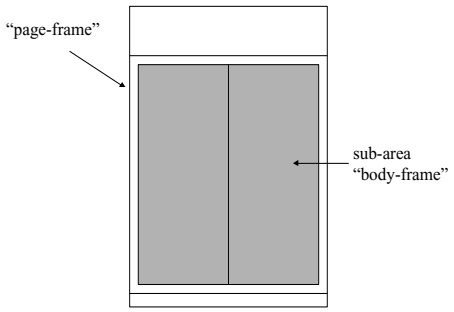

Figure 2: Visualized area model

head, a page body, and a footer for the page number, and in which the page body itself is divided into two columns, then the following annotation would define a corresponding area model. Here, the example's area model consists of a specification of the area-root (called "page-frame"), and the specification of one particular sub-area located in row-2 (called "body-frame"):

```
<area-root id="page-frame" cols="1" rows="3"
      hspacing="100" vspacing="10 85 5"
      height="16cm" width="14cm">
  <sub-area id="body-frame" location="row-2"
      cols="2" rows="1" hspacing="50 50"
      vspacing="100"/>
</area-root>
```

The attribute `vspacing=''10 85 5''` means that the running head takes 10% of the entire page height, the page body 85% and the page number 5%. The page body consisting of two columns is indicated by the hspacing attribute value "50 50", i.e., that both columns are equal in width and take half of the parent unit's width.[4] This area model is visualized in Figure 2.

The area model then provides logical names for the precise positioning of the layout units identified in the layout structure proper.

4.3. RST base

The RST base presents the rhetorical structure of the document. The rhetorical structure is annotated following the Rhetorical Structure Theory (RST) of Mann and Thompson (1988). In RST, a **span** is a continuous text fragment consisting either of a nucleus and one or more satellites (mononuclear relation), or of a number of nuclei which stand in a multinuclear relation (joint, sequence, ...) Some characteristics of RST vary between different research traditions, especially the granularity of the segmentation, the assumed set of rhetorical relations and the branching style of the rhetorical structure tree. We have also needed to make some extensions for the particularities of dealing with mixed verbal and visual information; clearly, when one wants to apply RST to modern, often multimodal, documents, new issues arise. Previous generalizations of RST to multimodal documents have either added new relations to model the relations between graphics and text (Schriver, 1996; Barthes, 1977) or parameterize the existing relation set by a mode parameter (André, 1995). We favour the second approach. However, there are other problems when generalizing RST to multimodal documents, which have not been addressed previously:

- The prominence of graphics in multimodal documents makes it often difficult to decide upon nuclearity in multimodal relations.
- The linear order of the constituents of the document is lost.
- The minimal unit for RST segmentation cannot be restricted to a clause or clause-like phrase.

We address these concerns briefly in turn.

Nuclearity in multimodal relations. Although graphical illustrations are often used to *rephrase* a text passage, it is often difficult to decide which of the two segments – the illustration or the text passage – is in fact nulear and which is the satellite. This seems to be a particular problem of graphics-text relations. To model this problem, we use the multinuclear **restatement** relation. A similar relation can also be found in Barthes under the name **redundant**.

Linear order. Conventional RST builds on the sequentiality of text segments. Relations are only possible (with some minor exceptions) between subsequent segments/spans (sequentiality assumption). With multimodal documents, the mutual spatial relations between the segments changes (from relations in a string-like object to relations in a graph). Segments can have not only a left and a right, but also an upper and a lower neighbour segment. In general one can imagine neighbouring segments in any direction, not only the four which presuppose a rectangular-based page layout. In addition to this, there can be more than one neighbour in each direction. The simpliest solution to apply RST (with its sequentiality assumption) to such a document would be to introduce a reading order on the segments of the document, which is then used as the sequence behind the RST structure. However, this can easily fail to reflect the actual reading behavior. A better, more straightforward generalization of the sequentiality assumption, which we will adopt here, is to restrict RST relations to pairs (sets) of document parts (segments/spans) which are adjacent in any direction. But again, in real documents, one can sometimes find a layout where the rhetorical structure obviously is in conflict with this adjacency condition. Our hypothesis here is that this is generally possible, but that in such a case an explicit navigational element is required so as to indicate the intimate relation between two separated layout units.

Clause as segment. The clause usually serves as minimal unit in RST. There are also approaches, which allow prepositional phrases to be a segment on their own. This is straightforward because both approaches assume something which denotes an action, an event or a state – also called eventualities – as the basic unit. However, if we move to modern documents, particularly multimodal documents, it is questionable whether the clause/PP basis should be kept. Typical examples in multimodal documents are:

[4] For the time being, we ignore space for margins, at least as long as they do not contain footnotes or other text.

- a diagram picturing a certain object and a text label which identifies (puts a name to) this object
- a list with an initiating sentence fragment, as in:

In the box are: ◇ three cordless handsets ◇ the base unit ◇ a mains power lead with adapter ◇ a telephone line cable ◇ two charger pods

- an attribute-value table, as in:

Juvenile	Grey-brown, flecked becoming whiter, adult plumage after three years.
Nest	Mound of seaweed on bare rocky ledge.
Voice	Harsh honks and grating calls at colony.

The cited examples are all expressions of states, or of static relationships between two objects or between an object and a property such as: identification, location, possession, and predication relations. In a traditional linear text, such relations would have been expressed as *is*- and/or *has*-clauses. Each such clause would constitute **one** basic RST segment. In our examples above, however, the two constituents of such a static relation clause are broken out and printed as separate layout units—in the first example, they are even given in differing modes. It is their mutual arrangement on the page plus possible extra graphical devices that expresses the relation between them. This raises the question as to what counts as a minimal unit for an RST analysis in such documents. We solve this issue by introducing a new component for annotation distinct from RST: we analyse the object-object/property relations, if they are clearly separate layout units, according to a small set of relations based on Halliday (1985), which we term 'intraclausal-relations'.

The tag used to mark the basic RST units is <**segment**>. In order to find out which base units form segments, one has to filter out those base units which are in the document for navigational reasons only. These are, for example, page numbers, running heads, footnote labels, document deictic expressions. We also consider headings as navigational elements, and do not include them in the RST analysis. In addition to these segments, we compose other complex segments consisting of more than one base unit for the cases where a intraclausal-relation is expressed on the page by two (or more) separate layout units. Typical examples are diagram + label, table cell$_{i,1}$ + table cell$_{i,2}$ in a two-column table, list initiating sentence fragment + list items. And, finally, sentences disrupted into two base units by page/column breaks only form one segment in the RST base.

The GeM XML annotation for RST aims to overcome some drawbacks found in existing RST annotation approaches. The two standards common in the RST community are those provided by the annotation tools of Daniel Marcu and Mick O'Donnell (see, e.g., www.sil.org/~mannb/rst/toolnote.htm). In both these tools, the annotated output is primarily seen as the program-internal representation of RST structures to be visualized as graphical trees with the help of the tool, but not as output to be used for further XML processing; we describe the pros and cons of the alternatives more in the technical documentation.

4.4. Navigation base

Navigation in a document is performed with the help of pointers, text pieces which tell the reader where the current text, or 'document thread', is continued or which point to an alternative continuation or continuations. The addresses used by such pointers are either names of RST spans or names of layout chunks. For long-distance navigation, typical nodes in the RST structure and in the layout structure have been established for use in pointers; in particular, chapter/section headings are names for RST spans and page numbers are names for page-sized layout-chunks, which tend to be used for navigation. However, there can also be other name-carrying layout-chunks or RST spans such as, for example, figures, tables, enumerated formulas, and so on. The navigation base of a document lists all these "names" which have been defined in this document to be actually or potentially used in pointers. We call the names of RST spans **entries** because they are usually placed immediately before the text of this span. We call the name of a layout-chunk an **index**.

The tag for an entry definition is <**entry**>. We allow entries simultaneously to be segments. We annotate the definition of an index at the page where it is defined, and refer with xref to the base unit which serves as the identifier.

Beside the list of entries and indices, which just defines addresses, the most important part of the navigation base consists of all pointers occuring in the document. The surface realization of pointers are "document deictic expressions", a term coined by Paraboni and van Deemter (2002). Document deictic expressions occur either within sentences or as separate layout units. We have marked the first type as embedded base units and the second as main level base units in the GeM base. In the navigation base, we specify the semantic meaning of such a document deictic expression as **pointer**. We distinguish pointers which operate on the layout structure, and pointers which operate on the RST structure. A pointer (or link) operating on the RST structure points from the current segment (which entails the document deictic expression) to an RST span – the goal RST span – which is layouted at a different place and is not adjacent. A pointer operating on the layout structure points from the layout chunk (which entails the document deictic expression) to another layout chunk which is not adjacent. Another distinction is the pointer type, which indicates different pointing situations. A **continuation** pointer is used in the situation where the layout of an article is broken into two non-adjacent parts. The second part is often printed several pages later than the first part. Continuation pointers are typically layout-operating pointers. **Branching** pointers are used in the situation where a certain piece of information is with respect to its content appropriate at two (or

more) places in the same document. The designer has decided to put it at one of the possible places. In order to indicate the other possible place, a pointer is given at the other location. A third type of pointer is the **expansion pointer**. It is used when more information is available, but not central to the writer's goal. An expansion pointer points to this extra information. Coming along a branching or an expansion pointer, the reader has the choice between two alternatives to continue reading the document. With a continuation pointer there is only the choice between reading continuation or stopping.

4.5. Uses of the corpus

The main results found so far in use of the corpus have been local, in that we are uncovering the rather wide variation that exists between selected layout structures on the one hand and rhetorical organization on the other *within single documents*. In surprisingly many cases, this variation goes beyond what might be considered 'good' design: in fact, we would argue that such designs are flawed and would be improved by a more explicit attention to the rhetorical force communicated by particular layout decisions. This represents the use of the corpus for document critique and improvement (cf. Delin and Bateman (2002)); here further corpus collection is nevertheless essential in order to map further the limits of acceptable functional variation.

We are also exploring the formulation of constraints over collections of corpus entries—e.g., over the pages of a book, or over collections of books in a series, etc.—by means of further annotation levels in which values from the primary annotation levels are partially specified. These need to be hierarchically related. It is at these 'meta' levels that the role of Waller's production and canvas constraints become particularly clear. We are employing this information as an important source of input in a prototype automatic document generation system capable of producing the kinds of variation and layout forms seen in our corpus, thus extending the early generation work in this spirit presented in Bateman et al. (2001).

Finally, we are still searching for more effective means of interogating the corpus maintained in the GeM style. Queries expressed in the XML Xpath language allow simple retrieval of information maintained in the corpus, but are cumbersome for more complex queries. Whether further developments such as XQL or XQuery will bring benefits is not yet clear. Somewhat disappointing was the unsuitability of the previous generation of linguistic-oriented corpus tools, which, despite considerable investment, seem to have been outstripped by the very rapid developments seen in the mainstream XML community. Most of our current work is done directly with XMLSpy and XLST tools such as Xalan. We have found the non-linearity and the non-consecutive nature of the units grouped within our annotation scheme as presenting a major problem for annotation models that have been developed in the speech processing tradition where contiguity of units is the expected case.

5. Follow-up goals, challenges and requirements

We expect that the details of annotation will be refined further as we approach a wider range of documents. It is now a major challenge to produce workable annotation schemes and corresponding corpus collections that include the kind of information we have argued to be necessary in this paper. This information represents a crucial bridging between technicalities of document production and the real issues of design faced in the publishing industry. Corpora built in this way will face two-ways: both to further linguistic and computational plinguistic research and development and to practical issues of design and evaluation. We believe that this needs a firm place in any roadmap now envisaged for language resource construction.

With this in mind we are also exploring a second round of corpus collection and annotation; it is our conviction that only a thorough corpus-oriented study of documents will allow further motivated theoretical and practical statements to be made about the meaning resources that such documents offer. If language resources are to be constructed that include documents of the kind targetted within GeM, then information such as that captured in the GeM annotation scheme will be crucial.

Here there are several issues that require concerted effort. Theoretically, the acceptance of the value and role of rhetorical analyses as giving a fine-grained description of communicative intentions is not uncontroversial. There are attempts in progress to produce corpora of texts annotated rhetorically. We believe this is also essential for multimodal documents. However, as we have detailed above, there are also significant issues that need now to be faced when we move away from linear presentations even to two-dimensional page-based presentations.

More practically, there are issues concerning how much information can be obtained from existing annotation and industry-standard markups: for example, the information maintained in professional document preparations tools such as QuarkXpress or Adobe Framemaker, InDesign, etc. Providing conversion tools to the kinds of linguistically motivated corpus annotations described here would open up a huge area of data. The genre and design knowledge encoded implicitly in style sheets and templates needs also to be made available so that it may be subjected to the kinds of study described above.

Of particular interest to us at present are further extensions across languages so as to compare cultural variation in visual/verbal presentations and further, more detailed comparison of documents variants created by repurposing (e.g., print-to-web, web-to-palmtop, etc.). In both cases, we are concerned that quite ordinary, everyday documents be considered equally, such as bills, consumer letters, instruction manuals, newspapers—these are the documents which users encounter in their everyday lives and understanding how they can be best structured could have significant practical benefits. The acquisition of annotated data across genre and cultures should also therefore be a high priority task.

Finally, we also require that the GeM annotation should

be able to fit into broader annotation schemes. Thus any kind of artifact that includes two-dimensional presentations (for example, a video embedded in a webpage) may also receive a GeM annotation for that component of the information offering. Our claims concerning coherence and consistency of information presentation decisions across text, visuals and layout can then be investigated here also. In such cases, the GeM annotation offers an annotation slice consisting of several annotation levels contributing to more comprehensive annotations that take in other important aspects of the artifact's design beyond that considered within the GeM model. In this respect, we consider it a crucial design feature that such annotation slices be additive and open rather than excluding and closed.

Abstract

In this paper we describe how the project "Dutch Human Language Technologies Platform" has contributed to creating the preconditions for establishing a roadmap for Human Language Technologies in the Dutch speaking area. Our overview of the results obtained so far reveals that the goals of all four action lines have been achieved and that there are clear directions for how to proceed in the near future. We hope that our experiences will be useful to other countries that intend to start similar initiatives.

1. Introduction

Establishing a roadmap for Human Language Technologies for a given language requires that first a number of important basic elements be defined, such as:

1. what is minimally required to guarantee an adequate digital language infrastructure for that language?
2. what is the current situation of HLT in that language?
3. what needs to be done to guarantee that at least what is required be available?
4. how can 3 best be achieved ?
5. how can we guarantee that once an adequate HLT infrastructure is available, it also remains so?

It is exactly these questions that were at the core of the activities that in the last two years were carried out within the framework of the Dutch-Flemish project "Dutch Human Language Technologies Platform". The ultimate aim of this project is to further the development and secure the usability of an adequate digital language infrastructure for Dutch, which is required to maximise the outcome of future efforts and to guarantee progress in the field of HLT.

In this paper we will report on our approach and our experiences in carrying out the activities envisaged in this project, because we think that this information can contribute to the aim of this workshop: establishing a roadmap for Human Language Technologies for the next decade.

2. The Dutch HLT Platform: action plan

The plan to set up a Dutch HLT platform was launched by the Dutch Language Union (Nederlandse Taalunie, NTU) which is an intergovernmental organisation established in 1980 on the basis of the Language Union Treaty between Belgium and the Netherlands. The NTU has the mission of dealing with all issues related to strengthening the position of the Dutch language (see also www.taalunie.org). In addition to the NTU, the relevant Flemish and Dutch ministries and organisations are involved in the HLT Platform. The various organisations have their own aims and responsibilities and approach HLT accordingly. Together they provide a good coverage of the various perspectives from which HLT policy can be approached.

The rationale behind the Dutch HLT platform was not to create a new structure, but rather to co-ordinate the activities of existing structures. The platform is a flexible framework within which the various partners adjust their respective HLT agendas to each other's and decide whether to place new subjects on a common agenda. Initially, the Dutch HLT platform was set up for a period of five years (1999-2004).

To achieve the objectives mentioned above, an *Action plan for Dutch in language and speech technology* was defined, which encompasses various activities organised in four action lines:

2.1. Action line A: performing a 'market place' function

The main goals of this action line are to encourage co-operation between the parties involved (industry, academia and policy institutions), to raise awareness and give publicity to the results of HLT research so as to stimulate market take-up of these results.

2.2. Action line B: strengthening the digital language infrastructure

The aims of action line B are to define what the so-called BLARK (Basic LAnguage Resources Kit) for Dutch should contain and to carry out a survey to determine what is needed to complete this BLARK and what costs are associated with the development of the material needed. These efforts should result in a priority list with cost estimates which can serve as a policy guideline.

2.3. Action line C: working out standards and evaluation criteria

This action line is aimed at drawing up a set of standards and criteria for the evaluation of the basic materials contained in the BLARK and for the assessment of project results.

2.4. Action line D: developing a management, maintenance and distribution plan

The purpose of this action line is to define a blueprint for management (including intellectual property rights), maintenance, and distribution of HLT resources.

Soon after the HLT Platform was set up it was decided that survey (action line B) and evaluation (action line C) be carried out in an integrated way because the actual availability of a product is not determined merely by its existence, but depends heavily on the quality of the product itself.

In the remainder of this paper we analyse the results of each action line in detail and in the final section we consider how this work has paved the way to a roadmap for Dutch HLT.

3. Action line A: results

In setting up HLT projects such as the *Spoken Dutch Corpus* and *NL-Translex*, much time was invested in the search for the appropriate responsible (funding) bodies in the Netherlands and Flanders. Moreover, various studies had indicated that the fragmentation of responsibilities made it difficult to conduct a coherent policy and meant that the field lacked transparency for interested parties. For these reasons the NTU, as the coordinator of the HLT Platform, stimulated the creation of a network aimed at:

disseminating the results of research in the field of HLT;

bringing together demand and supply of knowledge, products and services;

stimulating co-operation between academia and industry in the field of HLT.

After only two years of activity the HLT Platform has already produced important results. The success of Action line A is also partly due to the fact that the NTU acts as the National Focal Point (NFP) in the HOPE (Human Language Technology Opportunity Promotion in Europe) project. HOPE is a multi-country, shared-cost accompanying measure project of the IST-Programme of the European Commission that aims at providing awareness, bridge-building and market-enabling services to boost opportunities for market take-up of the results of national and European HLT RTD. The key focus is on helping to accelerate the volume of HLT transfer from the research base to the market by creating communities of interest between the critical players in the development and value chain. The aims of HOPE clearly coincide with the aims of Action line A.

At the beginning of the HOPE project an extensive informational website on the HLT sector in The Netherlands and Flanders was established by the NTU. This website provides up-to-date information on all relevant actors in the field of HLT (i.e. researchers, developers, integrators, users and policy makers) on how the HLT sector evolves on a cross-border Dutch/Flemish level, and on HLT related events throughout Europe. All this information is presented in Dutch and English.

The site also includes a calender of HLT events and a form for people who want to be included in the contacts database, as well as links to the HLTCentral website. All information on HLT related programmes and actions of the European Commission is provided on a separate website, established and maintained by subcontractor Senter/EG-Liaison, which is the most knowledgeable party on this subject. These two sites have one entry point from the HOPE point-of-view, via an intermediate site that was developed to provide clarity on where to find which information. This intermediate site (also in Dutch and English) has been placed on http://www.hltcentral.org/euromap/ and should be considered as the common homepage for the two websites. Visitors who do not find answers to their questions on the website can contact the NTU or Senter/EG-Liaison directly (preferably by e-mail) and may expect to receive quick and accurate replies.

Part of the infodesk task is also to conduct mailings to national contacts. These mailings are done on an ad-hoc basis, either at a third party's request (e.g. if an organizing committee wants to announce an event) or on the NFP's own initiative (e.g. if there is important news about an EC programme). From the beginning of the HOPE project, an extensive contacts database has been compiled by the NFP. At present, this database contains almost a thousand persons from over six hundred organisations in The Netherlands and Flanders. It is a valuable backbone for all information activities of the NFP.

The Dutch/Flemish NFP also visits companies with HLT related needs to demonstrate the benefits of HLT, to solicit a clear picture of the company's knowledge state and future plans, and to provide information of cross-linking services where appropriate. The NFP, in collaboration with its partners in The Netherlands and Flanders, has organised various seminars and workshops, which were attended by people from industry, academia, and policy institutions. The aim of such events is to further enhance awareness of recent developments in the HLT sector at the national and international level, such as the dissemination of information on European Commission HLT actions and their relevance to the national situation. Note that the cross-border Flemish/Dutch level should be considered here as the "national" level. The first national seminar took place in March 2001, and was a major event with over 150 participants. The second seminar was held in November 2001 and was directly related to the general survey carried out under action line B and C. Two other events are being organised for 2002. To conclude, we can safely state that in two years time the activities carried out within Action line A have certainly contributed to creating transparency and structure in the HLT field in The Netherlands and Flanders.

4. Results of Action lines B and C

The field survey comprised the following three stages: defining the BLARK for Dutch, making an inventory of available HLT resources, establishing a priority list. These three stages are described in more detail below.

4.1. Defining the BLARK

In defining the BLARK a distinction was made between applications, modules, and data:

Applications: refers to classes of applications that make use of HLT. The following classes were defined: CALL (Computer Assisted Language Learning), access control, speech input, speech output, dialogue systems, document production, information access, and multilingual applications or translation modules.

Modules: refers to the basic software components that are essential for developing HLT applications.
Data: refers to data sets and electronic descriptions that are used to build, improve, or evaluate modules.

In order to guarantee that the survey is complete, unbiased and uniform, a matrix was drawn up by the steering committee describing (1) which modules are required for which applications, (2) which data are required for which modules, and (3) what the relative importance is of the modules and data. This matrix (subdivided in language technology and speech technology) is depicted in Table 1, where "+" means important and "++" means very important.

This matrix serves as the basis for defining the BLARK. Table 1 shows for instance that monolingual lexicons and annotated corpora are required for the development of a wide range of modules; these should therefore be included in the BLARK. Furthermore, semantic analysis, syntactic analysis, and text pre-processing (for language technology) and speech recognition, speech synthesis, and prosody prediction (for speech technology) serve a large number of applications and should therefore be part of the BLARK, as well. Note that only language specific modules and data were considered in this survey.

Based on the data in the matrix the BLARK for Dutch should consist of the following components:

4.1.1. Language technology BLARK

Modules:
- Robust modular text pre-processing (tokenisation and named entity recognition),
- Morphological analysis and morpho-syntactic disambiguation,
- Syntactic analysis,
- Semantic analysis.

Data:
- Monolingual lexicon,
- Annotated corpus written Dutch (a treebank with syntactic, morphological, and semantic structures),
- Benchmarks for evaluation.

4.1.2. Speech technology BLARK

Modules:
- Automatic speech recognition (including tools for robust speech recognition, recognition of non-natives, adaptation, and prosody recognition),
- Speech synthesis (including tools for unit selection),
- Tools for calculating confidence measures,
- Tools for identification (speaker identification as well as language and dialect identification),
- Tools for (semi-) automatic annotation of speech corpora.

Data:
- Speech corpora for specific applications, such as CALL, directory assistance, etc.,
- Multi-modal speech corpora,
- Multi-media speech corpora,
- Multi-lingual speech corpora,
- Benchmarks for evaluation.

4.2. Inventory and evaluation

In the second stage, an inventory was made to establish which of the components - modules and data - that make up the BLARK are already available; i.e. which modules and data can be bought or are freely obtainable for example by open source. Besides being available, the components should also be (re-)usable. Obviously, components can only be considered usable if they are of sufficient quality; therefore, a formal evaluation of the quality of all modules and data is indispensable. Given the limited amount of time, only a formal evaluation was carried out by using a checklist with the following items: availability, programming code, platform, documentation compatibility with standard packages, reusability, adaptability and extendibility.
The information on availability, the matrix in Table 1 and the preliminary inventory were submitted to a group of HLT experts from both industry and academia, so that a balanced picture could be obtained.

Based on this information a second matrix was filled in which the availability of the components in the BLARK (cf. Table 2) was described. Availability in this matrix is expressed in numbers from 1 (‘module or data set is unavailable’) to 10 (‘module or data set is easily obtainable’).

At the end of the second stage, all information gathered was incorporated in a report containing the BLARK, the availability figures together with a detailed overview of available HLT resources for Dutch, a priority list of components that need to be developed, and a number of recommendations. This report was considered as being provisional as feedback on this version from a lot of actors in the field was considered desirable.

4.3. Feedback

One of the aims of Action lines B and C was that the majority of the actors in the HLT field would subscribe to the priorities and recommendations for the future. To this end, the provisional report containing the inventory, the priority lists and the recommendations was sent to a total of about 2000 people active in the HLT field who were asked to send their comments by email. After the relevant comments had been incorporated in the report, the same group of people was invited to participate in a workshop in which the results (overview, BLARK, priority lists and recommendations) were officially presented to the public.

On this occasion some people were given the opportunity to publicly present their views on the results of the survey. The workshop was concluded with a general discussion between the audience and a panel of five experts that were responsible for the survey.

The workshop provided useful information that could be used to complete the final report. A number of important points that emerged form this workshop are listed below:
- Cooperation between universities, research institutes and companies should be stimulated.
- For all components in the BLARK it should be clear how they can be integrated with off-the-shelf software packages. Furthermore, documentation and information about performance should be readily available.
- Control and maintenance of all modules and data sets in the BLARK should be guaranteed.
- Feedback from users on the quality and the performance of the various components should be processed in a structured way.

Special attention should be paid to the issue of open source policy and its possible effects for companies.

Table 2 Availability of modules and data

4.4. Inventory, priority list and recommendations

The survey of Dutch and Flemish HLT resources resulted in an extensive overview of the present state of HLT for the Dutch language. By combining the BLARK with the inventory of components that are available and of sufficient quality, the following priority for language and speech technology lists were drawn up.

4.4.1. Priority list for language technology:

1. Annotated corpus written Dutch: a treebank with syntactic and morphological structures,
2. Syntactic analysis: robust recognition of sentence structure in texts,
3. Robust text-preprocessing: tokenisation and named entity recognition,
4. Semantic annotations for the treebank mentioned above,
5. Translation equivalents,
6. Benchmarks for evaluation.

4.4.2. Priority list for speech technology:

1. Automatic speech recognition (including modules for non-native speech recognition, robust speech recognition, adaptation, and prosody recognition),
2. Speech corpora for specific applications (e.g. directory assistance, CALL),
3. Multi-media speech corpora (speech corpora that also contain information from other media such as newspapers, WWW, etc.),
4. Tools for (semi-) automatic transcription of speech data,
5. Speech synthesis (including tools for unit selection),
6. Benchmarks for evaluation.

On the basis of the inventory and the reactions from the field the following recommendations were made:

- existing parts of the BLARK should be collected, documented and maintained by a central institution;
- the BLARK should be completed by financing the development of the resources prioritised;
- the BLARK should be made available to industry and academia through open source development;
- benchmarks, test corpora, and methods for evaluation and validation should be developed.
- the training of qualified HLT researchers should be encouraged.

5. Results of Action line D: the HLT Blueprint

In many cases official bodies such as ministries and research organisations are prepared to finance the development of language resources and no longer feel responsible for what should happen to these materials once the project has finished. However, materials that are not maintained quickly lose value. Moreover, unclear intellectual property right arrangements can create difficulties for exploitation. The purpose of action line D was to draw up a blueprint for management, maintenance and distribution of basic language materials that have been developed with government money. This includes, among other things, dealing with intellectual property rights issues, with the acquisition of resources, the adaptation of data and modules to other systems and applications,

making documentation available, providing a help desk function, maintaining and updating the material. Finally, this blueprint should provide guidelines for organizing a structural form of co-operation in this respect and should serve as an instrument for field organisations as well as for funding bodies.

The *Blueprint for management, maintenance and distribution of digital materials developed with public money (Blueprint)*, P. van der Kamp, T. Kruyt en P.G.J. van Sterkenburg) was prepared in the period 2000 -2001 by a team of language technology experts of the Institute for Dutch Lexicology, INL. In addition to the general aim of providing guidelines for the acquisition, management, maintenance and distribution of HLT materials, the *Blueprint* aims at providing information to be used by policy organisations when assessing research projects aimd at developing HLT materials, for preparing policy plans concerning the acquisition, management, maintenance and distribution of HLT materials and practical information on how to acquire, manage, maintain and distribute HLT materials, answers to questions concerning the (re)usability of HLT materials after the consortia that were set up for their development cease to exist. All this information is presented in the *Blueprint* in nine chapters that, apart from the introductory chapter 1, deal with the following topics:

- Acquisition of HLT resources (Chapter 2)
- Processing of acquired data (Chapter 3)
- Linguistic processing of HLT resources (Chapter 4)
- Management of HLT resources (Chapter 5)
- Maintenance of HLT resources (Chapter 6)
- Distribution of HLT resources (Chapter 7)
- Support to users (Chapter 8)
- Recommendations for future policy (Chapter 9)

The following eight recommendations for future policy are made in the final chapter:

1. An HLT agency is necessary
   In order to prevent that HLT materials developed with government money outside a permanent infrastructure become obsolete and therefore useless, a legal body such as an HLT agency is required.
2. Organisation form of HLT agency and role of NTU
   This HLT agency could be a Dutch-Flemish consortium of institutions and should not be related to one existing institution in particular, because not all expertise is available in one single institution. A co-ordinator could be appointed by NTU to ensure that the interests of the whole HLT field are represented.
3. Tasks of the HLT agency.
   Primary tasks of an HLT agency:
   Task 1. Management
   Task 2. Guarantee accessibility of data and software
   Task 3. Maintenance
   Secondary tasks of an HLT agency:
   Task 4. User support
   Task 5. Acquisition
   Distribution should be entrusted ELDA and LDC.
4. Costs to be met by the government.
   Since extra costs for personnel and hardware will be incurred, additional government funding is required.
5. Costs to be met by the users of the HLT agency
   Depending on the specific use and user, general conditions must be agreed on that guarantee fair tariffs.
6. Acceptance of HLT data and software by the HLT agency.
   The HLT agency can refuse HLT resources that do not meet certain quality standards or that are not essential for a wide range of applications.
7. International participation.
   The HLT agency should be given the possibility, through government funding, to participate in European and/or global projects that are related to its tasks.
8. Development and maintenance of HLT expertise.
   Given the considerable shortage of language and speech technologists, the government should stimulate policies that are aimed at developing and maintaining expertise in the field of HLT.

6. Future prospects

In the previous sections we have provided an overview of the results obtained within Action lines A and D. This has revealed that the aims identified in the *Action plan for Dutch in language and speech technology* have been achieved, at least for these two action lines. Now it remains to be seen how these results will be used in the future in order to achieve the ultimate aim of the "Dutch Human Language Technologies Platform" project: to further the development and secure the usability of an adequate digital language infrastructure for Dutch. To this end in the following sections we consider our future plans with respect to Action lines A (5.1) and D. (5.2).

6.1. Action line A

Since Action line A has already contributed to creating a co-operative framework in the HLT field in The Netherlands and Flanders, our future activities will be directed to maintaining and enlarging it. This entails among, other things, keeping our databases and websites up to date, ensuring communication between interested partners, gradually enlarging the initial network, identifying and promoting the inclusion of new representatives; increasing the visibility and the strategic impact of relevant results and new initiatives; fostering cooperation; providing a forum for discussing, exchanging and sharing experiences, best practices, information data and tools.

6.2. Action lines B and C: HLT priorities

The future activities of these two action lines will be directed to ensuring that the priorities identified in the survey are realized so that an adequate HLT infrastructure for Dutch is obtained.

6.3. Action line D: implementation of the recommendations in the HLT Blueprint

In the near future a number of Dutch-Flemish digital HLT resources will become available. These development projects, in many cases, do not provide a permanent infrastructure. As projects aimed at the development of digital basic resources mostly result in intermediary products, extra efforts and investments are needed in order to implement them in applications that find their way to the end users. Furthermore, when planning such large scale projects a lot of time is invested in building the

necessary structures (often at a supra-institutional level) and finding the right experts. The completion of a project often means that the managerial and operational structures cease to exist. Therefore it is of vital importance that the right measures are timely taken in order to ensure that the resources are stored in such a way that they will be expertly managed and maintained. When establishing an adequate infrastructure for maintenance of digital basic resources, proper attention should be given to a) intellectual rights, overall responsibility and co-ordination, b) actual physical management and maintenance of the resources and c) maintenance of expertise. In the following sections we will describe the facilities that we envisage to implement in the Dutch speaking area in the near future.

6.3.1. Necessary facilities

A. Intellectual rights, responsibility, co-ordination: ***NTU***

A careful transfer of intellectual rights is of crucial importance to the exploitation of resources. Furthermore, after completion of projects a visible policy responsibility is needed, even if the actual management and maintenance is carried out by an HLT agency (see B).

Organisational structure: The NTU (Nederlandse Taalunie/Dutch Language Union), representing a permanent Dutch-Flemish infrastructure, can act as the appropriate legal body handling all legal affairs. A member of the NTU will be appointed as co-ordinator and supervise from a policy point of view management, maintenance and exploitation of HLT basic resources that are contributed to the HLT agency (see B)..

The NTU will look after the interests of the entire HLT field and will function as a kind of 'broker' by:

- supervising the activities of the HLT agency (see B) and the various HLT committees (see C);
- looking after legal issues;
- stimulating the application of international standards;
- stimulating funding bodies to stipulate that in proposals proper attention is paid to allocating funding for management and maintenance and that resources financed with public funding be made available through the HLT agency;
- playing an intermediate role in the acquisition of digital data, e.g. from the industry.

B. Management and maintenance of digital resources: HLT agency

The *Blueprint* recommends the co-operation of the institutes in a consortium, an **HLT agency**, as this makes it possible to use dispersed expertise and infrastructure. This construction clearly has a number of advantages:

- efficient use of persons and means can be cost-reducing;
- combining resources and bringing together different kinds of expertise can create surplus value (e.g. extra applications);
- offering resources through one window (one-stop-shop) will create optimal visibility and accessibility;
- in international projects the Dutch language area can act as a strong partner;

Organisational structure: The HLT agency can take the form of a Dutch-Flemish consortium of organisations contributing their resources and expertise in a virtual resource centre. These organisations should strike binding agreements for a determined period of time. One Dutch-Flemish organisation (e.g. the Dutch Institute of Lexicology in Leiden) should be appointed as responsible co-ordinator.

- management: taking the appropriate (mostly technical) measures so as to make sure that data and software remain operational and usable;
- accessibility data and software: facilitating reusability of HLT resources: e.g. technical, legal and administrative settlements so as to optimise the route from developer via HLT agency to the distributor;
- maintenance: taking the appropriate measures to ensure long-term usability of data and software: technical maintenance of formats of HLT data, HLT software, system and application software, equipment; maintenance of legal contracts; content management of the HLT data and annotations;
- service: help desk, service to the users of the HLT data and HLT software (e.g. advising, maintenance of website and mailing lists, supplying tailor made data or software on demand);
- acquisition: active acquisition of HLT data and HLT software developed by the industry or research institutes;
- evaluation and validation: contributing to establishing international standards and methods for evaluating and validating HLT resources.

For the actual, physical distribution of the resources appeal will be made on the expertise of organisations s.a ELRA and LDC as they have the proper expertise and marketing tools.

C. Expertise: Dutch-Flemish steering committees and HLT management committee

In dissolving the managerial and operational infrastructure after the completion of a project, valuable specific knowledge concerning the project may be lost causing difficulties in the exploitation of the results. All the same it would not be realistic to maintain these structures. A solution would be to install a number of Dutch-Flemish **steering committees** and one co-ordinating Dutch-Flemish **HLT management committee**. The tasks of these committees should not be too heavy, but to ensure continuity and effectiveness a strong secretarial support should be provided

Organisational structure: For each completed large scale project the results of which are contributed to the HLT agency, a steering committee should be installed. Each steering committee delegates one representative to a co-ordinating HLT management committee. For small scale projects it has to be examined whether the necessary expertise is already present in the HLT management committee. Probably one expert, responsible for the combined 'small' projects, will be added to this committee. The various committees should receive the appropriate secretarial support.

Tasks: The steering committees will be responsible for specific resources and specific domains. They will

- act as a knowledge base for questions concerning the resources contributed to the HLT agency;
- act as intrinsic supervisors on management, maintenance and exploitation of specific resources;
- act as advisors in specific domains s.a. language and speech technology, terminology, lexicology;
- be instrumental in the organisation of 'major repairs' of the resources that are put in their custody;
- be instrumental in developing the appropriate infrastructure for new projects or updating of existing results in their domain.

The HLT management committee will be responsible for the co-ordination, overall management, maintenance and distribution of HLT resources. It will

- act as general knowledge base and give advise in the broad field of language and speech technology, terminology, lexicology etc..
- act as general intrinsic supervisor on management, maintenance and exploitation of finished resources;
- be instrumental in developing the appropriate personnel infrastructure for new projects or updating of existing results.

6.3.2. Financing

Since the exploitation of basic resources will not result in considerable revenues, the authorities have expressed their explicit wish to make these resources available as broadly as possible. This results in keen prices: cost price for non-commercial research, a higher but not prohibitive price for commercial organisations. Consequently, the implementation of the above mentioned structures requires extra funding. Since a considerable percentage of the development costs should be allocated to management and maintenance, by combining the infrastructures required for different projects the percentage the costs would decrease. This applies as much to the material infrastructure (equipment, data, software, licences, etc…) as to the immaterial infrastructure (experts, personnel etc.). As is stressed in the recommendations of the *Blueprint*, the activities of the HLT agency cannot be carried out by the consortium partners in addition to their daily work, but require extra staff. Based on the data in the *Blueprint* and on experiences in other projects, a number of persons will be appointed at one or more of the organisations forming the HLT agency (e.g. experts on language and speech technology, IT-specialist, administrative personnel etc.). One overall co-ordinator and at least one secretary of the committees will be appointed at the NTU.

It is to be expected that the costs will increase with the increase of project results contributed to the HLT agency. These costs should be covered with funds allocated to management, maintenance and accessibility at the start of the development of new projects.

6.3.3. Conclusions

After the completion of projects aimed at developing HLT resources, efforts are needed to ensure long-term usability of the results. Timely attention to intellectual property rights, management, maintenance and distribution can guarantee that investments pay off in the future. In this respect, it is recommended, to make optimal use of existing expertise and infrastructure. In concrete this would mean that in the Dutch speaking area:

- the co-ordinating policy responsibility and as much intellectual property rights as possible should be placed in the hands of the NTU;
- the actual exploitation (management, maintenance and distribution) should be entrusted to a Dutch-Flemish HLT agency, that will take the shape of a consortium of institutions but acts as a one-stop-shop of digital HLT resources for the Dutch language
- the existing expertise should be combined as much as possible in a number of Dutch-Flemish steering committees consisting of representatives of projects, the results of which are contributed to the HLT agency and a co-ordinating Dutch-Flemish HLT management committee.

The NTU envisages to implement the above mentioned structures in its new long-term policy plan (2003-2007).

7. General conclusions

In this paper we have reported on the activities that in the last two years have been carried out within the framework of the project "Dutch Human Language Technologies Platform". In particular, we have focussed on two of the four action lines within this project: Action line A, which was aimed at raising awareness of the results of HLT research and promoting communication among interested partners, and Action line D which was concerned with management, maintenance and distribution of HLT resources.

Our overview of the results obtained so far has revealed that a cooperative framework has been created and that there are clear plans to set up a structure that will take care of all HLT resources developed with public funding, so that they will remain available for all interested parties: an HLT agency. In other words, the goals of action lines A and D have been achieved (for the results of B and C, the reader is referred to Binnenpoorte et al. (2002)) and clear directions for how to proceed in the near future have also been outlined. To conclude, it seems that in the Dutch speaking area pioneering work has been carried out from which other countries can probably profit in their attempts to start similar initiatives.

8. Acknowledgements

We are indebted to the steering committees of Action lines B, C, and D and to the authors of the Blueprint (P. Van der Kamp, T. Kruyt, and P. Van Sterkenburg) and of the Report B and C (G. Bouma, W. Daelemans, A. Dirksen, D. Heijlen, F. de Jong, J.-P. Martens, A. Nijholt, H. Strik, D. van Compernolle, F. van Eynde, and R. Veldhuis) for their invaluable contribution to the work presented in this paper.

SPEECH-RELATED TECHNOLOGIES

Where will the field go in 10 years?

Niels Ole Bernsen, NISLab, Denmark (editor)

Abstract

This paper is a draft position paper for discussion at the ELSNET Brainstorming Workshop 2000-2010 in Katwijk aan Zee, The Netherlands, on 23-24 November, 2000. The paper first describes some general emerging trends which are expected to deeply affect, or even transform, the field of speech technology research in the future, including trends towards advanced systems research, natural interactivity, multimodality, and medium-scale science. A timeline survey of future speech-related technologies is then presented followed by analysis of some of the implications of the proposed timelines. Timeline projections may turn out to have been false, of course, but even their turning out to be true is subject to future actions which are (not) taken to make them true. Accordingly, the final part of the paper discusses some actions which would seem desirable from the point of view of strengthening the position of European speech-related research.

1. Introduction

The term *speech-related research* has been chosen to designate the topic of the present paper for lack of ability to invent a more appropriate term, if there is one. At least, the term partly manages to convey the author's expectation that the field of speech research will change rather dramatically in the coming ten years as speech technologies become merged with other technologies into a field which, so far, lacks a name.

According to many observers, the coming decade will be the decade of speech technologies. Computer systems, whether stationary or mobile, wired or wireless, will increasingly offer users the opportunity to interact with information and people through speech. This has been made possible by the arrival of relatively robust, speaker-independent, spontaneous (or continuous) spoken dialogue systems in the late 1990s as well as through the constantly falling costs of computer speed, bandwidth, storage, and component miniaturisation. The presence of a speech recogniser in most appliances combined with distributed speech processing technologies will enable users to speak their native tongue when interacting with computer systems for a very large number of purposes. Although no doubt exaggerated as just presented, there probably is some truth to this vision of a breakthrough in the application of speech technologies in the coming years. If this is the case, it would seem worthwhile that we lift our sights and take a long-term view of the issues ahead. This may help setting a reasonable research agenda for the coming years of advanced speech systems research and development, one which does not succumb to the usual hype associated with fashionable technologies. Today, some believe that "the speech problem" has been solved already. Some believe that speech, because of its naturalness, is the solution to every conceivable problem of user-system interaction. On the other hand, surprising as it may seem, some human factors and interactive systems experts believe that we have just arrived at the touch-tone telephony stage and share no notion of the actual state-of-the-art in the field with its practitioners. Since

all of those beliefs are far from the truth, it is important to provide a more balanced picture of the state-of-the-art in speech technologies in order to set the stage for solid progress.

In what follows, Section 2 presents some trends in the speech-related research field. Section 3 excels in guesswork by estimating the times of appearance of a range of novel speech-related technologies. Section 4 discusses implications of the timelines presented in Section 3. Section 5 proposes a series of actions which would appear appropriate given the preceding discussion.

2. Some Trends

The speech field is making progress on a broad scale as demonstrated by the 900 or so papers and posters presented at the recent International Conference on Spoken Language Processing (ICSLP) in Beijing, October 2000. [To be illustrated by listing topics.] Three points may be made on the preceding list of current topics in speech research. Firstly, the wealth of topics that are being addressed in current fundamental and applied research obviously demonstrates that "the speech problem" has *not* been solved but continues to pose a series of major research challenges. [Mention some of them.] Secondly, the breadth of the speech topics that are being addressed could be taken as evidence that the speech field is simply doing *business as usual,* albeit on a larger and more ambitious scale than ever before. Thirdly, however, it is clear from the topics list that *the speech field is no longer separate from many other fields* of research but is in a process of merging into something which might perhaps be called the general field of interactive technologies. This latter trend, it may be argued, is the single most important factor which will influence the speech field in the future and which already suggests that the field is in a state of profound transformation.

Interactive technologies

It is relatively straightforward to explain why the speech field is gradually merging into the general field of interactive technologies. Since speech now works for a broad range of application purposes, a rapidly growing fraction of the speech research community are becoming involved in advanced interactive *systems* research rather than continuing to work on improving the speech *components* which form part of those systems. In advanced interactive systems research, speech is increasingly being used not as a stand-alone interactive modality as in, e.g., spoken language dialogue systems over the telephone, speech dictation systems, or text-to-speech systems, but as a modality for exchanging information with computer systems in combination with other modalities of information representation and exchange. Moreover, speech is not just an interactive technology among many others. Spontaneous speech is an extremely powerful input/output modality for interacting with computer systems, a modality which, furthermore, is available and natural to the large majority of users without any need for training in using it for interactive purposes.

The ongoing shift from speech components research to research on integrating speech in complex interactive systems has a number of important implications for the speech field. Speech researchers are becoming systems researchers and engineers. Far more than components research, systems research and engineering is exposed to the full complexity of today's world of information and telecommunications technologies. Few, if any, groups can build full systems on their own from scratch. To stay competitive, they have to *follow closely* the global developments in relevant systems architectures, platforms, toolkits, available components of many different kinds, de facto standards, work in standards committees, market trends etc. They need larger and much more *interdisciplinary teams* in order to keep up with competitive developments. They need *access* to platforms and component technologies in order to avoid having to do everything by themselves. And they need expertise in *software systems engineering best practice as specialised to the kind of systems*

they are building, including expertise in systems and usability evaluation. As we shall see in Section 4, they need even more than this, such as *hardware* access or expertise, development *resources, behavioural research* in new domains, and skills in *form and contents design.*

Compared to traditional research on improving a particular speech component technology, the world of advanced interactive systems research would appear to be orders of magnitude more complex. Moreover, that world is quite diffuse for the time being. It does not have a single associated *research community,* being inhabited instead by researchers from most traditional ITC (Information Technologies and Telecommunications) research communities. The world of advanced interactive systems research does not have any clear *evolutionary direction,* being characterised rather through ever-changing terms of fashion, such as 'ubiquitous computing', 'things that think', 'wearable computing', 'the disappearing computer' or 'ambient intelligence'. Significantly, all or most of those terms tend to refer to combined hardware and software systems rather than to components, and none of them refer to the traditional communities in the ITC field, such as speech processing, natural language (text) processing, machine vision, robotics, computer graphics, neural networks, machine learning, or telecommunication networks. Indeed, most of our current stock of inspired and visionary terms for describing the future of interactive technologies tends to be rather vague with regard to the technologies which they include or, if any, exclude.

Rather than trying to clarify what might be meant by the terms of fashion mentioned above, it may be useful to look at two other developments in conceptualising the field of advanced interactive systems research of which speech research has begun to form a part. To be sure, the concepts to be discussed are expressed by fashion terms as well, but at least it would seem that those concepts are of a more systematic and theoretically stable nature at this point.

Natural interactivity

When being together, most humans interact through speech when they exchange information. The telephone allows them to use spoken interaction at a distance as well, and the function of the telephone will soon be shared, or even taken over, by computing systems. When humans interact through speech, it does not matter if they are just a twosome or if they are more than two together. Moreover, except when speaking over the telephone, speech is not their only modality for information exchange. Gesture, lip movements, facial expression, gaze, bodily posture, and object manipulation all contribute to adding information, however redundant, to the spoken message. Together with speech, those modalities constitute *full natural human-human communication.* Moving beyond current technologies, we envision not just a single human speaking on the telephone or to a (desktop) computer in order to get a particular task done. Rather, the vision is one in which multiple humans speak together whether or not they are in the same physical location whilst using the system as an increasingly equal partner in communication. The system mediates their communication when needed, understands full natural communication, and produces full natural communication itself, increasingly acting as its human counterparts in communication. In order to take this vision into account, it would seem timely to abandon the traditional model of interaction which is called 'human-computer interaction', and replace it with the more general model of *natural human-human-system interaction* (HHSI). Natural HHSI, it appears, it a necessary end-point of current research in speech technologies. Thus, natural interactivity may serve as an important, even if distant, guidepost for the role of speech research in the complex world of interactive systems research.

The received picture of the role of theory in engineering goes something like this. It is hardly ever possible to deduce from theory a complete specification of the artefact that would constitute an optimal solution to some engineering problem. The reason is that the complexity

of the problem space involved always exceeds the power of theory. On the other hand, without theory (of physics, chemistry, computation etc.), it would not have been possible to build many of the artefacts we use in our daily lives. Thus, theory has a necessary supporting function in engineering. This is clear in the case of natural interactivity. To achieve the ultimate goal of natural HHSI, we need far better theory than is available at present: about how humans behave during natural interaction, about the behavioural phenomena which are relevant to the development of fully natural interactive systems, about how these phenomena are interrelated, about how they should be encoded etc. We also need a novel theory of natural communication which can replace speech acts theory and discourse theory by taking the notion of a complete communicative act as its basic notion.

Multimodality

The trend towards multimodal interactive systems reflects the trend towards blending of traditional research communities noted above as well as the increasing role of speech in future interactive systems. Multimodal systems are systems which offer the user combinations of input/output modalities for (or ways of) exchanging information with computer systems. Given the naturalness and expressive power of speech, speech input and speech output have the potential for becoming key modalities in future interactive systems. However, compared to natural interactivity, our current understanding of multimodality is much less capable of providing guideposts for future advanced interactive systems research in general and research on multimodal systems which include speech modalities in particular. Much too little is known about how to create good modality combinations which include speech for a variety of interactive purposes. This topic has become an active field of research, however (Bernsen 1997a, Benoit et al. 2000, Bernsen 2001). Further progress in this field is likely to complement research on natural interactivity in providing guideposts for speech-related research in the complex world of advanced interactive systems. In fact, these two research directions are intertwined in so far as it remains an open issue for which application purposes technologies, such as, e.g., animated speaking characters might provide useful solutions.

Medium-scale science

The final trend to be mentioned is the trend towards medium-scale science in advanced interactive systems research. Increasingly, it is becoming evident that the standard 3/4/5-team, low-budget, 3-year isolated advanced systems research project is often an inefficient means of achieving significant research progress. In many projects, the participants share discouraging experiences, such as the following: even if small, the project is only able to start almost one year after its conception because of the administrative processing needed to release the funding for the project; when the project begins, the participants discover that their objectives have already been achieved elsewhere; the participants spend the first half of the project trying to identify the best platform to work from only to discover that they cannot get access to it; the participants spend half of the project building and putting together a low-quality version of the contextual technologies they need before they can start addressing their core research objectives; at the start of the project, the participants realise that it will take too long to produce the data resources they need, such as tagged corpora, and decide instead to work with sub-optimal resources which they can get for free; etc. One way to avoid, or reduce the number of, such experiences is to launch larger-scale concerted research efforts which have a better chance of moving beyond the state of the art. World-wide, experiments are currently underway on how to carry out such medium-scale science. In the US DARPA Communicator project which addresses spoken language and multimodal dialogue systems, for instance, all participants start from shared core technologies without having to build these themselves (http://fofoca.mitre. org/). In the German SmartKom project which addresses multimodal

communication systems, the budget is large enough for the participants to build and integrate the technologies needed (http://smartkom.dfki.de/start.html). In the European Intelligent Information Interfaces (i3, http://www.i3net.org/) and CLASS (http://www.class-tech.org/) initiatives, whilst the traditional 3-year small-scale project topology has been preserved, major efforts are being made to promote cross-project collaboration, synergy, and critical mass.

For reasons too obvious to mention, relatively small-scale research should continue to exist, of course. Still, the complexity of the world of advanced interactive systems research is not likely to go away. This raises the question of whether we need more medium-scale science and less small-scale science in order to make efficient use of the funds available for advanced interactive systems research. If this question is answered in the affirmative, the important issue becomes how best to do medium-scale science, i.e. which model(s) to adopt for the larger-scale research efforts to come.

3. Estimated Technology Timelines

This section attempts to estimate the time of first appearance of a broad selection of generic and/or landmark speech technologies including natural interactivity technologies and multimodal technologies involving speech. Some qualifications are necessary to the proper interpretation of the proposed predictions. Despite the numerous uncertainties involved in estimating technology progress, timelines, when properly estimated, qualified, and peer reviewed, do seem a useful means of conveying a field's expectations to the outside world and serving as a basis for actions to be undertaken to support research in the field.

Qualifications

(a) As in all timeline forecasts, there is some uncertainty in the forecasts below with respect to whether the technology is deployable or will in fact have been deployed in products at the suggested time. The claim for the figures below rather tend towards the *deployable* interpretation which is the one closest to the point of view of research. The *actual deployment* of a deployable technology is subject to an additional number of factors some of which are unpredictable, such as company technology exploitation strategies, pricing strategies, and the market forecasts at deployability time. Thus, several years may pass before some of the technologies below go from deployability to actually being used in mass products. This implies that one cannot from the estimations below construct scenarios for the Information Society in which people in general will be using the described technologies at the times indicated. In other words, the years below refer to "earliest opportunity" for actual deployment in what may be sometimes rather costly systems to be embraced by relatively few customers. Similarly, given the fact that there are thousands of languages in the world, it goes without saying that a technology has been established when it works in at least one of the top languages, a "top language" being defined as a language used by developers in the more affluent parts of the world.

(b) Another point related to (a) above is to do with underlying "production platforms". For many advanced, and still somewhat futuristic, speech and language -related systems, it is one thing to have produced a one-of-a-kind demonstrator system but quite another to have produced the system in a way which enables oneself or others to relatively quickly produce more-of-the-same systems in different application domains. An example is the so-called intelligent multimedia presentation systems which will be discussed in more detail in Section 4. Several examples exist, such as the German WIP system and corresponding systems from the USA. However, as long as we haven't solved the problem of how to produce this kind of system in a relatively quick and standardised way, intelligent multimedia presentation

systems are not going to be produced in numbers but will remain research landmarks. The timeline list below mostly avoids mentioning systems of this kind, assuming for the kinds of systems mentioned that the "production platform" issue has been solved to some reasonable extent at the time indicated.

(c) There is some, inevitable because of the brevity of the timeline entries, vagueness in what the described technologies can actually do.

(d) It is assumed that, after a certain point in time which could be, say, 2006, the distinction between technology use for the web and technology use for other purposes will have vanished.

(e) There is no assumption about *who* (which country, continent, etc.) will produce the described landmark results. However, given the virtually unlimited market opportunities for the technologies listed as a whole, it is expected that a consolidated technology timeline list will command keen interest among decision makers from industry and funding agencies.

(f) There is nothing about (software) agent technologies below. It is simply assumed that what is currently called software agent technologies will be needed to achieve the results described and will be available as needed.

(g) In principle, of course, any technology timeline list is subject to basic uncertainty due to the "if anything is done about it" –factor. If nothing will be done, nothing will happen, of course. However, most of the technologies listed below are being researched already and the rest will no doubt be investigated in due course. The uncertainty only attaches to who will get there first with respect to any given technology, who will produce the product winners, and how much effort will be invested in order to achieve those results before anybody else.

Technology timelines

Basic technologies

Hypotheses lattices, island parsing, spotting in all shapes and sizes for spoken dialogue	2001
Continuous speech recognisers in OSs for workstations in top languages	2002
Continuous speech recognisers in mobile devices (10000 words vocabulary) in top languages	2003
High quality competitive (with concatenated speech) formant speech synthesis in top languages	2003
Task-oriented spoken dialogue interpretation by plausibility in context and situation	2003
Generally usable cross-language text retrieval	2003
Multilingual authoring in limited domains by constructing conceptual representations	2003
Usable ontological lexicons for limited domains	2003
Usable translation systems for written dialogues (multilingual chatting)	2003
Useful speaker verification technology	2004
Seamless integration of spoken human/machine and human/human communication	2004
First on-line prosodic formant speech synthesis in top languages	2004
Simple task-oriented animated character spoken dialogue for the web	2004
Concept-to-speech synthesis	2004
Stylistically correct presentation of database content	2004
Superficial semantic processing based on ontological lexicons	2004

Max. 2000 words vocabulary task-oriented animated character dialogue for the web	2005
Prosodic formant speech synthesis replaces concatenated speech in top languages	2005
Full free linguistic generation (from concepts)	2005
Robust, general meta-communication for spoken dialogue systems	2005
Writer-independent handwriting recognition	2005
Learning at the semantic and dialogue levels in spoken dialogue systems	2006
Useful multiple-speaker meeting transcription systems	2006
Task-oriented fully natural animated characters (speech, lips, facial expression, gesture) output (only)	2007
Context sensitive summarization (responsive to user's specific needs)	2007
Answering questions by making logical inferences from database content	2007
Speech synthesis with several styles and emotions in top languages	2008
Continuous speech understanding in workstations with standard dictionaries (50000 words) in top languages	2008
Controlled languages with syntactic and semantic verification for specific domains	2008
Large coverage grammars with automatic acquisition for syntactic and semantic processing for limited applications	2008
Task-oriented fully natural speech, lips, facial expression, gesture input understanding and output generation	2010

Systems

First personalised spoken dialogue applications (book a personal service over the phone)	2002
Useful speech recognition-based language tutor	2003
Useful portable spoken sentence translation systems	2003
Useful broadcast transcription systems for information extraction	2003
First pro-active spoken dialogue with situation awareness	2003
Current spoken dialogue systems technology for the web (office, home)	2004
Satisfactory spoken car navigation systems	2004
Current spoken dialogue systems technology for the web (in cars)	2005
Useful special-purpose spoken sentence translation systems (portable, web etc.)	2005
High quality translation systems for limited domains with automatic acquisition	2005
Small-vocabulary (>1000 words) spoken conversational systems	2005
Medium-complexity (wrt. semantic items and their allowed combinations) task-oriented spoken dialogue systems	2005
Multiple-purpose personal assistants (spoken dialogue, animated characters)	2006
Task-oriented spoken translation systems for the web	2006
Useful speech summarisation systems in top languages	2006
Useful meeting summarisation systems	2008
Usable medium-vocabulary speech/text translation systems for all non-critical situations	2010
Medium-size vocabulary conversational systems	2010

Tools, platforms, infrastructure

Standard tool for cross-level, cross-modality coding of natural interactivity data	2002
Infrastructure for rapid porting of spoken dialogue systems to new domains	2003
Platform for generating intelligent multimedia presentation systems with spoken interaction	2005
Science-based general portability of spoken dialogue systems across domains and tasks	2006

Other problems which were strongly felt when producing the list above include: (i) the fact that there is plenty of continuity in technology development. "Continuity" may not be the right term because what happens is that what is later perceived as a new technological step forward is constituted by a large number of smaller steps none of which could be mentioned in a coarse-grained timeline exercise such as the one above. General speaker identification, robust speech recognition in hard-to-model noise conditions, "real" speaker-independent recognition (almost) no matter how badly people speak, or pronounce, some language, are all examples of minute-step progress. (ii) Another problem is to do with speech in fancy-termed circumstances, such as 'ambient intelligence' applications. It may be that there is a hard-core step of technological progress which is needed to achieve speech-related ambient intelligence but then again, may be there isn't. Maybe this is all a matter of using the timelined speech technologies above for a wide range of systems and purposes. Similarly, it is tempting to ask, for instance: "When will I have a speech-driven personal assistant?". But everything depends on what the personal assistant is supposed to be able to do. Some personal assistant technologies exist already. Thus, it does not seem possible to timeline the appearance of speech-driven personal assistants even if this might be attractive for the purpose of advertising the potential of speech technologies.

How well is Europe doing?

No attempt has been made, so far, to annotate the technology timelines with indications of how well, or how badly, European research is doing and hence how likely it is that a particular technology will be made deployable in Europe before anywhere else. In most of the timelined cases above, this would seem to depend primarily on the financial resources and research support mechanism which will be available to European research in the coming decade. In some cases, the US is presently ahead of Europe, such as with respect to continuous speech recognisers in workstations or broadcast transcription systems. In other cases, Europe has the lead, such as in building a standard tool for cross-level, cross-modality coding of natural interactivity data, continuous speech recognisers in mobile devices, advanced spoken dialogue systems, and spoken car navigation systems.

Beyond 2010

Beyond 2010 lie the dreams, such as unlimited-vocabulary spoken conversational systems, unlimited-vocabulary spoken translation systems, unlimited on-line generation of integrated natural speech, lips, facial expression and gesture communication, unlimited on-line understanding of natural speech, lips, facial expression and gesture communication by humans, summarisation-to-specification of any kind of communication, multimodal systems solutions on demand, and, of course, full natural interactive communication.

4. Implications of the Timelines

When analysing the implications of the timelines in Section 3, a number of uncertainties come up with respect to how the market for speech products will develop. At present, most speech

products are being marketed by some 5-10 major companies world-wide. These companies are growing fast as are hundreds of small start-up companies many of which use basic technologies from the larger technology providers. It may be assumed that this market structure will not continue in the future. Rather, speech recognition and synthesis technologies would seem likely to become cheap, or even free and open source, components which will come with all manner of software and hardware systems. The implication is that all ITC providers who want to, will provide value-added speech products and that the basic speech technologies will not be dominated by a small number of large suppliers. Some important share of the speech market, including de facto standards in various areas, will probably be picked up by large custom software and mobile phone technology suppliers, such as Microsoft and Nokia, but that is likely to happen in any realistic scenario for the coming decade. The conclusion is that, during the coming decade, speech will be everywhere, in all sorts of products made by all sorts of companies. But will speech be everywhere in bulk? This raises a second uncertainty.

In one scenario, speech will be present in all or most ITC products by 2010, and speech will be popular and will be used as much as input keys, input buttons, and output graphics displays are being used today. In another scenario, however, speech uptake will be slow and arduous. Several reasons could be given for the latter scenario. Thus, (a) it may take quite some time before speech recognition is being perceived by users to be sufficiently robust to make users switch to speech where speech is better ideally. (b) It may take quite some time before the field and the market has sorted out when to use speech as a stand-alone modality and when to use speech in combination with other input/output modalities. If these two (a + b) take-up curves do not grow in any steep manner, speech may still be widespread by 2010, but speech will still not be as important an input/output modality as it is likely to become later on. For the time being, we would appear to have too little information to be able to decide between the two scenarios just discussed. There is simply not enough data available on user uptake of speech technologies to enable a rational decision to be made.

Exploitation today

Already today, there is a great exploitation potential for speech technologies because of the simple facts that (i) the technologies which already exist in a few top languages could be ported to hundreds of other languages, and (ii) the types of applications which already exist can be instantiated into numerous other applications of similar complexity. At this end of the speech technology spectrum, the emphasis is on flexible and versatile production platforms, quality products, and low-cost production rather than on research. This is particularly true of low-complexity over-the-phone spoken language dialogue information systems using continuous speech input. Users would seem to have adopted these systems to a reasonable extent already. The same degree of user acceptance does not appear to characterise the uptake of, e.g., spoken language dictation systems or simple spoken command systems for operating screen menus. Even if purchased by widely different groups of users, the former would appear to be used primarily by professionals, such as lawyers and medical doctors, and the latter hardly seems to be used at all. Also, text-to-speech systems for the disabled and increasingly for all users, do appear to have a significant exploitation potential already.

Key technologies: speech-only

The timelines in Section 3 highlight a series of key speech-only technologies which are still at the research stage, including:

- prosody in on-line speech synthesis;
- multi-speaker broadcast and meeting transcription;

- speech summarisation;
- speech translation; and
- conversational spoken dialogue.

Prosody in on-line speech synthesis

Prosody in on-line speech synthesis is probably important to the speed of take-up of speech technologies because users would appear likely to prefer prosodic speech output to non-prosodic speech output. However, there do not seem to exist firm estimates as to how much prosody matters. Reasonably clear and intelligible non-prosodic text-to-speech already exists for some top languages and might turn out to be satisfactory for most applications in the short-to-medium term.

Multi-speaker broadcast and meeting transcription

Multi-speaker broadcast transcription forms the topic of massive US-initiated research at the moment and appears likely to start becoming widely used in practice relatively soon. Like *meeting transcription* technology, multi-speaker broadcast transcription technology has a large potential for practical application as well as for acting as a driving force in speech and natural language (text) processing research. Once multi-speaker broadcast speech audio and meeting speech audio can be useably transcribed so that first application paradigms for these technologies have been achieved, the transcriptions can be further processed by other technologies, such as speech summarisation and speech translation technologies. It would be very valuable for European speech research if Europe could launch a meeting transcription technology evaluation campaign before the US (evaluation campaigns will be discussed below).

Speech summarisation

Speech summarisation is being experimented with already, often by using text or transcribed speech instead of raw speech data. Speech and text summarisation technology including intelligent speech and text search would seem to hold enormous potential by enabling users to obtain at-a-glance information on the contents of large repositories of information. The same applies to related technologies, such as question-answer systems which enable the user to obtain answers to specific questions from large repositories of information. Progress in these fields is difficult because of the difficulty of the research which remains to be done. However, the difficulties ahead are counter-balanced by expectations that far-less-than-perfect solutions could help to establish first application paradigms which, in their turn, might help accelerate progress.

Speech translation

Despite the embattled 40-year history of language (text) translation systems, speech translation is now being researched across the world because of the realisation that far-less-than-perfect paragraph-by-paragraph translation could yield useful applications in the shorter term. In their turn, those first application paradigms could serve as drivers of further progress. The German Verbmobil project (http://verbmobil.dfki.de/), for instance, demonstrated just how difficult human-human spoken dialogue translation is. Once application paradigms have been achieved, however, speech translation technology would appear set to gain an enormous market. Still, it may take quite some time before there is a massive growth in the market for speech translation products, due to the difficulty of the research which remains to be done.

Conversational spoken dialogue

For some time, the term ‘conversational spoken dialogue’ has been a catch-all for next-step spoken language dialogue systems, such as those explored in the DARPA Communicator

project. However, the DARPA Communicator agenda remains focused on task-oriented dialogue, such as flight ticket reservation. Even if conducted through mixed initiative spoken dialogue in which the human and the machine exchange dialogue initiative in the course of their dialogue about the task, task-oriented spoken dialogue might not qualify as conversational spoken dialogue. Conversational spoken dialogue is mixed-initiative, to be sure, but in conversational spoken dialogue there is no single task and no limited number of distinct tasks which have to be accomplished. Rather, spoken conversation systems may be characterised as *topic-oriented.* It is the breadth and complexity of the topic(s) on which the system is able to conduct conversation which determine its strength. Research on spoken conversation systems is still limited. Obviously, however, spoken conversation systems hold an enormous application potential because they represent the ultimate generalisation of the qualities which everybody seem to appreciate in task-oriented mixed initiative spoken language dialogue systems.

Key technologies: multimodal systems

In addition to speech-only technologies, the timelines in Section 3 highlight a series of multimodal speech systems technologies which are still at the research stage in most cases, including:

- intelligent multimodal information presentation including speech;
- natural interactivity;
- immersive virtual reality and augmented reality.

Intelligent multimodal information presentation including speech

Intelligent multimodal information presentation including speech is a mixed bag of complex technologies which do not seem to have any clear research direction at the present time. The reason is that the term *multimodality,* as pointed out in Section 2 above, refers to a virtually unlimited space of combinations of (unimodal) modalities. Thus, Modality Theory (Bernsen 1997b, 2001) has identified an exhaustive developers' toolbox of unimodal input/output modalities in the media of graphics (or vision), acoustics (or hearing), and haptics (or touch) consisting of more than a hundred unimodal modalities. The number of possible combinations of these unimodal input/output modalities is evidently staggering and, so far, at least, no way has been found to systematically generate a subset of good and useful modality combinations which could be recommended to system developers. The best current approach is to list modality combinations which have been found useful already in experimental or development practice. Obviously, given the limited exploration of the space of possible modality combinations which has taken place so far, those combinations constitute but a tiny fraction of the modality combinations which eventually will be used in HHSI. The same lack of systematicity applies to the subset of useful modality combinations which include speech output and/or speech input. Thus, for instance, it is known that speech and static graphics image output is a useful modality combination for some purposes and that the same holds for combined speech and pen input into various output domains as well as for speech and pointing gesture input into, e.g., a static graphics map output domain. The qualifying term *intelligent* is being used to distinguish intelligent multimodal information presentation systems from traditional multimedia presentations. In traditional multimedia presentations, the user uses keyboard and mouse (or similar devices) to navigate among a fixed set of output options all of which have been incorporated into the system at design-time. In intelligent multimodal information presentation systems, the system itself generates intelligent multimodal output at run-time. This may happen through run-time language and/or speech generation coordinated with run-time graphics image generation and in many other ways as

well. Some years ago, a reference model for intelligent multimodal information presentation systems was proposed by an international consortium of developers (Computer Standards and Interfaces 18, 6-7, 1997). Since then, little systematic development has happened, it appears, which is probably due to the fact that the field is as open-ended at it is. Still, it would appear that (i) the field of intelligent multimodal information presentation systems is an extremely promising approach to complex interactive information presentation, such as in interactive systems for instruction tasks for which several output modalities are needed, including speech. In order to advance research in this field, research is needed on Modality Theory in order to identify potentially useful modality combinations as well as on next-step architectures and platforms for intelligent multimodal information presentation.

Natural interactivity

As argued in Section 2, fully natural interactive systems represent a necessary vision for a large part of the field of interactive systems. Furthermore, spontaneous speech input/output is fundamental to natural interactive systems. Given this (latter) fact, it would seem that speech research is set to take the leading role in the development of increasingly natural interactive systems. Already today, this research and development process can be broken down into a comprehensive, semi-ordered agenda of research steps. The steps include, at least, (i) *fundamental research on human communicative behaviour,* including identification of the relevant phenomena which are being coordinated in human behaviour across abstraction levels and modalities, such as speech prosody and facial expression; validated coding schemes for these phenomena; and standard tools for coding the phenomena in order to create research and training resources in an efficient and re-usable fashion; (ii) *speech and graphics integration* in order to achieve full run-time coordination of spoken output with lip movement, facial expression, gaze, gesture and hand manipulation, and bodily posture; (iii) *speech and machine vision integration* in order to enable the system to carry out run-time understanding of spoken input in combination with lip movement, facial expression, gaze, gesture and hand manipulation, and bodily posture; and (iv) *conversational spoken dialogue* as discussed above. Other relevant technologies include, i.a., machine learning and 3D graphics modelling of human behaviour. Although research in underway on (i) through (iv), there is no doubt that the field might benefit strongly from a focused effort which could connect the disparate research communities involved and set a stepwise agenda for achieving rapid progress. The application prospects are virtually unlimited, as witnessed by the consensus in the field that increased natural interaction tends to generate increased trust in HHSI.

Immersive virtual reality and augmented reality

It is perhaps less clear what are the speech technology application prospects of immersive virtual reality. Today, immersive virtual reality requires that users are wired up with 3D goggles, force feedback data gloves, data suits, and/or wired surfaces and other wired equipment, such as flight cockpits or bicycles. At the present time, it seems uncertain to which extent and for which purposes immersive virtual reality technologies will be found useful in the future. The primary purposes for which these technologies are being used to day are advanced technology exhibition and demonstration, and the building of rather expensive simulation setups, such as flight simulators. Furthermore, it is far from clear which role(s) speech will come to play in immersive virtual environments. These remarks also apply to *augmented reality* technology.

Other research and supporting measures needed

In order to promote efficient research progress on advanced interactive systems which include speech as a modality, technology research is far from sufficient. As pointed out in Section 2,

present and future advanced systems research takes place in an extremely complex context in which leading research efforts must incorporate global state-of-the-art developments in many different fields. World-leading speech-related systems research should be accompanied by the following kinds of research, at least:

- state-of-the-art generic platforms;
- generic architectures;
- hardware;
- specialised best practice in development and evaluation;
- standard re-usable resources;
- behavioural research;
- neural basis for human natural communicative behaviour;
- design of form and contents;
- porting technologies to languages, cultures and the web;
- the disabled;
- maintenance for uptake.

State-of-the-art generic platforms

In order to effectively aim at exploitable results from early on, speech-related systems research needs to build upon existing state-of-the-art generic platforms including APIs. If a state-of-the-art generic platform is not available to the researchers, either because it does not yet exist or because it is inaccessible for proprietary reasons, researchers have to build it themselves. This is not possible in small-scale research projects which have an additional research agenda which presupposes a working platform. The consequence is that the research project will either build upon some sub-optimal platform in order to complete the research agenda, or build a better platform but not complete the research agenda. Both consequences are unacceptable, of course, but the former may work temporarily if the research aims are very advanced ones. However, when the research aims have been achieved or, at least, somehow explored, there will typically be no practical way of continuing the research in order to produce a state-of-the-art generic platform which could bring the research results towards the market. Two implications seem to follow: (i) it would be highly desirable if companies could be encouraged to make their most advanced platforms accessible to researchers. (ii) If a state-of-the-art generic platform is missing altogether, it should either be produced in a separate project or projects should be made so large as to include platform development. Both implications would seem to require a transformation of existing European research funding mechanisms.

Generic architectures

It would seem likely that overall research speed and efficiency in Europe could be accelerated by research on *generic architectures* for future systems, such as conversational spoken dialogue systems, intelligent multimodal information presentation systems which include speech, or natural interactive systems. In the absence of research initiatives on generic architectures for future systems, research projects are likely to specify idiosyncratic architectures which may satisfy their present needs but which do not sufficiently take into account global developments nor prepare for the next steps in advanced systems development. For the time being, there does not appear to be any European speech-related initiative in this field apart from the CLASS project which was launched in the autumn of 2000 (http://www.class-tech.org/). For efficiency, work on generic architectures should be done as

a collaborative effort between many small-scale research projects and industry as in CLASS, or between a medium-scale research project and industry.

Hardware

Increasingly, advanced systems demonstrators require *hardware* design and development. For many research laboratories, this is a new challenge which they are ill-prepared to meet. Moreover, there is no strong tradition for involving hardware producers in the field of speech technologies, primarily because the need for involving them is a rather recent one. Ways must be found to forge links with leading hardware producers in order to make emerging hardware available to researchers. This problem has much in common with the platform issue discussed above.

Specialised best practice in development and evaluation

Advanced speech systems research is conducted in a software engineering space bounded by, on the one hand, general software engineering best development and evaluation practice and, on the other, emerging ISO standards and de facto standards imposed by global industrial competition. Between these boundaries lies software engineering best practice in development and evaluation specialised for various speech-related systems and component technologies. This field remains ill-described in the literature. Apart from the DISC project on best practice in the development and evaluation of spoken language dialogue systems (www.disc2.dk), some work on evaluation in EAGLES Working Groups during the 1990s (http://www.ilc.pi.cnr.it/ EAGLES96/home.html), various national evaluation campaigns, and planned work in CLASS, little work has been done in Europe. By contrast, massive work has been done on component evaluation in the US over the last fifteen years. The result is that the speech-related technology field is replete with trial and error, repetitions of mistakes, and generally sub-state-of-the-art approaches. These negative effects are multiplied by the presence in the field of a large number of developers who are new to the field.

Admittedly, the field of software engineering best practice in development and evaluation specialised for various speech systems and component technologies is difficult and costly to do something about under present conditions. Technology *evaluation* campaigns are costly to do and require serious logistics. Yet the US experience would seem to indicate that technology evaluation campaigns are worth the effort if carried out for key emerging technologies including some of the technologies described in this paper. When a technology has gone to the market, industry does not want to participate any more and rather wants, e.g., evaluation toolkits for internal use. For emerging technologies, however, technology evaluation campaigns are an efficient means of producing focused progress. In fact, all participants tend to become winners in the campaigns irrespective of their comparative scorings according to the metrics employed, because everybody involved learns how to improve, or when to discard, their technologies and approaches. For Europe, technology evaluation campaigns for key emerging technologies could be a means of creating lasting advances on its global competitors. In order to take care of the complex logistics needed for the campaigns, it is worth considering to establish a European agency similar to the US NIST (National Institute for Standards in Technology) whose comprehensive experience with technology evaluation campaigns makes it comparatively easy to plan and launch campaigns in novel emerging technologies. Alternatively, NIST might be asked to undertake to run technology development and evaluation campaigns in Europe, provided that this does not offend political and industrial sensibilities too much.

Effective *development* best practice work specialised for speech technologies is difficult to do under the current European funding mechanisms. The reason is that development best practice work requires access to many different components, systems and approaches in order to

create an effective environment for the discussion and identification of best practice. This environment can only be established across many different small-scale projects or within medium-scale projects. CLASS is the first example of such an environment.

Standard re-usable resources

The term *resources* covers raw data resources, annotated data resources, annotation schemes for data annotation, and annotation tools for efficient automatic, semi-automatic or manual annotation of data. Resources are crucial for many different purposes, such as research into coding schemes or the training of components. Also, resources tend to be costly to produce. This means that, if the relevant resources are not available, research projects often take the easy way out which is to use less relevant but existing and accessible resources for their research. The results are sub-optimal research results and slowed-down progress. Common to resources of any kind is the need for standardisation. If some resource is not up to the required standards, its production is often a waste of effort because the created resource cannot be used for anything useful. In its strategy paper from 1991, ELSNET (http://www.elsnet.org/) proposed the establishment of a European resources agency. This recommendation was adopted through the creation of ELRA (European Language Resources Agency http://www.icp.inpg.fr/ELRA/ home.html) in 1995. ELRA is now a world-recognised counterpart to the US LDC (Linguistic Data Consortium, http://www.ldc.upenn.edu/). Still, ELRA is far from having the capacity to produce on its own all the resources and standards needed for efficient research progress. By contrast with technology evaluation campaigns, Europe has been active in the resources area during the 1990s. Today, there is a strong need to continue activities in producing publicly available resources and standards for advanced natural language processing, natural interactive systems development, evaluation campaigns as described above, etc. Recently, the ISLE (International Standards for Language Engineering) Working Group on Natural Interactivity and Multimodality (http://www.isle.nis.sdu.dk) has launched cross-Atlantic collaboration in the field of resources for natural interactivity and multimodality.

Behavioural research

Humans are still far superior to current systems in all aspects of natural interactive communication. Furthermore, far too little is known about the natural interactive behaviour which future systems need to be able to reproduce as output or understand as input. There is a strong need for basic research into human natural communicative behaviour in order to chart the phenomena which future systems need to reproduce or understand. This research will immediately feed into the production of natural interactive resources for future systems and components development, as described above.

Neural basis for human natural communicative behaviour

Related to, but distinct from, basic research into human natural communicative behaviour is basic research into the neural basis for human natural communicative behaviour. In the heydays of cognitive science in the 1980s, many researchers anticipated steady progress in the collaboration between research on speech and language processing, on the one hand, and research into the neural machinery which produces human speech and language on the other. However, massive difficulties of access to how human natural communicative behaviour is being produced by the brain turned out to prevent rapid progress in linking neuroscience with speech and language processing research. Today, however, due to the availability of technologies such as MR imaging and PET scanning, as well as the increasing sophistication of the research agenda for the speech technology field, the question arises if it might be timely to re-open the cognitive science agenda just described. Potential results include, among others, input to generic architecture development (cf. above), identification of biologically

motivated units of processing, such as speech and lip movement coordination, and identification of biologically motivated modalities for information representation and exchange. Relevant research is already going on in the field of neuroscience but, so far, few links have been established to the fields of speech technologies and natural interactive systems more generally.

Design of form and contents

Yet another consequence of the increasing emphasis on systems as opposed to system components is the growing importance of form and contents design. It is a well-established fact that design and development for the web requires skills in contents design and contents expression which are significantly different from those which have been developed through centuries for text on paper. In order to develop good demonstrator systems for the web or otherwise, there is a need for strongly upgraded skills in the design and expression of multimodal digital contents. For instance, it is far from sufficient to have somehow gleaned that speech might be an appropriate modality for some intelligent multimodal information presentation instruction system and to have available a state-of-the-art development platform for building the system. To actually develop the system, professional expertise in form and contents design is required. At the present time, few groups or projects in the speech field are adequately staffed to meet this challenge.

Porting technologies to languages, cultures and the web

Right now, the gap between the "have" countries whose researchers have access to advanced speech and natural interactivity components and platforms, and the "have-not" countries whose researchers cannot use those technologies for their own purposes because they speak different languages and behave differently in natural interactive communication, seems to be increasing. There is therefore a need to *port advanced technologies to different languages and cultures* both in Europe and across the world. The market will close the gap eventually in its own way, of course. However, in order to rally the full European research potential in the field in a timely fashion, it would appear necessary to actively stimulate the porting of technologies to new languages and cultures. From a research point of view, the best way to make this happen might be to include in medium-to-large-scale projects the best researchers from "have-not" countries even if, by definition, those researchers have to spend significant time catching up on basic technologies and resources before being able to actively contributing to the research agenda.

There is another sense of the 'porting technologies' -phrase in which Europe as a whole risks falling behind global developments. It is that of *porting speech, multimodal and natural interactivity technologies to the web.* The claim here is not that this is not happening already. The claim is that this cannot happen fast enough. In order to increase the speed of porting technology to the web, it would seem necessary to strongly promote advanced components and systems development for the web. It is far from sufficient to wait until some non-speech technology has been marketed for the web, such as electronic commerce applications, and then try to "add speech" to the technology. A much more pro-active stance would appear advisable, including a strongly increased emphasis on form and contents design as argued above.

The disabled

Advanced technologies for the disabled have a tendency to lag behind technology development more generally for the simple reason that the potential markets for technologies for the disabled are less profitable. Correspondingly, advanced technologies development for the disabled tends to be supported by small separate funding programmes rather than being integrated into mainstream programme research. In many cases, however, it would appear that

systems and components technologies could be developed for any particular group of users before being transferred into applications for many other user groups. To the extent that this is the case, there may be less of a reason to confine the development of technologies for the disabled to any particular research sub-programme.

Maintenance for uptake

Finally, the small-scale science paradigm of small and isolated research projects does not at all cater for the fact that, in the complex world of advanced systems research, a wealth of prototype systems, proto-standard resources, web-based specialised best practice guides, etc., are being produced which have nowhere to go at the end of the projects in which they were developed. Their chances of industrial uptake, re-use by industry and research, impact on their intended users, etc., might become very substantially increased if it were possible to maintain them and make them publicly accessible for, say, two years after the end of projects. For this to happen, there is a need for (i) a stable web portal which can host the results, such as the present HLT (Human Language Technologies) portal under development (http://www.HLTCentral.org); (ii) open source clauses in research contracts for technologies which have nowhere to go at the end of a project; and (iii) financial support for maintenance. These requirement are likely to impose considerable strain of current European research support mechanisms. However, with some legal effort and a modest amount of financial support, the many research results produced in the speech-related field in Europe which are not being taken up immediately and which are not within the remit of ELRA, could gain much more impact than is presently the case.

5. Proposed Actions

Early preparations for the European Commission's 6th Framework Programme (FP6) including IST (Information Society Technologies) research are now in progress. It is premature to make predictions with any degree of certainty as to how the IST part of FP6 will shape up. Current information suggests an increased emphasis on basic research compared to the present FP5. In addition, it is possible that FP6 will include opportunities for the medium-scale research initiatives which were called for on several occasions above, i.e. large-scale "clusters" of projects all addressing the same research topic in a coordinated fashion. Finally, the current covering title for FP6 IST research is "ambient intelligence" which is one of the terms of fashion quoted in the present paper. Given the timelines and their analysis above, it does not seem to matter much which covering term is being chosen for FP6. "Ambient intelligence" is as apt as several others for FP6 and future advanced interactive systems research but, as argued in Section 3, it is far from clear if ambient intelligence requires us to focus on any particular segment of future speech-related technologies. However, the possible, increased emphasis on basic research as well as the possibility of carrying out medium-scale science in speech-related technologies are to be welcomed in the light of the argument above.

5.1 Research priorities for speech-related technologies 2000-2010

Taking into our stride the transformations of the field of speech-related research from speech-only to interactive systems in general, and from components research to interactive systems research, the top priorities in speech-related technologies research are:

- multi-speaker meeting transcription development and evaluation campaigns;
- speech summarisation development and evaluation campaigns;
- speech translation prototypes, generic platforms, and generic architectures. Development and evaluation campaigns are highly desirable;

- conversational spoken dialogue prototypes, generic platforms, and generic architectures. Development and evaluation campaigns are highly desirable;
- next-step prototypes, generic platforms, and generic architectures for intelligent multimodal information presentation;
- next-step prototypes, generic platforms, and generic architectures for natural interactive systems.

As soon as theoretically and practically feasible, all of the above advanced speech, multimodal and natural interactivity technologies should be developed for the web including hardware, form and contents design. The fact that some top research priorities have been mentioned above emphatically does not preclude the desirability of continuing "business as usual" in the field of speech-related research, including continued research into *all* of the technologies which have been mentioned earlier in the present paper. On the contrary, business as usual is actually assumed by the above top priorities list which focuses on technologies over and above business as usual. This also applies to next-step research into already deployed speech-related technologies, such as mixed initiative, task-oriented spoken dialogue systems.

For basic research leading to novel concepts, theories and formalisations, the top priorities are:

- basic research into human natural communicative behaviour;
- a novel theory of natural communication which can replace speech acts theory and discourse theory by taking the notion of a complete communicative act as its basic notion;
- research on Modality Theory in order to identify potentially useful modality combinations;
- establishment of collaborative links to research into the neural basis for human natural communicative behaviour.

5.2 Research organisation needed

Medium-scale science is needed for, at least, the coordinated development of natural interactive systems prototypes, generic platforms, generic architectures, best practice in development and evaluation, and standard resources. A large, medium-scale science project with these objectives should include the porting of technologies to new languages and cultures.

It is quite possible that the medium-scale science model could be applied to research into other speech-related technologies, such as speech translation technologies, conversational spoken dialogue systems, or speech technologies for ambient intelligence.

For researchers in small-scale speech-related projects, in particular, the creation of a generic platforms and hardware "bourse" through contributions from European industry would be of great importance.

Finally, we should stop having research programme ghettos for technologies for the disabled.

5.3 Infrastructural actions needed

In order to promote maximum uptake of the research results produced, it would be highly desirable to have funding for low-cost ways of maintaining research results for later uptake.

Given the emphasis on technology development and evaluation campaigns above, Europe needs to establish an evaluation and standards agency. It is not evident to the present author

that current political and industrial sensibilities would allow the US NIST to undertake to run technology development and evaluation campaigns in Europe.

This having been said, there is much to be said for increasing global collaboration on many aspects of speech-related research, such as creating a coordinated global infrastructure for resources distribution.

Towards a Road Map on Human Language Technology: Natural Language Processing

Editors: Andreas Eisele, Dorothea Ziegler-Eisele

Version 2 (March 2002)

Abstract

This document summarizes contributions and discussions from two workshops that took place in November 2000 and July 2001. It presents some visions of NLP-related applications that may become reality within ten years from now. It investigates the technological requirements that must be met in order to make these visions realistic and sketches milestones that may help to measure our progress towards these goals.

1. Introduction

Scope of this Document

One of the items on ELSNET's agenda for the period 2000-2002 is to develop views on and visions of the longer-term future of the field of language and speech technologies and neighboring areas, also called ELSNET's Road Map for Human Language Technologies. As a first step in this process, ELSNET's Research Task group is organizing a series of brainstorming workshop with a number of prominent researchers and developers from our community. The first one of these workshops took place in November 2000 under the general motto “How will language and speech technology be used in the information world of 2010? Research challenges and infrastructure needs for the next ten years". The second one was co-organized in July 2001 by ELSNET and MITRE as part of ACL-2001 and had the somewhat more specific orientation on “Human Language Technology and Knowledge Management (HLT-KM)”. This workshop brought together more than 40 researchers from industry and academia and covered a considerable range of topics related to KM and HLT in general.

This paper aims at summarizing and organizing material from both workshops, but concentrates on applications and technologies that involve NLP, i.e. the processing of written natural language, as speech-related technologies and new models of interactivity have already been covered in documents presented around the first workshop. In the discussion of question answering and summarization, vision papers and roadmaps compiled by researchers in the US and published by NIST have been taken as an additional source of inspiration.

The Growing Need for Human Language Technology

Natural language is the prime vehicle in which information is encoded, by which it is accessed and through which it is disseminated. With the explosion in the quantity of on-line

text and multimedia information in recent years there is a pressing demand for technologies that facilitate the access to and exploitation of the knowledge contained in these documents.

Advances in human language technology will offer nearly universal access to on-line information and services for more and more people, with or without skills to use computers. These technologies will play a key role in the age of information and are cited as key capabilities for competitive advantage in global enterprises.

Extraction of knowledge from multiple sources and languages (books, periodicals, newscasts, satellite images, etc.) and the fusion into a single, coherent textual representation requires not only an understanding of the informational content of each of these documents, the removal of redundancies and resolution of contradictions. Also, models of the user are required, the prior knowledge that can be assumed, the level of abstraction and the style that is appropriate to produce output that is suitable for a given purpose.

More advanced knowledge management (KM) applications will be able to draw inferences and to present the conclusions to the user in condensed form, but let the user ask for explanations of the internal reasoning. In order to find solutions for problems beyond a static pool of knowledge, we need systems that are able to identify experts, who have solved similar problems. Again, advanced NLP capabilities will be required to appraise the aptitude of candidates from documents authored by them or describing prior performance.

But also outside of KM, sophisticated applications of NLP will emerge over the next years and decades and find their way into our daily lives. The range of possibilities is almost unlimited. An important group of applications is related to electronic commerce, i.e. new methods to establish and maintain contact between companies and their customers. Via mobile phones, e-mail, animated web-based interfaces, or innovative multi-channel interfaces, people will want to make use of all kinds of services related to buying and selling goods, home-banking, booking of journeys, and the like. Also in the area of electronic learning a considerable growth is expected within the coming years.

Multilinguality

Whereas English is still the predominant language on the WWW, the fraction of non-English Web pages and sites is steadily increasing. Contrasting earlier apprehensions, the future will probably present ample opportunities for giving value to different languages and cultures. However, the possibility to collect information from disparate, multilingual sources also provides considerable challenges for the human user of these sources and for any kind of NLP technology that will be employed.

One of the major challenges is lexical complexity. There will be about 200 different languages on the web and thus about 40.000 potential language pairs for translation. Clearly, it will not be possible to build bilingual dictionaries that are comprehensive both in the number of language pairs and in the coverage of application domains. Instead, multilingual vocabularies need to provide mappings into language independent knowledge organization structures, i.e. common systems of concepts linked by semantic relations. However, the definition of such an “interlingua” will be difficult in cases in which languages make distinctions of different granularity.

Research Trends and Challenges

The field of human language technology covers a broad range of activities with the goal of enabling people to communicate with machines using natural communication skills.

Although NLP can help to facilitate knowledge management, it requires a large amount of specialized knowledge by itself. This knowledge may be encoded in complex systems of linguistic rules and descriptions, such as grammars and lexicons, which are written in dedicated grammar formalisms and typically require many person-years of development effort. The rules and entries in such descriptions interact in complex ways, and adaptation of such a sophisticated system to a new text style or application domain is a task that requires a considerable amount of specialized manpower.

One way to cope with the difficulties in the acquisition of linguistic knowledge was to restrict attention to shallower tasks, such as looking for syntactic "chunks" instead of a full syntactic analysis. Whereas this has proven rather successful for some applications, it obviously severely limits the depth to which the meaning of a document or utterance is taken into account.

Another approach was to shift attention towards models of linguistic performance (what occurs in practice, instead of what is principally possible) and to use statistical or machine learning methods to acquire the necessary parameters from corpora of annotated examples. These data-driven approaches offer the possibility to express and exploit gradual distinctions, which is quite important in practice. They are not only easier to scale and adapt to new domains, their algorithms are also inherently robust, i.e. they can deal, to a certain extent, gracefully with errors in the input.

Statistical parsers, trained on suitable tree banks, now achieve more than 90% precision and recall in the recognition of syntactic constituents in unseen sentences from English financial newspaper text.

However, a lot of work remains to be done, and it is not obvious how the success of corpus-driven approaches can be enlarged along many dimensions simultaneously. One challenge is that analysis methods need to work for many languages, application domains and text types, whereas the manual annotation of large corpora of all relevant types will not be economically feasible. Another challenge is that, other than syntax, many additional levels of analysis will be required, such as the identification of word sense, the reference of expressions, structure of argumentation and of documents, and the pragmatic role of utterances. Often, the theoretical foundation that is required before the annotation of corpora can begin is still lacking.

One could say that for corpus-driven approaches the issue of scalability of the required resources shows up again, albeit in a somewhat different disguise. Hence, research in NLP will have to address this issue seriously, and find answers to the question how better tools and learning methods can reduce the effort of manual annotation, how annotated corpora of a slightly different type could best be re-used, how data-driven acquisition processes can exploit and extend existing lexicons and grammars, and finally how analysis levels for which the theoretical basis is still under development could be advanced in a data-driven way.

Structure of this Document

The remainder of this document is structured as follows. In Chapter 2 we describe a number of prototypical applications and scenarios in which NLP will play a crucial role. Whereas each of these scenarios is discussed mainly from a user's perspective, we also give indications, which technological requirements must be met to make various levels of sophistication of these applications possible. In Chapter 3, the technologies that have been mentioned earlier are discussed in more detail, and we try to indicate which levels of functionality may be expected within the timeframe of this study. These building blocks are

then put into a tentative chronological order, which is displayed in Chapter 4. Finally, Chapter 5 gives some general recommendations about beneficial measures concerning the infrastructure for the relevant research.

2. Applications of NLP

Recent developments in natural language processing have made it clear that formerly independent technologies can be harnessed together to an increasing degree in order to form sophisticated and powerful information delivery vehicles. Information retrieval engines, text summarizers, question answering and other dialog systems, and language translators provide complementary functionalities which can be combined to serve a variety of users, ranging from the casual user asking questions of the web to a sophisticated, professional knowledge worker.

Though one cannot strictly separate the following applications from each other, because one can act as a part of another, we try to dissect the large field of existing and future applications in the hope of making the field as a whole more transparent.

Information Retrieval (IR)

What is called information retrieval today is actually but a foretaste of what it should be. Current systems neither understand the information need of the user, nor the content of the documents in their repositories. Instead of meaningful replies, they just return a ranked, and often very long list of documents that are somehow related to the given query, which is typically very short. A better name for this restricted functionality would be text retrieval.

Information retrieval systems must understand a query, retrieve relevant information, and present the results. Retrieved information may consist of a long document, multiple documents of the same topic, etc and good systems should present the most important material in a clear and coherent manner.

Current information retrieval techniques either rely on an encoding process using a certain perspective or classification scheme to describe a given item, or perform a superficial full-text analysis, searching for user-specific words. Neither case guarantees content matching.

The ability to leverage advances in input processing (especially natural language query processing) together with advances in content-based access to multimedia artifacts (e.g., text, audio, imagery, video) promises to enhance the richness and breadth of accessible material while at the same time improving retrieval precision and recall and thus reducing the search time. Dealing with noisy, large scale, and multimedia data from sources as diverse as radio, television, documents, web pages, and human conversations (e.g., chat sessions and speech transcriptions) will offer challenges.

One important part of IR would be multi-document summarization that can turn a large set of input documents into several different short summaries, which can then be sorted by topics or otherwise put into a coherent order.

Summarization

Summarization will enable knowledge workers access to larger amounts of material with less required reading time. The goal of automatic text summarization is to take a partially structured source text, extract information content from it and present the most important content in a condensed form in a manner sensitive to the needs of the user and task. Scalability to large collections and the generation of user-tailored or purpose-tailored summaries are active areas of research.

The summarization can either be an extract consisting entirely of material copied from the input, or an abstract containing material not present in the input, such as subject categories, paraphrases of content, etc.

For extraction shallower approaches are possible, as frequently the sentences may be extracted out of context. The transformation here involves selecting salient units and synthesizing them with the necessary smoothing (adjusting references, rearranging the text…). Training by using large corpora is possible.

Abstracts need a deeper level of analysis, the synthesis involves natural language generation and some coding for a domain is required.

Depending on their function, three types of abstracts can be distinguished: An indicative abstract provides a reference function for selecting documents for more in-depth reading. An informative abstract covers all the salient information in the source at some level of detail and evaluative abstracts express the abstractor's views on the quality of the work of the author.

Characteristics for the summarization are the reduction of the information content (compression rate), the fidelity to the source, the relevance to the user's interest, and the well-formedness regarding both to syntactic and discourse level. Extracts need to avoid gaps, dangling anaphora, ravaged tables and lists, abstracts need to produce grammatical, plausible output.

Some current applications of summarization are:

1. Multimedia news summaries: watch the news and tell what happened while I was away
2. Physicians' aids: summarize and compare the recommended treatments for this patient
3. Meeting summarization: find out what happened at that teleconference I missed
4. Search engine hits: summarize the information in hit lists retrieved by search engines
5. Intelligence gathering: create a 500-word biography of Osama bin Laden
6. Hand-held devices: create a screen-sized summary of a book
7. Aids for the Handicapped: compact the text and read it out for a blind person

Though there are already promising approaches towards mastering all types of summaries, there are still obstacles to overcome such as the need for robust methods for the recognition of semantic relations, speech acts, and rhetorical structure.

Question Answering (QA)

The straightest way to get access to the gigantic volume of knowledge around us is probably asking questions by communicating with other persons, computers or machines.

An important new class of systems will move us from our current form of search on the web (type in keywords to retrieve documents) to a more direct form of asking questions in natural language, which are then directly responded to with an extracted or generated answer. Currently it is rather straightforward to get an answer to "what questions" (what is the capital of China, what are the opening hours of the hermitage etc.), whereas "why questions" (why did the new market fail) are normally not answered by an information retrieval query, unless the answer happens to be present in the information database, or can be inferred afterwards by the user from the answers she gets.

In the next decade time has come to find answers to why questions from information systems by letting the systems make the appropriate inferences. This requires very sophisticated automatic reasoning methods, based on systematic extraction of information from texts, storing the information in a systematized way, which lends itself to reasoning and inference rules that will be able to draw the proper conclusions from the knowledge stored in the information database.

We can subdivide the long-term goal of building powerful, multipurpose information management systems for QA in simpler subtasks that can be attacked in parallel at varying levels of sophistication, over shorter time frames.

Clearly there is not a single, archetypical user of a Q&A system. In fact there is a full spectrum of questions, starting with simple factual questions, which could be answered in a single short phrase found in a single document (e.g. "Where is the Taj Mahal?"). Next, questions like "What do we know about Company xyz?", where the answer cannot be found in a single document but will require retrieving multiple documents, locating portions of answers in them and combining them into a single response. This kind of question might be addressed by decomposing it into a series of single focus questions.

Finally there are very complex questions, with broad scope, using judgment terms and needing deep knowledge of the user's context to be answered. Imagine someone is watching a television newscast, becomes interested in a person, who appears to be acting as an advisor to the country's Prime Minister. And now the person wants to know things like: "Who is this individual. What is his background? What do we know about the political relationship of this person and the Prime Minister and/or the ruling party?". The future systems that can deal with this type of questions must manage the search in multiple sources in multiple media/languages, the fusion of information, resolution of conflicting data, multiple alternatives, adding interpretation, drawing conclusions.

In order to realize this goal, research must deal with question analysis, response discovery and generation from heterogeneous sources, which may include structured and unstructured language data of all media types, multiple languages, multiple styles, formats and also image data i.e. document images, photography and video.

To the extent to which NLP research will learn to master the challenges of source selection, source segmentation, extraction, and semantic integration across heterogeneous sources of unstructured and semi-structured data, NLP technology will help us to reduce the time,

memory, and attention required to sift through many returned web pages from a traditional search by providing direct answers to questions.

Semantic Web

The standardization committee for the WWW (called W3C) expects around a billion web users by 2002 and an even higher number of available documents. However, this success and exponential grow makes it increasingly difficult to find, to access, to present, and to maintain the information of use to a wide variety of users.

The semantic web will bring structure to the meaningful content of Web pages, creating an environment where software agents roaming from page to page can readily carry out sophisticated tasks for users.

The semantic web is not a separate web but an extension of the current one, in which information is given well-defined meaning better enabling computers and people to work in cooperation. With the help of ontologies large amounts of text can be semantically annotated and classified.

Currently pages on the web use representations rooted in format languages such as HTML or SGML. The information content, however, is mainly presented by natural language. Thus, there is a wide gap between the information available for tools that try to address the problems above and the information kept in human readable form.

The semantic web will provide intelligent access to heterogeneous and distributed information enabling software agents to mediate between the user needs and the available information sources.

The first steps in weaving the semantic web into the structure of the existing web are already under way. In the near future, these developments will usher in significant new functionality as machines become much better able to process and "understand" the data that they merely display at present.

What is required: creation of a machine understandable semantics for some or all of the information presented in the WWW i.e.

- Developing languages for expressing machine understandable meta-information for documents, in the line of RDF, DAML, and similar proposals.
- Developing terminologies (i.e., name spaces or ontologies) using these languages and making them available on the web.
- Integrating and translating different terminologies
- Developing tools that use such languages and terminologies to provide support in finding, accessing, presenting and maintaining information sources.

Developing such languages, ontologies and tools is a wide-ranging problem that touches on the research areas of a broad variety of research communities.

Creation of the relevant tools will require a better knowledge of what the users want to know from websites, i.e. these developments need to be based on a user-centered process view.

Another crucial issue will be: “Who is going to populate the semantic web?” The semantic markup that is required by automated software agents needs to be very easy to create and supporting tools need to be provided, otherwise this wonderful idea will not have significant impact for a long time. Advanced NLP technology that can “guess” the correct semantic annotation and propose suitable markup semi-automatically will enable conformance to the needs of software agents with minimal manual effort.

Dialogue Systems

No matter if people want to buy something, find or use a service or just need information, dialog systems promise user-friendly and effective ways to achieve these goals, even for first time users.

Despite the apparent resemblance to QA systems, there are several specific problems to be solved concerning dialogue modality and structure. Input to a dialog system might be via keypad, voice, pointing device, combinations thereof, or other channels, so all errors and incompleteness of spontaneous natural language will show up. In contrast to QA systems, there will be mixed initiatives of speaker and system and the scope is much wider if we take into account that the focus during natural dialogue may often change. Also, the utterance made during a dialog can only be correctly interpreted based on the dialog context and the mutual knowledge that has been accumulated before it was made.

In future we require systems that can support natural, mixed initiative human computer interaction that deals robustly with context shift, interruptions, feedback and shift of locus or control.

Open research challenges include the ability to tailor flow and control of interactions and facilitate interactions including error detection and correction tailored to individual physical, perceptual and cognitive differences.

Motivational and engaging life-like agents offer promising opportunities for innovation.

Agent/user modeling: Computers can construct models of user beliefs, goals and plans as well as models of users’ individual and collective skills by processing materials such as documents or user interactions/conversations. While raising important privacy issues, modeling users or groups of users unobtrusively from public materials or conversations can enable a range of important knowledge management capabilities

tracking of user characteristic skills and goals enhances interaction as well as discovery of experts by other users or agents

A central problem for the development of dialogue systems is the fact that contemporary linguistics is still struggling to achieve a genuine integration of semantics and pragmatics. A satisfactory analysis of dialogue requires in general both semantic representation i.e. representation of the content of what the different participants are saying and pragmatic information, i.e. what kinds of speech acts they are performing (are they asking a question, making a proposal…)

Analysis of a dialog needs to explain the purpose behind the utterances it consists of. Determining the semantic representation of an utterance and its pragmatic features must in general proceed in tandem. A dialogue system identifying the relevant semantic and pragmatic information will thus have to be based on a theory in which semantics and

pragmatics are both developed with the formal precision that is a prerequisite for implementation and suitably attuned to each other and intertwined.

Applications in Electronic Commerce

New technological possibilities can quickly impact the interaction between companies and their customers. One example are dialog systems that allow customers to obtain personal advises or services. For reasons indicated above, these systems are difficult to build, but once this investment has been done, they can be operated at low cost for the company.

Another example, which may be even sooner to come, is the creation of systems that support processing of emails sent by customers. According to business analyses, e-mail has already now become one of the most common forms of customer communication. For numerous businesses that are not well-prepared, this has transformed e-mail into a severe pain point, giving rise to the pressing need to adopt e-mail response management systems.

Obviously, NLP technologies that are able to extract the salient facts from email messages can constitute a central part of these systems. Due to the potential complexity of the queries and additional problems like ungrammatical input and spelling errors, the correct interpretation of arbitrary messages is far from easy. However, there are several factors that alleviate the situation: Messages that are too difficult for automatic processing can be routed to human agents. In cases in which doubts about the correctness of generated responses persist, these responses can always be checked by manual inspection. Historical data about email exchange with customers can be used to bootstrap the models that are required for the system. Depending on the business, a significant fraction of the emails may be amenable to NLP, including requests for information material, business reports, certificates, statements of account, scheduling requests, conference registrations etc.

e-Learning

Using modern technology to facilitate learning is one of the most promising application domains of NLP. Good QA systems that are able to give answers to the point, or summarization systems that can adapt to the user's prior knowledge and present important additions in a way that is easy to understand could immediately take the place of a good teacher, which an unlimited supply of time and patience. One technology is ripe to build these tools, using them for e-learning will one of the biggest opportunities to our knowledge society.

However, as the European society evolves more and more into multilingualism, it is natural to ask how NLP can help to make language learning easier and more effective. We can imagine systems to help train children to write and to speak a foreign language. There will be combinations of multi-modal aids for the handicapped. A child will write a sentence and the system will correct it and tutor him about the problems. A child will read a text aloud and the system will monitor which words are not right and why and will analyze where the pronunciation problems are. Later the system would suggest some pronunciation exercises in the particular problem.

Systems that are able to guess the intention of a speaker from the speaker's utterances in a flexible and intelligent way will offer a plethora of possibilities for e-learning. As similar capabilities are required for dialog systems in general, there will be significant synergy effects between these fields of research.

Translation

The idea of machine translation (MT) has been one of the driving forces in the early days of NLP. However, even after more than 50 years of effort, current systems still produce output of limited quality, which is suitable for assimilation of foreign-language documents, but not for the production of publishable material. But even if the old dreams did not come true, MT will play an increasing role in the multilingual world.

Last year, for the first time, English constituted less than half the material on the web. Some predict that Chinese will be the primary language of the web by 2007. Given that information on the web will increasingly appear in foreign languages and not all users will be fluent in those languages, there will be a need to gist or skim content for relevance assessment and/or provide high quality translation for deeper understanding. Some forms of translation for information access is already today available in the web at no cost. The increasing demand for these services will give a push to improve their quality and the providers will find ways to increase vocabularies and translation quality semi-automatically from terminological resources, bilingual corpora and similar sources. Also the need for interactive systems that can give rough translations of chat sessions in real time will create interesting challenges.

Clearly, any systematic collection of lexical and terminological information in the form of domain-specific ontologies will help to build better MT systems for these domains. Conversely, the construction of ontologies can be facilitated by automatic alignment of existing translations, as this will naturally lead to a clustering of the vocabulary along the relevant semantic distinctions.

These developments will also have an impact on improved systems for high-quality translation for the dissemination of documents. Chances are that hybrid combinations of symbolic and stochastic translation engines, able to learn relevant terminology from translation memories will eventually achieve a level of performance that will make them useful for the professional translator. Combined with multi-modal workbenches where voice input, keyboard and mouse interaction will make the composition of the target text as convenient as possible, these new technologies may help at least in some easier domains, where so far the effort of the human translator is dominated by low-level activities such as entering the text, adjusting the formatting, copying names and numbers, which are clearly amenable to partial automation.

3. Technologies for NLP

This chapter contains a more detailed discussion of some of the technologies that are required for the applications mentioned in the last chapter. Most of the material is organized along traditional fields of research in NLP, describing technologies that already exist, but must be further developed to achieve the ambitious goals. Some technologies cannot be assigned to one specific level, because they serve a more generic purpose, such as the extraction of relevant knowledge from text corpora.

Low-Level Processing

Most systems that analyse natural language text typically start by segmenting the text into meaningful tokens. Sometimes, the exact spelling of these tokens needs to be brought into a

canonical form, so that it can match with a lexical entry. Both processes can be based on matching the input against regular expressions, for which efficient algorithms exist. Whereas this task looks straightforward from the distance, there are actually some subtle details that need to be considered. Quite often, a decision whether a word should be split at a special character or whether a dot ends a sentence or is part of the preceding word depends on the vocabulary of the domain and on layout conventions used in this document, so that general rules cannot be defined. Documents that need to be analyzed may contain markup from text processors, which needs to be stripped or interpreted in a suitable way. The knowledge required in these preliminary stages of processing can already be quite specific, so that a manual creation of suitable rule systems is not economically feasible.

Current research on the automatic tokenization and normalization of texts therefore concentrates on the question how the knowledge required by these methods can automatically be derived from examples, using techniques statistical or machine learning approaches.

Another difficulty is the treatment of noise in the input. Output of speech recognition systems often contains recognition errors at rather high rates. Utterances entered interactively or printed documents that have undergone OCR have similar problems. Unfortunately, the distortion of even a single character can mess up the linguistic analysis of the complete input. But of course, we expect NLP systems to deal gracefully and intelligently with small distortions and errors in the input.

To make systems more robust against noisy input, probabilistic techniques for the restoration of distorted signals, which have shown to be quite effective in speech recognition, need to be adapted and generalized to new applications. However, training simple-minded statistical models on massive amounts of data will often not be feasible. By now, statistical language models that incorporate grammatical knowledge are able to give slight improvements over n-gram approaches, and it seems plausible to expect that future improvements of these will be easier to use in specific situation where training data is scarce. Large vocabularies, many types of distortions, and the need to use fine-grained contextual knowledge for improved predictive models constitute significant research challenges. Most likely, there will be some synergy between language models used in speech and similar models that will be developed for low-level processing and correction of written ill-formed input.

Once the segmentation into basic units has been performed, the next step is to identify suitable lexical entries for each token and, in cases where more than one entry applies, to determine which one is most appropriate in the given context. This process is called part-of-speech disambiguation or POS tagging and is usually done with statistical models or machine-learning approaches trained on manually tagged data. Current technology achieves rather high accuracy on newspaper text, but again, performance suffers significantly when a model trained on a certain set of data is applied to text from a different domain. As the output of the POS tagger is typically used as input to subsequent modules, tagging errors may hamper the correct analysis of much more than the affected word. Research on high-quality POS tagging will face problems that are similar to those of language modelling: It requires detailed information about a large number of rare words that may be quite specific to the given domain and application, which is difficult to construct, no matter which road to lexical acquisition is taken. Any effort that will support the construction, distribution, sharing and re-use of large, domain-specific lexical resources will doubtlessly also help to improve the accuracy of POS tagging on text from these domains.

The next step in the analysis of text is to identify groups of words that belong together and refer to one semantic entity. Often, these phrases contain names, and for many practical applications, it is important to classify these expressions according to the type of entity they denote (Person, City, Company, etc.). Depending on the application, the classification may be more or less fine-grained. Again, it is obvious that improved lexical knowledge will help to improve the performance of named entity recognition. But we cannot in all cases rely on a lexical resource to cover the relevant entities. A text may discuss the opening of a new company, which will therefore not be contained in the lexicon. To handle such cases intelligently, we need mechanisms that can exploit contextual clues for the correct classification of unknown entities and we need effective mechanisms that propagate information about new entities into the lexical repositories, so that the system as a whole learns from the texts it sees, similar to the way a human reader would do.

Syntactic Analysis

The goal of syntactic analysis is to break down given textual units, typically sentences, into smaller constituents, to assign categorical labels to them, and to identify the grammatical relations that hold between the various parts.

In most applications of language technology the encoded linguistic knowledge, i.e. the grammar, is separated from the processing components. The grammar consists of a lexicon, and rules that syntactically and semantically combine words and phrases into larger phrases and sentences.

Several language technology products on the market today employ annotated phrase-structure grammars, grammars with several hundreds or thousands of rules describing different phrase types. Each of these rules is annotated by features and sometimes also by expressions in a programming language.

The resulting systems might be sufficiently efficient for some applications but they lack the speed of processing needed for interactive systems, such as applications involving spoken input, or systems that have to process large volumes of texts, as in machine translation.

In current research, a certain polarization has taken place. Very simple grammar models are employed, e.g. different kinds of finite-state grammars that support highly efficient processing. Some approaches do away with grammars altogether and use statistical methods to find basic linguistic patterns. Other than speed, these shallow and statistically trained approaches have advantages in terms of robustness, and they also implicitly perform disambiguation, i.e. when more than one analysis is possible, they make a decision for one reading (which of course may be the wrong one).

On the other end of the scale, we find a variety of powerful linguistically sophisticated representation formalisms that facilitate grammar engineering. These systems are typically set up in a way that all logically possible readings are computed, which increases the clarity (no magic heuristics hidden in procedures), but also slows down the processing. Despite their nice theoretical properties it has so far been difficult to adapt these systems to the needs of real-world applications, where speed, robustness, and partial correctness in typical cases are more urgent than theoretical faithfulness and depth of analysis.

How will this situation evolve? The two approaches will continue to compete for potential applications, and the current advantage for shallow approaches will diminish as more ambitious applications get within reach, and as languages are used that require richer analysis.

This will give incentives for shallow approaches to struggle for higher accuracy and more detailed analyses, whereas the deep processing will be forced to find workable solutions for the problems with speed and robustness. In the ideal case, more fine-grained forms of integration will be found, i.e. hybrid systems that will keep the advantages of both worlds as far as possible.

The simplest integration will just use shallow analysis as a fallback mechanism when deep analysis fails. In this case, results from both approaches need to be translated into one common representation, and the development of such a "common denominator" will be a significant challenge. To achieve an even more fine-grained cooperation between both approaches, deep analysis may be equipped with the ability to locally fall back to more superficial processing, driven by the need to deal with a specific problem in the input. Vice versa, the results of shallow analysis might be combined into a more detailed structure incrementally, based on rules from a deep grammar. Also analyses of corpus data obtained with shallow tools can be mined for linguistic knowledge that is then fed into resources used by a deep parser, and vice versa.

Research challenges will be how to find syntactic parsers that are at the same time fast, robust, deliver a detailed analysis that is correct with high probability and that are easily to adapt to special domains.

Semantic Analysis

The goal of semantic analysis is to assign meanings to utterances, which is an essential precondition for most applications of NLP. However, what level of abstraction is required in this phase depends on the difficulty of the task. Extraction of answers to simple factual questions from a given text will require less depth in analysis than the summarization of a lengthy treatise in few paragraphs.

We can dissect the task of semantic analysis into several subtasks, depending on the linguistic level where it takes place. Most important are the semantic tagging of ambiguous words and phrases, and the resolution of referring expressions.

The disambiguation of word senses needs to identify the meaning that should be assigned to a given word. The hardest part of this task is to define the set of meanings that should be considered in this task, i.e. to select the appropriate granularity for the conceptualization. The emergence of standardized, large-scale ontological resources will help to solve this part of the task, as the concepts that appear in such ontologies are a natural choice for the meanings of single words or simple phrases. Additionally, multilingual corpora that are aligned on the level of words and phrases can serve as an approximation to sense-tagged corpora, so draft ontologies and models for sense disambiguation can be extracted from these.

Considerable efforts in defining useful evaluation metrics for sense disambiguation are pursued in the ongoing SENSEVAL activities. So far, the methods used by the participants of SENSEVAL are mostly based on simple statistical classification using features extracted from the context of word occurrences. To the extent to which robust, high quality systems for syntactic analysis will appear, this will also help to obtain improved accuracy in the semantic disambiguation.

The resolution of referring expression such as pronouns or definite noun phrases is the ability to identify their target, which may be expressions that appear prior in the text, abstractions of material that appeared earlier, or entities that exist independently from the text in existing

background knowledge. Seen in a more general way, the task is to cull out objects and events from multimedia sources (text, audio, video). An example challenge includes extracting entities within media and correlating those across media. For example this might include extracting names or locations from written/spoken sources and correlating those with associated images. Whereas commercial products exist to extract named entities from text with precision and recall in the ninetieth percentile, domain independent event extractors work at best in the fiftieth percentile and performance degrades further with noisy, corrupted, or idiosyncratic data.

Therefore work on the resolution of referring expression and the identification of entities in text and multimedia documents remains important fields of activity for the future.

Discourse and Dialogue

Extracting the knowledge contained in documents and understanding and generating natural dialog behavior requires more than the resolution of local semantic ambiguities. Intelligent analysis needs to consider the global argumentative structure of documents and discourse, and dialogs need to be analyzed for pragmatic content.

Computational work in discourse has focused on two different types of discourse: extended texts and dialogues, both spoken and written, yet there is a clear overlap between these two: dialogues contain text-like sequences spoken by a single individual and texts may contain dialogues. But application opportunities and needs are different. Work on text is of direct relevance to document analysis and retrieval applications, whereas work on dialogue is of import for human-computer interfaces regardless of the modality of interaction. Both are divisible into segments (discourse segments and phrases) with the meaning of the segments being more than the meaning of the individual parts.

The main focus of the research is the interpretation beyond sentence boundaries, the intentional and informational approach.

According to the informational approaches, the coherence of discourse follows from semantic relationships between the information conveyed by successive utterances. As a result, the major computational tools used here are inference and abduction on representations of the propositional content of utterances.

According to the intentional approaches the coherence of discourse derives from the intentions of speakers and writers and understanding depends on recognition of those intentions.

One difficulty is to build models of human-machine-dialog when initially only examples of human-human interaction exist, which may not be relevant. Bootstrapping suitable models will therefore require Wizard-of-Oz studies with simulated systems.

Natural Language Generation

In many of the applications mentioned above, systems need to produce high-quality natural language text from computer-internal representations of information. Natural language generation can be decomposed into the tasks of text planning, sentence planning and surface realization. Text planners select from a knowledge pool which information to include in the output and out of this create a text structure to ensure coherence. On a more local scale, sentence planners organize the content of each sentence, massaging and ordering its parts.

Surface realizers convert sentence-sized chunks of representation into grammatically correct sentences.

Generator processes can be classified into points on a range of sophistication and expressive power, starting with inflexible canned methods and ending with maximally flexible feature combination methods. It is safe to say that at the present time one can fairly easily build a single-purpose generator for any specific application, or with some difficulty adapt an existing sentence generator to the application, with acceptable results. However, one cannot yet build a general-purpose sentence generator or a non-toy text planner. Several significant problems remain without sufficiently general solutions:

- Lexical selection is one of the most difficult problems in generation. At its simplest this question involves selecting the most appropriate single word for a given unit of input. However as soon as the semantic model approaches a realistic size and as soon as the lexicon is large enough to permit alternative locutions, the problem becomes very complex. The decision depends on what has already been said, what is referentially available from context, what is most salient, what stylistic effect the speaker wishes to produce and so on. What is required: development of theories about and implementations of lexical selection algorithms, for reference to objects, events states, etc., and tested with large lexical.

- Discourse structure (see also there) So far, no text planner exists that can reliably plan texts of several paragraphs in general. What is required: Theories of the structural nature of discourse, of the development of theme and focus in discourse, and of coherence and cohesion; libraries of discourse relations, communicative goals and text plans: implemented representational paradigms for characterizing stereotypical texts such as reports and business letters; implemented text planners that are tested in realistic non-toy domains.

- Sentence planning: Even assuming the text planning problem is solved, a number of tasks remain before well-structured multi-sentence text can be generated: These tasks, required for planning the structure and content of each sentence, include: pronoun specification, theme signaling, focus signaling, content aggregation to remove unnecessary redundancies, the ordering of prepositional phrases, adjectives, etc. What is required: Theories of pronoun use, theme and focus selection and signaling, and content aggregation; implemented sentence planners with rules that perform these operations; testing in realistic domains.

- Domain modeling: a significant shortcoming in generation research is the lack of large, well-motivated application domain models, or even the absence of clear principles by which to build such models. A traditional problem with generators is that the inputs are frequently hand-crafted, or are built by some other system that uses representation elements from a fairly small hand-crafted domain model, making the generator's inputs already highly oriented toward the final language desired….What is required: Implemented large-size (over 10.000 concepts) domain models that are useful both for some non-linguistic application and for generation; criteria for evaluating the internal consistency of such models; theories on and practical experience in the linking of generators to such models: lexicon of commensurate size.

Probably the problem least addressed in generator systems today is the one that will take the longest to solve. This is the problem of guiding the generation process through its choices when multiple options exist to handle any given input.

The generator user has to specify not only the semantic content of the desired text, but also its pragmatic – interpersonal and situational – effects. Very little research has been performed on this question beyond a handful of small-scale pilot studies. What is required: Classifications of the types of reader characteristics and goals, the types of author goals, and the interpersonal and situational aspects that affect the form and content of language; theories of how these aspects affect the generation process; implemented rules and/or planning systems that guide generator systems' choices; criteria for evaluating appropriateness of general text in specified communicative situations.

Effective presentations require the appropriate selection of content, allocation to media, and fine grained coordination and realization in time and space. Discovery and presentation of knowledge may require mixed media (e.g., text, graphics, video, speech and non-speech audio) and mixed mode (e.g., linguistic, visual, auditory) displays tailored to the user and context. This might include tailoring content and form to the specific physical, perceptual, or cognitive characteristics of the user. It might lead to new visualization and browsing paradigms for massive multimedia and multilingual repositories that reduce cognitive load or task time, increase analytic depth and breadth, or simply increase user satisfaction. A grand challenge is the automated generation of coordinated speech, natural language, gesture, animation, non-speech audio, generation, possibly delivered via interactive, animated lifelike agents. Preliminary experiments suggest that, independent of task performance, agents may simply be more engaging/motivating to younger and/or less experienced users.

Ontologies

Large-scale ontologies are becoming an essential component of many applications including standard search (such as Yahoo and Lycos), e-commerce (such as Amazon and eBay), configuration (such as Dell and PC-Order), and government intelligence (such as DARPA's High Performance Knowledge Base program). As discussed in the preceding paragraphs, ontologies will constitute a major source of knowledge needed for several levels of NLP.

Ontologies are increasingly seen as an important vehicle for describing the semantic content of web-based information sources and they are becoming so large that it is not uncommon for distributed teams of people to be in charge of the ontology development, design, population, and maintenance.

Ontologies define a vocabulary for researchers who need to share common understanding of the structure of information in a domain. It includes machine-interpretable definitions of basic concepts in the domain and relations among them. The principal reasons to use an ontology in machine translation (MT) and other language technologies are to enable source language analyzers and target language generators to share knowledge, to store semantic constraints and to resolve semantic ambiguities by making inferences using the concept network of the ontology. An ontology contains only language independent information and many other semantic relations as well as taxonomic relations.

Though the utility of domain ontologies is now widely acknowledged in the IT (Information Technology) community, several barriers must be overcome before ontologies become practical and useful tools. One important achievement would be to reduce the time and cost of identifying and manually entering several thousand concept descriptions by developing

automatic ontology construction. Another important task is to find arrangements that make development and sharing of ontologies commercially attractive.

Some challenges for ontology research:

Work on ontologies needs to provide generally applicable top-ontologies that cover most important core concepts that will be needed for many domains. Extensions to new domains could then start by enriching these top-ontologies in a specific direction, reducing the initial effort for creating new ontologies, for merging independently developed extensions, and for rapid customisation of existing ontologies.

This requires that ontology-creators are willing to share parts of their work and find suitable processes to organize cooperation. It also requires the development of standards for the languages in which ontologies are specified and can be interchanged (e.g. along the lines of the OIL proposal). Here, the challenge is to find suitable compromises between expressive power and depth on one hand and ease of use on the other hand. Ideally, one specification language should be able to cover the whole spectrum up to advanced knowledge representation as used in the CYC project.

Incremental improvement of ontologies needs to be facilitated by specialized tools for easy visualization and modification. These tools (and the representations they work on) need to be domain-independent and suited even for casual users, and their design needs to be based on a user-centred process view.

It must be easy to plug in ontologies into various NLP-based tools such as tools for information extraction, organization and annotation of document collections (semantic Web), environments for terminology management and controlled language. This will permit to audit the contained knowledge in manifold ways, and will allow for rapid quality improvement.

What is required: tools that support broad ranges of users in (1) merging of ontological terms from varied sources, (2) diagnosis of coverage and correctness of ontologies, and (3) maintaining ontologies over time.

Lexicons

Lexical knowledge – knowledge about individual words in the language – is essential for all types of natural language processing. Developers of machine translation systems, which from the beginning have involved large vocabularies, have long recognized the lexicon as a critical (and perhaps the critical) system resource. As researchers and developers in other areas of natural language processing move from toy systems to systems which process real texts over broad subject domains, larger and richer lexicons will be needed and the task of lexicon design and development will become a more central aspect of any project.

A basic lexicon will typically include information about morphology and on the syntactic level, the complement structures of each word or word sense. A more complex lexicon may also include semantic information, such as a classification hierarchy and selectional patterns or case frames stated in terms of this hierarchy. For machine translation, the lexicon will also have to record correspondences between lexical items in the source and target language; for speech understanding and generation, it will have to include information about the pronunciation of individual words. For this purpose the overall lexicon architecture and the representation formalism used to encode the data are important issues.

No matter if we want to build an ontology or a lexicon, in general for this kind of high-quality semantic knowledge base, manual processing is indispensable. Traditionally computer lexicons have been built by hand specifically for the purpose of language analysis and generation. However, the needs for larger lexicons are now leading to efforts for the development of common lexical representations and co-operative lexicon development.

The area is ripe – at least for some levels of linguistic description – for reaching in the short term a consensus on common lexical specifications. We must expand the experiences with the sorts of semantic knowledge that could be effectively used by multiple systems. We must also recognize the importance of the rapidly growing stock of machine-readable text as a resource for lexical research. The major areas of potential results in the immediate future seem to lie in the combination of lexicon and corpus work. There's a growing interest from many groups in topics such as sense tagging or sense disambiguation on very large text corpora, where lexical tools and data provide a first input to the systems and are in turn enhanced with the information acquired and extracted from corpus analysis.

Machine Learning

As mentioned above, the acquisition of knowledge continues to impose on of the biggest difficulties to the application of NLP technologies. This holds both for linguistic knowledge (grammars lexicons) and for world knowledge (ontologies, facts). In order to make extensions of NLP to new domains possible, the acquisition process needs to be supported by algorithms that can exploit existing textual material and extract knowledge of various types from it.

Approaches to these methods can be found in various fields of research, such as statistical language models, bilingual alignment, grammar induction, statistical parsing, statistical classification technology, Bayesian networks and other ML methods used in artificial intelligence research, data mining techniques etc.

Due to the specific nature of lexical information, it is important to pick or develop methods that scale to large vocabularies and large sets of features and that can exploit multiple sources of evidence in a good way. Also, the methods need to be able to use a rich set of existing background knowledge, so that no effort is wasted in re-discovering what was already known.

It is important to have methods that can use richly annotated training data, but do not require that large datasets have to be annotated in this way. Instead, methods should be able to draw a maximum of advantage from raw data without annotation using unsupervised learning approaches. Also, it will be important to guide the effort of human annotation so that time is spent in the most efficient way, using active learning methods. Tools and processes for managing annotation projects (including assessment of quality levels) need to be developed and shared on a broad basis.

Whenever possible, one should try to use models that contain explicit linguistic representations (ideally organized along different strata) so that partial reuse of models and rapid adaptation to slightly different is facilitated.

4. Milestones

Some relevant items not included in Bernsen 2000.

Basic technologies

Short term

- accurate syntactic analysis for well-formed input from specific domains
- simple methods for minimizing annotation effort during domain adaptation
- ML algorithms that combine active and unsupervised learning for optimal exploitation of data
- generally applicable annotation schemes for semantic markup of text
- standards for encoding and exchange of ontological resources emerge
- top-level ontologies generally available
- tools for semi-automatic construction and population of ontologies from text
- tools for simple semantic enrichment of Web pages
- approaches to markup of discourse structure and pragmatics

Medium term

- improved methods for minimizing annotation effort during domain adaptation
- tools for adaptation of syntactic analysis to specific application with minimal human effort
- accurate syntactic analysis for slightly ill-formed input for restricted domains
- improved syntactic analysis of input with uncertainties (word lattices)
- machine learning methods that exploit and extend existing knowledge sources
- sufficiently accurate semantic analysis of free text from restricted domains
- generic schemes for the annotation of pragmatic content
- schemes for annotation of discourse and document structure
- generally usable ontologies exist for many domains
- NL generation verbalizes information extracted/deduced from multiple sources for QA
- Agent/user models for dialogs of moderate complexity

Long term

- accurate syntactic analysis for ill-formed input from multiple domains
- sufficiently accurate semantic analysis of free text from multiple domains
- recognition of pragmatic content in text and dialog
- NL generation produces stylistically adequate and well-structured text

Systems

Short term

- QA systems are able to answer simple factual questions
- Summarization system produce well-formed extracts from short documents
- automated e-mail response systems deliver high-quality replies in easy cases
- MT for information assimilation

Medium term

- QA systems that deduce answers from information in multiple sources
- Summarization systems are able to merge multiple documents
- Summarization systems are able to deliver different types of summaries
- Integration of translation memories with MT enables fast domain-adaptation
- Mixed-initiative dialogue systems for services and e-commerce

Long term

- Translator's workbenches based on TM, MT, and multi-modal input facilities
- QA systems that are able to explain their reasoning

5. Recommendations for NLP research in Europe

1. Build and make publicly available at low cost large-scale multilingual lexical resources, with broad coverage, generic enough to be reusable in different application frameworks
2. To turn special attention to the development of better ontologies which are reusable across domains in order to encode static world knowledge
3. Creation of large common accessible multilingual corpora of syntactical and semantically annotated data annotated also beyond sentence boundaries

4. Encourage development of statistical and machine-learning methods that facilitate bootstrapping of linguistic resources

5. Common standards will improve the effectiveness of people's cooperation, the identification of the requirements for the system specification, the inter-operability among systems and the possibility of re-using and sharing system components.

6. Integration of language processing into the rest of cognitive science, artificial intelligence and computer science e.g. some ambitious projects centered on NL but combining various techniques and different areas of AI. New type of projects: Very different for scale, ambition and timeframe

7. Establishment of centers of excellence as focus points for projects for a period of five to ten years.

8. Encourage systematic evaluations (but how ?)

The Workshop Programme

Agenda (Morning Session)

Technical Papers (**8:00-9:20**)

8:00-8:20 *'Multilingual Terminology Databanks for Web Mining*'
António Ribeiro, Universidade Nova de Lisboa

8:20-8:40 *'Grammar Learning by Partition Search*'
Anja Belz, ITRI University of Brighton

8:40-9:00 *'A Semantic-driven Approach to Hypertextual Authoring'*
R. Basili, A. Moschitti, M.T. Pazienza and F.M. Zanzotto, University of Rome, Tor Vergata

9:00-9:20 *'Advantages of ontology-based user profiling in the NAMIC project'*
Jan De Bo and Ben Majer, VUB STARLab, University of Brussels

9:20-10:05 Invited Talk *'Methods, representation and linguistic bias in Adaptive IE'*
Roberto Basili, University of Rome, Tor Vergata

10:05-10:25 Coffee

Technical Papers (**10:25-11:45**)

10:25-10:45 '*Description of Events: An Analysis of Keywords and Indexical Names'*
Khurshid Ahmad, Paulo C F de Oliveira, Pensiri Manomaisupat, Matthew Casey and Tugba Taskaya, University of Surrey

10:45-11:05 *'Learning IE patterns: a terminolgy extraction perspective.'*
Roberto Basili, Maria Teresa Pazienza, Fabio Massimo Zanzotto, University of Rome, Tor Vergata

11:05-11:25 *'Unsupervised Event Clustering in Multilingual News Streams'*
Martijn Spitters and Wessel Kraaij, Department of Multimedia Technology & Statistics, The Netherlands

11:25-11:45 *'Large-scale Multilingual Information Extraction'*
R. Catizone, A. Setzer and N. Webb, Univeristy of Sheffield

11:45-12:30 Invited Talk*: 'User Driven Information Extraction for the Web'*
Fabio Cirevegna, University of Sheffield

12:30-1:30 Panel and Round Table on *Adaptive Technologies and their implications on advanced HLT applications (IR, IE, Q&A and KM)*

panelists:

Nino Varile (EC Commission)
F. Gardin (AISoftware)
Y. Wilks (Univeristy of Sheffield)
M.T. Pazienza (University of Rome, Tor Vergata)
Francesco Danza (Knowledge Stones S.p.A.)
Remi Zajac (Systran Software)

Workshop Organisers

Roberta Catizone, University of Sheffield

Abstract

This paper presents on-going research on a methodology to build multilingual terminology databanks from parallel texts in several languages. Web mining is a potential application for these databanks for they allow not only multilingual document content modelling but also multilingual retrieval of documents matching a user's query in different languages. We start by describing a methodology to align parallel texts and to extract multiword term Translation Equivalents, using language independent and statistically supported techniques. Next, we present some approaches for multilingual mining in order to provide the context for this work. Finally, we discuss how these multilingual terminology databanks can be used in the framework of multilingual mining.

1. Introduction

In an increasingly multilingual Web, monolingual web search engines have become unable to mine the web and retrieve simultaneously documents written in different languages for a query made in a particular language. It may be the case that the most relevant documents are not written in the language the query was made; the user may not know what language to choose to retrieve the best documents. Current monolingual search engines cannot help on this. Thus, it would be wise to have multilingual web miners which would allow multilingual web searches and provide the user either the original document if the user understands the language it is written in or a translation of the document in a language selected by the user. Multilingual web search engines must be able to cope with Cross-Language Information Retrieval (CLIR) if they are to satisfy their customers. CLIR addresses precisely the possibility of making queries in one language and retrieving relevant documents in other languages (Brown *et al.*, 2000).

Google Inc., the company that owns the popular Google web search engine, has recently released a note stressing an increase in the number of web pages written in languages other than English: "Of the 2 billion web pages in Google's index [http://www.google.com], more than a quarter are in languages other than English" (Google Inc., 2001a). In fact, English is steadily becoming less *the* language of the Web. As more web pages are written in other languages, web searches are doomed to be confined to the documents written in the same language of the query if web search engines are not able to handle searches in multilingual documents. In a world which promotes information exchange, this seems to do the opposite through divisions and to raise the issue whether a 'Multilingual Information Society'[1] can actually be real.

Although users' experience says that they are better off with English for Web searches world wide, a press release also from Google Inc. (2001c) reports a growing trend in the number of web searches done in languages other than English in its own web search engine.

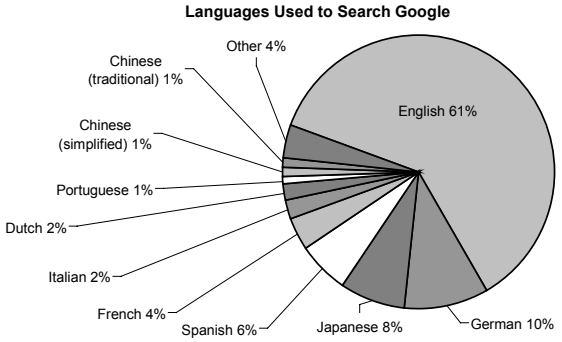

Figure 1: Languages used for searches with the Google web search engine in 2001 October (Google Inc., 2001c).

As Figure 1 shows, more than a third of the web searches done in 2001 October in the Google web search engine were in languages other than English[2].

This current trend emphasises the use of web engines for searches in various languages and again puts this work into perspective. In Europe alone it is often the case that each country has its own set of official languages and possibly even other regional languages, as it is the case of Spain (Basque, Castilian – commonly referred to as Spanish –, Catalan and Galician), Switzerland (French, German, Italian and Romansh) or the United Kingdom (English, Gaelic and Welsh). Consequently, should a query be done in one of these particular languages, a monolingual web search engine is bound to limit the query to documents written only in the query language.

This paper proposes using multilingual terminology databanks in order to model the contents of multilingual documents and, thus, to provide multilingual access. It describes a method to build multilingual terminology databanks from parallel texts in order to provide an extra multilingual layer for web search and enable searches in documents written in several languages.

[1] This is the name of a programme supported by the European Commission, which aims at protecting and safeguarding pluralism, diversity and the principle of equality among all languages (http://www.hltcentral.org/page-762.0.shtml).

[2] The same trend had also been noticed earlier in 2001 August (Google Inc., 2001b), before the 2001 September 11 attacks in New York, USA, which could have biased the results since more users would be choosing English to search, for example, 'World Trade Centre' or 'Anthrax'.

This paper is structured as follows: the next section gives an overview of what parallel texts are and how they can be aligned. Section 3 describes how to build multilingual terminology databanks from the aligned parallel texts. Section 4 describes how the multilingual databanks can be used for multilingual mining and presents several methodologies that have been proposed. Finally, section 5 presents some conclusions and section 6 draws some future work.

2. Aligning Parallel Texts

In this section we will describe several approaches to parallel texts alignment. First, we start by describing what parallel texts are. Section 2.2 and 2.3 present previous sentence and word alignment methodologies. Section 2.4 describes the alignment method we used.

2.1. Parallel Texts

Parallel texts are sets of texts which are translations of each other in different languages, like the proceedings of the Canadian Parliament – the Canadian Hansards –, which are published in both English and French, or the Official Journal of the European Communities published in the eleven official languages of the European Union[3]. They have proven to be rich linguistic resources for multilingual text processing and they have become available in a wide range of languages,

However, before it is possible to use them to identify translations of multilingual terms, parallel texts must be aligned first. Text alignment aims at establishing correspondences between parallel texts automatically, either between paragraphs, sentences, or even at sub-sentential level between text segments, phrases, words or sequences of characters.

There have been mainly two approaches to alignment of parallel texts: *sentence alignment* establishes correspondences between sentences only and *word alignment* tries to go a bit deeper into sub-sentential level by establishing correspondences between text segments or words.

2.2. Previous Sentence Alignment Techniques

Back in the early 1990s, sentences were considered as the basic units for alignment. Texts were split into sequences of sentences and alignment algorithms would attempt at making correspondences between the sentences in the parallel texts.

Kay and Röscheisen (1993) were the first to propose an alignment methodology. They assumed that for two sentences written in different languages to correspond, the words in them must also correspond. Their algorithm started by suggesting a tentative alignment of sentences by aligning the first and the last ones of each parallel text. Then, equivalent words were used to align the others. Two words were considered equivalent if they tended to co-occur in the same tentatively aligned sentences. A measure of similarity was computed and if it scored higher than a specific value, it would mean those words were indeed translations. Finally, sentences were aligned if the number of words associating them was greater than an empirically defined threshold.

In other alternative approaches, less knowledge based, sentences were aligned if they had a proportional number of words (Brown *et al.*, 1991) or characters (Gale and Church, 1991). Each of these authors started from the fact that long sentences tend to have long translations and, conversely, short sentences tend to have short translations. This correlation was the basis for their statistical models. Their algorithms would group sequences of sentences till they had proportional sizes

Brown *et al.* (1991, p. 175) remarked that the error rate was slightly reduced from 3.2% to 2.3% when using some linguistic knowledge like time stamps, question numbers and author names found in the parallel texts. This confirmed the fact that it was sufficient to look at sentence lengths in order to align sentences. Extra linguistic knowledge did not improve the results significantly.

Simard *et al.* (1992) proposed a sentence alignment algorithm which would first align text segments based on the length-based algorithm suggested by Gale and Church (1991), and, if it did not produce a 'clear' single best alignment of two text segments, it would proceed into a second pass counting the number of *cognates* shared between them.

According to the Longman Dictionary of Applied–Linguistics, a *cognate* is "a word in one language which is similar in form and meaning to a word in another language because both languages are related" (Richards *et al.*, 1985, p. 43). For example, the words *Parliament* and *Parlement*, in English and French respectively, are cognates. However, if two words have the same or similar forms in two languages but different meanings, they are called false cognates or false friends (Richards *et al.*, 1985, p. 103). For example, the English word *library* and the French word *librairie* are an example of false cognates (Melamed, 1999, p. 114): *library* is translated as *bibliothèque* in French and, conversely, *librairie* as *bookstore* in English.

Simard *et al.* (1992) used a simple rule to test if two words were cognates by checking whether their first four characters were identical (Simard *et al.*, 1992, p. 71), as in *Parliament* and *Parlement*. This simple heuristic proved to be quite useful, providing a great number of lexical cues for alignment though it has some shortcomings. According to it, the English word *government* and the French word *gouvernement* are not cognates. Also, *conservative* and *conseil* ('council'), in English and French respectively, are wrongly considered as cognates (Melamed, 1999, p. 113). The rule is sensitive to variations in the first four letters but it does not distinguish different word endings.

In order to align English and Chinese sentences, Wu (1994) also used the method based on proportional lengths. He also began by applying a method similar to the one used by Gale and Church (1991) and reported results not much worse than those expected by this algorithm. Still, he claimed sentence alignment precision over 96% when the method incorporated a seed bilingual lexicon of words commonly found in the texts to be aligned (e.g. names of months, like *December* and its equivalent in Chinese 十二月). So, again Wu's work confirmed that the use of lexical cues would be beneficial for alignment.

The problem with the alignment algorithms which rely solely on sentence sizes is that they tend to break down

[3] Danish (da), Dutch (nl), English (en), Finnish (fi), French (fr), German (de), Greek (el), Italian (it), Portuguese (pt), Spanish (es) and Swedish (sv).

when sentence boundaries are not clearly marked in the parallel texts. Sentences need to be clearly identified which means taking the most advantage of the cues provided by full stops. Full stops have to be clearly interpreted in order to check whether they mark a sentence boundary. However, that is not always the case.

Gale and Church (1991, p. 179) reported that only 53% of the full stops found in the Wall Street Journal were used to mark sentence boundaries. Full stops may be part of abbreviations (*Dr. A. Bromley*), numbers (*1.3%*), they are not usually found in headlines (*Tyre production*), they may not even exist because they were not added, or they were either lost or mistaken for noise in the early days when electronic versions of parallel texts were still rare and texts needed to be scanned.

2.3. Previous Word Alignment Techniques

Word alignment is much more fine-grained than sentence alignment since it is no longer done just at sentence level but at word level. Aligned text segments are shorter and, thus, it becomes easier to establish correspondences. However, in contrast with sentence alignment algorithms which permit a margin of tolerance for occasional wrong word matches since sentences generally have many words, they are no longer 'safety nets' for word level alignment. Consequently, the penalty on wrong word matches becomes higher and achieving a high precision becomes harder. Should word alignment be the goal, the alignment algorithm must be more 'careful' in order to avoid wrong word matches.

Church (1993) showed that by adding some lexical information, alignment of parallel text segments was possible without requiring sentence delimiters. He exploited the notion of orthographic cognates proposed earlier by Simard *et al.* (1992). He used a similar rule: use equal 4-grams in order to find 'cognate' (similar) sequences of characters in the parallel texts, i.e. sequences of four characters which are equal in the texts. The method built a graph where a dot at co-ordinates (x, y) meant that there was a match between the 4-grams in positions x and y of both texts. The reliable dots were filtered using an empirically estimated search space.

Fung and Church (1994) dropped the requirement for clear sentence boundaries on a case-study for English-Chinese. It was also the first time alignment procedures were being tested on texts between non-Latin languages and without finding sentence boundaries. Each parallel text was split into K pieces and word correspondences were identified by analysing their distribution across those pieces. In particular, a binary vector of occurrences with size K (hence, the K-vec) would record the occurrence of a word in each of the pieces. Should the word occur in the i-th piece of the text, then the i-th position of the vector would be set to '1'. Next, the K-vecs of English and Chinese words were compared in order to find whether two words corresponded. In this way, it was possible to build a rough estimate of a bilingual lexicon to feed the algorithm of Church (1993). In this case, dots would be drawn in the graph each time two translations occurred.

This method was extended in Fung and McKeown (1994). It was also based on the extraction of a small bilingual dictionary based on words with *similar distributions* in the parallel texts. However, instead of K-vecs, which stored the occurrences of words in each of the K pieces of a text, Fung and McKeown (1994) used vectors that stored the distances between consecutive occurrences of a word (DK-vec's). For example, if a word appeared at offsets (2380, 2390, 2463, 2565, ...), then the corresponding distances vector would be (10, 73, 102, ...). Should an English word and a Chinese word have similar distance vectors, then they would be used as potential cues for alignment.

In Simard and Plamondon (1998), sentences were aligned using 'isolated' cognates as anchors, i.e. cognates that were not mistaken for other cognates within a text window whose width was set to 30% of the text size. Yet, the alignment algorithm would start by aligning words. Each occurrence of a cognate became a dot in a graph according to its offset in each of the parallel texts. Some of those points were filtered if they lied outside an empirically defined search space which would mean they were "not in line" with their neighbouring points. The heuristic values used were found empirically so as to provide the best results and make the best selection of the good alignment cues.

Melamed (1999) also used orthographic cognates. His algorithm filtered noisy correspondence points, i.e. points which were not reliable, according to several heuristics which helped define what a good anchor was. In order to measure word similarity, he defined the ratio of the Longest Common Sub-sequence of characters as follows:

$$Ratio(w_1, w_2) = \frac{Length(Longest\ Common\ Sub\text{-}Sequence(w_1, w_2))}{Max(Length(w_1), Length(w_2))}$$

where w_1 and w_2 are the two words to be compared (Melamed, 1999, p. 113). This measure compares the length of the longest common sub-sequence of characters with the length of the longest token. For example, for *government* and *gouvernement*, the ratio is 10 (the length of *government*) over 12 (the length of *gouvernement*) whereas the ratio is just 6 over 12 for *conservative* and *conseil* ('council'). This measure tends to favour long sequences similar to the longest word and to penalise sequences which are too short compared to a long word. So, for this very reason, it fails to consider *gouvernement* and *governo* in French and Portuguese as cognates because *governo* is shorter. Their ratio is also 6 over 12.

For alignment purposes, Melamed (1999) selects all pairs of words which have a ratio above a certain threshold, empirically selected. Still, this comparison measure seems to provide better results than the one first proposed by Simard *et al.* (1992) but it is not also based on a statistically supported study.

2.4. The Alignment Methodology

In contrast with the previous approaches, Ribeiro *et al.* (2000) present a statistically supported method for word alignment of parallel texts which does not require either clearly delimited sentences or previous linguistic knowledge of the texts languages. It was applied to parallel texts in the 11 official languages of the European Union and also to parallel texts in Portuguese and Chinese (Ribeiro *et al.*, 2001a).

In particular, the alignment methodology selects alignment points using filters based on linear regression lines properties. The points are generated from the offsets of lexical cues provided by equal tokens (like numbers, proper names, punctuation marks) which occur with the

same frequency within a parallel text segment. Since the algorithm is recursive, even if some token happens not to have the same 'global' frequency, it may end up being used as an alignment point in a 'local' analysis of smaller text segments.

This algorithm was later extended in Ribeiro *et al.*, (2001b) to handle typical sequences of characters common to a particular pair of languages. Instead of using heuristics to identify cognate words or of using particular sizes of *n*-grams of characters to find similar sequences of characters, they made statistical data analyses of contiguous and non-contiguous sequences of characters to extract associated character units from each pair of languages. They were able to find typical sequences of characters in the beginning of words, such as •*Comis*, for *Comissão* and *Comisión* ('Commission') in Portuguese and Spanish, in the middle of words, as in *f_rma* which matches both *information* and *informação* in English and Portuguese respectively, or across word boundaries, as *i_re•ci* for the Portuguese–French pair as in *livre•circulação* and *libre•circulation* ('free movement').

The average alignment precision is over 90% for aligned parallel texts in Portuguese with all the other official languages of the European Union. This is the precision of a word alignment algorithm which, in contrast with other algorithms, does not rely on language specific knowledge, lists of stop words to avoid noise generated by frequent words or extra seed bilingual lexicons.

3. Building Multilingual Databanks

Aligned parallel texts are ideal sources to extract Translation Equivalents for they provide the correspondences between the original text and their translations in other languages. They allow easily the examination of the way specific words or terms are translated into other languages. Consequently, they can reduce the amount of effort necessary to build Translation Databanks.

For this experiment we used a sample of parallel texts from three sources: records of the Written Questions to the European Commission (ELRA, 1997), records of Debates in the European Parliament (ELRA, 1997) and Judgements of The Court of Justice of the European Communities in all the languages of the European Union.

In order to identify relevant multiword units, it has been common practice to do it by hand coding regular syntactic patterns, like the sequence 'Noun Noun' (e.g. *Web Mining*). Finite state automata are then used to recognise typical sequences of words in the texts which comply with these patterns. For example, Daille (1995) used several syntactic patterns to identify terms with two words such that they were either two nouns or a noun and an adjective, as in *liaison par satellite* ('satellite link') or *station terrienne* ('earth station'). Fung and McKeown (1997) also used specific syntactic patterns to extract multiword terms in order to compile a list of reliable pairs of translations for a further extension to their previous alignment algorithms (Fung and McKeown, 1994).

Although terms are generally covered by some characteristic patterns, this work has not started from a particular set of patterns so as not to constrain the structure of the multiword units.

In order to build the Multilingual Terminology Databank, we extracted terms from the parallel texts using a methodology described in da Silva *et al.* (1999). This methodology is based on the idea that the more cohesive a group of *n* words is, the higher its cohesiveness score. The algorithm assumes that the score of a good multiword unit must be a local maximum, i.e. the cohesion of the set of *n* words is higher than any subset of *n*–1 words contained in it and higher than the cohesion of any superset of *n*+1 words which contains it. Thus, the algorithm is able to select, for example, *common rules and standards* as a relevant multiword term but not *common rules and* or *common rules and standards for*, because the scores of these multiword units are lower. The figure below shows some extracted terms:

English	French	Portuguese
combined nomenclature	*autorités douanières*	*autoridades aduaneiras*
customs authorities	*États membres*	*Estados – Membros*
intervention agency	*matières nucléaires*	*materiais nucleares*
Member States	*nomenclature combinée*	*Nomenclatura Combinada*
nuclear material	*organisme d'intervention*	*organismo de intervenção*

Table 1: A sample of extracted multiword terms in English, French and Portuguese.

The methodology has proven to be quite adequate to be used across several languages. In this way, we were able to capture multiword terms for each language and build databanks of terms. However, it still remains to be seen how the relations between them can be established, i.e. how to build the multilingual terminology databank of equivalent translations.

The key issue in the extraction of Translation Equivalents is to find a correlation between co-occurrences of terms in the aligned parallel texts. In general, if two terms co-occur often in aligned text segments, then they are likely to be *equivalent*.

The alignment of parallel texts splits them into small aligned text segments and reduces the number of words / terms that must be checked for co-occurrence in each parallel text segment. The shorter the segments, the better. In order to identify Translation Equivalents, the *distribution similarity* of words / terms must be analysed in the aligned segments.

Following the conventional information retrieval methodology (Salton and McGill, 1983), the information on the occurrence of words (or terms) is usually represented in vector forms. For example, if a word *w* occurs in segments 1, 2 and 5 out of a total of five segments, then the following *occurrences vector* is built: *w* = (1, 1, 0, 0, 1). In this binary vector, each '0' and '1' represents the absence and presence of the word *w* in each of the five segments.

In this way, a set of occurrence vectors can be built for each of the terms found. Next, for each pair of source and target terms a *co-occurrence vector* is built where the *i*-th position of the vector is set to '1' if both terms occur in the *i*-th aligned text segment. Next, a *contingency table* is built for each pair of source–target terms by counting the number of '0's and '1's in the occurrences vectors.

n: 162347	*Επιτροπή των Ευρωπαϊκών Κοινοτήτων*	*× Επιτροπή των Ευρωπαϊκών Κοινοτήτων*
Comissão das Comunidades Europeias	*a*: 499	*b*: 102
× Comissão das Comunidades Europeias	*c*: 96	*d*: 161650

Table 2: Contingency table for the pair *Επιτροπή των Ευρωπαϊκών Κοινοτήτων* (Epitropé tos Europaikós Koinotétos) and *Comissão das Comunidades Europeias* ('Commission of the European Communities').

This table stores the *number of aligned segments* that contain:

a: both terms;
b: the Portuguese term but not the Greek term;
c: the Greek term but not the Portuguese term; and,
d: neither of those terms.

These amounts can be computed from the occurrences vectors as follows:

n: the size of the occurrences vectors;
a: the number of '1's in the co-occurrence vector;
b: the number of '1's found in the Portuguese term occurrences vector minus *a*;
c: the number of '1's found in the Greek term occurrences vector minus *a*; and,
d: $n - a - b - c$.

The difference between the total number of occurrences of both words may result either from different translations made by the translators themselves and / or from some occasional misalignment. Different translations may be due to syntactic constraints or to alternative translations the human translator decided to make.

Several measures of similarity have been proposed to use the information in the contingency tables in order to analyse the similarity of words and identify Translation Equivalents. We have used the Average Mutual Information as this similarity measure has proven to be appropriate for the task of identifying Translation Equivalents. The Average Mutual Information is computed as follows:

$$I(X;Y) = \sum_{x=\{0,1\}} \sum_{y=\{0,1\}} p(X=x, Y=y) \log_2 \left(\frac{p(X=x, Y=y)}{p(X=x)p(Y=y)} \right)$$

where X and Y are the two terms to be tested as translations. This formula is in contrast with the Specific Mutual Information, which is quite sensitive to rare co-occurrences, and which corresponds only to the last term of the sum. In this formula, $p(x = 1, y = 0)$ is the probability that term X occurs but term Y does not. Figure 2 shows some Translation Equivalents extracted in English, Greek and Portuguese.

Since we have used a general purpose terminology extractor, it extracts not only domain specific terms but also general language patterns. This happens because it tends to capture typical sequences of tokens independently of whether they are domain specific or not. The extractor was not developed to identify domain specific terminology though it is able to extract it too. We believe that by clustering documents and feeding those clusters of documents independently to the extractor it will be possible to distinguish domain specific terms from general language patterns. da Silva *et al.* (2001) proposes an unsupervised and language independent method to cluster documents to be used for this task.

Finally, by *re-feeding* the extracted Translation Equivalents back into the aligner it is possible to increase the number of potential anchors and, consequently, the number of new lexical cues available for the generation of correspondence points. The more correspondence points, the more fine-grained the alignment can be and the better the extracted equivalents can be. This means that alignment precision may improve. This is especially important for pairs of languages which share few lexical cues which can be used for alignment (like Portuguese and Chinese, as an extreme case).

4. Mining Multilingual Documents

Mining multilingual documents is a generalisation of the problem of mining documents that contain expressions which do not match exactly the ones in the query text. Fluhr (1995) made a survey of several approaches used for Multilingual Information Retrieval.

One traditional approach consists of using a *controlled vocabulary* both to index and retrieve documents, like the one used by Reuters or the Eurovoc (1995). Each document is indexed with a set of descriptors and queries are performed using this set of keywords. Queries are reformulated into the other languages by looking up the translations of the descriptors in a multilingual databank which contains the translations of each descriptor in the other languages.

English	Greek	Portuguese
JUDGMENT OF THE COURT	ΑΠΟΦΑΣΗ ΤΟΥ ΔΙΚΑΣΤΗΡΙΟΥ	ACÓRDÃO DO TRIBUNAL DE JUSTIÇA
Advocate General	γενικός εισαγγελέας	advogado – geral
Language of the case	Γλώσσα διαδικασίας	Língua do processo
Commission of the European Communities	Επιτροπή των Ευρωπαϊκών Κοινοτήτων	Comissão das Comunidades Europeias
Member States	κρατών μελών	Estados – membros
Act of Accession	Πράξεως Προσχωρήσεως	Acto de adesão
President of the Chamber	πρόεδρο τμήματος	presidente de secção
First Chamber	πρώτο τμήμα	Primeira Secção

Figure 2: A sample of Translation Equivalents obtained from the aligned texts in English, Greek and Portuguese.

However, the problem with this approach is that it limits queries to using the set of descriptors available instead of using full text words. An alternative method builds a matrix which links full text words to the set of controlled descriptors. This matrix can be built either manually or automatically by *learning* from previously indexed texts – a *text categorisation* task (Yang 1999). Once a query is posted, this matrix is looked up in order to find which descriptors are more associated with the words in the query. Finally, the translations of the descriptors are looked up in the multilingual databank in order to reformulate the query in the other languages.

Nevertheless, the use of controlled languages means that queries are somehow limited to the set of descriptors available. Alternative approaches can either translate the query – *query reformulation through translation* – or even the whole set of documents. Although there is some debate on the benefits and disadvantages of each one, reformulating the query through translation seems to be the simplest strategy since the latter option requires translating each document into all the other languages, which does not scale up well. Still, a query translated with errors may yield disappointing results if it has unresolved lexical ambiguities.

Anyhow, should parallel texts be available, they can become quite helpful. Some approaches exploit this fact by retrieving not only the documents most similar to the query posted but also their parallel versions. Then, the parallel texts can be used as a secondary query to retrieve similar untranslated documents in the other languages and even more parallel documents in the original query language should they be available.

In order for the search engine to retrieve the documents most similar to a query, several approaches have been suggested though most of them are based on the Vector Space model (Salton and McGill, 1983). In this model, documents are represented in a n-dimensional space, where n is the number of different words found in the texts – the term-document matrix. Both queries and documents are represented with n-dimensional vectors of term weights. Usually, terms are weighted using TF×IDF, the term frequency × the inverse document frequency of a term, i.e. the inverse of the number of documents in which the term occurs. Then, a document is considered relevant for a query if the query and the document vectors are *similar*. The similarity of two vectors can be computed using the cosine measure.[4]

In contrast with the previous model, the Generalised Vector Space Model (Wong *et al.*, 1985) takes into account the fact that terms are correlated. The assumption of this model is that two words are semantically similar if they tend to occur in the same documents, i.e. have similar document vectors in the term-document matrix. This Generalised model bears this in mind.

In the Pseudo-Relevance Feedback model, the initial query is expanded by adding to it terms found in the first set of retrieved documents, assuming that the top ranking documents are indeed relevant. This new extended query is posted again to the search engine in order to retrieve more documents (Salton and Buckley, 1990). Should there be parallel versions available for these documents, they can be used instead. This is the extension of the monolingual Pseudo-Relevance Feedback approach to multilingual retrieval suggested by Carbonell *et al.* (1997).

The Latent Semantic Indexing model (Deerwester *et al.*, 1990) is the next step after the previous model. It is also sensitive to co-occurrences of terms in the same document when it computes the similarity between the query and each document. The whole set of documents is *reduced* so that a smaller set is more representative for the content of the documents. This model was adapted to multilingual retrieval by Dumais *et al.* (1996), using parallel texts for training.

As for the approaches which expand the query and reformulate it with a translation, Machine Translation systems would probably be a good option and be able to provide good translations if queries were usually formulated as sentences or paragraphs. However, queries tend to be short and users tend to give isolated words for which Machine Translation systems performance degrades. Some alternative strategies have been suggested:

- look up each query word in a bilingual dictionary and use all possible translations;
- use a sentence aligned corpus and expand the query using every sentence in which all the query words co-occur; and,
- use an aligned corpus to build a translation databank.

The work presented in this paper fits in this last alternative. In this case, it becomes important to have good multilingual terminology databanks; otherwise, the reformulation of the query through the translation may not be correct if terms are not properly identified and translated. Carbonell *et al.* (1997) made an evaluation of several multilingual retrieval methods and concluded that query expansion by translation using a corpus-based 'translation matrix' provided the best results even when compared with a general purpose dictionary. Another reason why this approach seems to be better than a Machine Translation system is that it is easier to build a databank of translations for a new language, given parallel texts are available, than it is to build a Machine Translation system for the new language.

Thus, rather than translating each of the query words individually and providing all their possible translations, or using all sentences in which the words occur, the multilingual databank provides a simple means to make accurate translations of terms and, consequently, reduce their ambiguity. Furthermore, there are times when not even combining each of the possible word translations individually provides a possible compound translation, like *border crossing point* and *poste frontière* ('border post') in French, *hang gliding* and *asa delta* ('delta wing') in Portuguese, or even the common English phrasal verbs like *put up with* whose word for word translation are hardly combinable for other languages.

Thus, once a query is posted to a search engine, the multilingual databank of terminology can be used to translate the query terms into the available languages and posting subsequently monolingual searches in order to find relevant documents in the other languages. Had each of the query words been translated word for word, all alternative translations would have to be used which may lead to a long list of possible translations combinations. This increases the search space as more documents are bound to contain each of the words individually rather

[4] For a simple introduction, see, for example, Manning and Schütze (1999).

than the full correct translation. Also, a word for word translation may lead to no valid translation at all as shown with the examples above.

5. Conclusions

Currently, web search engines hardly support multilingual retrieval. Should a query be made in a language for which no relevant document exists, it will be unsuccessful. In the near future, it should be possible to access information independently of the language of the user and independently of the language in which the source text is written. This is what multilingual retrieval promises.

In this paper, we have made a small contribution to it. We have focussed on building multilingual terminology databanks from aligned texts in order to use them for multilingual retrieval. Compound words are particularly important in technical fields where their translation cannot be usually done word for word.

This paper has presented a methodology to extract terminology Translation Equivalents from aligned parallel texts so as to add a multilingual layer to search engines and allow multilingual searches by query expansion through translation to the other languages. In particular, this paper has described language independent and statistically supported methodologies to align parallel texts, extract multiword terms and find translation equivalents in the aligned texts. None of the techniques used assumes any language specific knowledge nor requires human hand coding of linguistic information.

We believe that by providing a multilingual terminology databank to multilingual search engines, it becomes possible to make reliable multilingual searches of compound terms as attested by Carbonell *et al.* (1997). Instead of building a databank of word translations in several languages, this work reports on the generation of a multilingual databank of multiword units from parallel texts. This makes translation of queries which contain compound terms less liable to errors. Also it reduces the search space of documents since terms can be identified in the query and translated as a unit instead of translating each of the words individually and retrieving documents which contain any of the possible translations.

6. Future Work

We need to make comparative evaluations on the retrieval performance on multilingual retrieval systems enhanced by the multilingual databank extracted from the parallel texts. It would also be interesting to check whether sub-sentential aligned text segments might be of some help for the translation of queries when the translation databank is not able to provide a translation. This strategy would simultaneously combine a query expansion approach based on a databank of translations with a query expansion approach based on aligned sub-sentential text segments.

As for the terminology extractor, its input needs to be normalised in order to avoid word variants. This will improve the accuracy of the translation equivalents extracted. In addition, it will increase the number of extracted translations by eliminating the sparse data problem due to alternative word variants. There are problems with highly inflectional languages like Greek, Finnish or even Portuguese. For example, the English adjective *public* can be translated into Portuguese as *público*, *pública*, *públicos*, or *públicas*, depending on the gender and number of the noun it qualifies. As a result, Translation Equivalents of terms which suffer variants tend to have low scores. We believe we can accomplish this task, also using language independent methods, by extracting typical sequences of characters using a methodology similar to the one used to extract typical sequences of characters in the alignment algorithm reported in Ribeiro *et al.* (2001b). This would identify common sequences of characters for inflected words though it may become harder for words which suffer radical changes when inflected. The verb *to be* is an English extreme case where a single word has eight variants: *be* / *being* / *am* / *are* / *is* / *was* / *were* / *been*.

Last but not the least, we need to distinguish domain specific terms from general language patterns. For this, we will use a method proposed by da Silva *et al.* (2001) to cluster documents according to domain specificity.

Grammar Learning by Partition Search

Anja Belz

Abstract

This paper describes Grammar Learning by Partition Search, a general method for automatically constructing grammars for a range of parsing tasks. Given a base grammar, a training corpus, and a parsing task, Partition Search constructs an optimised probabilistic context-free grammar by searching a space of nonterminal set partitions, looking for a partition that maximises parsing performance and minimises grammar size. The method can be used to optimise grammars in terms of size and performance, or to adapt existing grammars to new parsing tasks and new domains. This paper reports an example application to optimising a base grammar extracted from the Wall Street Journal Corpus. Partition Search improves parsing performance by up to 5.29%, and reduces grammar size by up to 16.89%. Parsing results are better than in existing treebank grammar research, and compared to other grammar compression methods, Partition Search has the advantage of achieving compression without loss of grammar coverage.

1. Introduction

Grammar Learning by Partition Search is a computational learning method that constructs probabilistic grammars optimised for a given domain or parsing task. The main idea behind this method is that new grammars can be derived from existing ones by simple operations on nonterminal sets. Automatically carrying out different combinations of such operations and testing the derived grammars' size and performance makes it possible to automatically optimise the grammars.

The main practical applications of Grammar Learning by Partition Search are the optimisation of an existing grammar's size and performance, and the adaptation of existing grammars to new tasks. Results for optimising a base grammar extracted from the Wall Street Journal Corpus (WSJC) are reported here, while results for adapting the same base grammar to different noun phrase extraction tasks are reported elsewhere (Belz, 2002).

This paper is organised in two main sections. Section 2. describes Grammar Learning by Partition Search. Section 3. reports experiments and results for NP identification and NP chunking.

2. Learning PCFGs by Partition Search

Partition Search Grammar Learning starts from the idea that new context-free grammars (CFGs) can be created from old simply by modifying the nonterminal sets, *merging* and *splitting* subsets of nonterminals. For example, for certain parsing tasks it is useful to *split* a single verb phrase category into verb phrases that are headed by a modal verb and those that are not, whereas for other parsing tasks, the added grammar complexity is avoidable. In another context, it may not be necessary to distinguish noun phrases in subject position from first objects and second objects, making it possible to *merge* the three categories into one.

The usefulness of such split and merge operations can be measured by their effect on a grammar's size (number of rules and nonterminals) and performance (parsing accuracy on a given task). Grammar Learning by Partition Search automatically tries out different combinations of merge and split operations and therefore can automatically optimise a grammar's size and performance on a given task.

2.1. Preliminary definitions

Definition 1 Set Partition

A partition of a nonempty set A is a subset Π of 2^A such that $\emptyset$ is not an element of Π and each element of A is in one and only one set in Π.

The partition of A where all elements are singleton sets is called the *trivial partition* of A.

Definition 2 Probabilistic Context-Free Grammar[1]

A Probabilistic Context-Free Grammar (PCFG) is a 4-tuple (W, N, N_S, R), where W is a set of terminal symbols, N is a set of nonterminal symbols, $N_S \in N$ is a start symbol, and $R = \{(r_1, p(r_1)), \ldots (r_m, p(r_m))\}$ is a set of rules with associated probabilities. Each rule r_i is of the form $n \rightarrow \alpha$, where n is a nonterminal, and α is a string of terminals and nonterminals. For each nonterminal n, the values of all $p(n \rightarrow \alpha_i)$ sum to one, or: $\sum_{i:(n \rightarrow \alpha_i, p(n \rightarrow \alpha_i) \in R} p(n \rightarrow \alpha_i) = 1$.

2.2. Generalising and Specialising PCFGs through Nonterminal Set Operations

2.2.1. Nonterminal merging

Consider two PCFGs G and G':

[1] This definition is for PCFGs with a single start symbol, to simplify the definition of PCFG Partitioning below.

$G = (W, N, N_S, R)$,
$W =$ { NNS, DET, NN, VBD, JJ }
$N =$ { S, NP-SUBJ, VP, NP-OBJ }
$N_S =$ S
$R =$ { (S -> NP-SUBJ VP, 1),
(NP-SUBJ -> NNS, 0.5),
(NP-SUBJ -> DET NN, 0.5),
(VP -> VBD NP-OBJ, 1),
(NP-OBJ -> NNS, 0.75),
(NP-OBJ -> DET JJ NNS, 0.25) }

$G' = (W, N', N_S, R')$,
$W =$ { NNS, DET, NN, VBD, JJ }
$N' =$ { S, NP, VP }
$N_S =$ S
$R' =$ { (S -> NP VP, 1),
(NP -> NNS, 0.625),
(NP -> DET NN, 0.25),
(VP -> VBD NP, 1),
(NP -> DET JJ NNS, 0.125) }

Intuitively, to derive G' from G, the two nonterminals NP-SUBJ and NP-OBJ are merged into a single new nonterminal NP. This merge results in two rules from R becoming identical in R': both NP-SUBJ -> NNS and NP-OBJ -> NNS become NP -> NNS. One way of determining the probability of the new rule NP -> NNS is to sum the probabilities of the old rules and renormalise by the number of nonterminals that are being merged[2]. In the above example therefore $p(\texttt{NP -> NNS}) = (0.5 + 0.75)/2 = 0.625$[3].

An alternative would be to reestimate the new grammar on some corpus, but this is not appropriate in the current context: merge operations are used in a search process (see below), and it would be expensive to reestimate each new candidate grammar derived by a merge. It is better to use any available training data to estimate the original grammar's probabilities, then the probabilities of all derived grammars can simply be calculated as described above without expensive corpus reestimation.

The new grammar G' derived from an old grammar G by merging nonterminals in G is a generalisation of G: the language of G', or $L(G')$, is a superset of the language of G, or $L(G)$. E.g., in the above example, det jj nns vbd det jj nns is in $L(G')$ but not in $L(G)$. For any sentence $s \in L(G)$, the parses assigned to s by G' form a superset of the set of parses assigned to s by G. The probabilities of parses for s can change, and so can the probability ranking of the parses, i.e. the most likely parse for s under G may be different from the most likely parse for s under G'. Finally, G' has the same number of rules as G or fewer.

2.2.2. Nonterminal splitting

Deriving a new PCFG from an old one by splitting nonterminals in the old PCFG is not quite the exact reverse of deriving a new PCFG by merging nonterminals. The difference lies in determining probabilities for new rules. Consider the following grammars G and G':

$G = (W, N, N_S, R)$,
$W =$ { NNS, DET, NN, VBD, JJ }
$N =$ { S, NP, VP }
$N_S =$ S
$R =$ { (S -> NP VP, 1),
(NP -> NNS, 0.625),
(NP -> DET NN, 0.25),
(VP -> VBD NP, 1),
(NP -> DET JJ NNS, 0.125) }

$G' = (W, N', N_S, R')$,
$W =$ { NNS, DET, NN, VBD, JJ }
$N' =$ { S, NP-SUBJ, VP, NP-OBJ }
$N_S =$ S
$R' =$ { (S -> NP-SUBJ VP, ?),
(S -> NP-OBJ VP, ?),
(NP-SUBJ -> NNS, ?),
(NP-SUBJ -> DET NN, ?),
(NP-SUBJ -> DET JJ NNS, ?) }
(VP -> VBD NP-SUBJ, ?),
(VP -> VBD NP-OBJ, ?),
(NP-OBJ -> NNS, ?),
(NP-OBJ -> DET NN, ?),
(NP-OBJ -> DET JJ NNS, ?) }

To derive G' from G, the single nonterminal NP is split into two nonterminals NP-SUBJ and NP-OBJ. This split results in several new rules. For example, for the old rule NP -> NNS, there now are two new rules NP-SUBJ -> NNS and NP-OBJ -> NNS. One possibility for determining the new rule probabilities is to redistribute the old probability mass evenly among them, i.e. $p(\texttt{NP -> NNS}) = p(\texttt{NP-SUBJ -> NNS}) = p(\texttt{NP-SUBJ -> NNS})$. However, then there would be no benefit at all from performing such a split: the resulting grammar would be larger, the most likely parses remain unchanged, and for each parse p under G that contains a nonterminal NT participating in a split, there would be at least two equally likely parses under G'.

The new probabilities cannot be calculated directly from G. The redistribution of the probability mass has to be motivated from a knowledge source outside of G. One way to proceed is to estimate the new rule probabilities on the original corpus — provided that it contains the information on the basis of which a split operation was performed in extractable form. For the current example, a corpus in which objects and subjects are annotated could be used to estimate the probabilities of the rules in G', and might yield the following rule set R' (which reflects the fact that in English, the NP in a sentence NP VP is (usually) a subject, whereas the NP in a VP consisting of a verb followed by an NP is an object):

$R' =$ { (S -> NP-SUBJ VP, 1),
(S -> NP-OBJ VP, 0),
(NP-SUBJ -> NNS, 0.5),
(NP-SUBJ -> DET NN, 0.5),
(NP-SUBJ -> DET JJ NNS, 0) }
(VP -> VBD NP-SUBJ, 0),
(VP -> VBD NP-OBJ, 1),
(NP-OBJ -> NNS, 0.75),
(NP-OBJ -> DET NN, 0),
(NP-OBJ -> DET JJ NNS, 0.25)

[2] Reestimating the probabilities on the training corpus would of course produce identical results.

[3] Renormalisation is necessary because the probabilities of all rules expanding the same nonterminal sum to one, therefore the probabilities of all rules expanding a new nonterminal resulting from merging n old nonterminals will sum to n.

Definition 3 PCFG Partitioning

Given a PCFG $G = (W, N, N_S, R)$ and a partition Π_N of the set of nonterminals N, the PCFG derived by partitioning G with Π_N is $G' = (W, \Pi_N, N_S, R')$, where:

$$R' = \Big\{ (a_1 \rightarrow a_2 \ldots a_n,\ p) \ \Big|\ \big\{(b_1^1 \rightarrow b_2^1 \ldots b_n^1,\ p^1),\ \ldots (b_1^m \rightarrow b_2^m \ldots b_n^m,\ p^m)\big\} \in \Omega,\ a_1 \in \Pi^N, b_i^j \in a_1,\ \forall i, 2 \leq i \leq n\ \big(\text{ either } a_i = b_i^j \in W, \text{ or } a_i \in \Pi^N, b_i^j \in a_i\ \big),\ p = \big(\textstyle\sum_{j=1}^m p^j\big)/|a_1|\ \Big\}, \text{ and}$$

Ω is a partition of R such that each $O \in \Omega$ contains all and only elements from R $(b_1^1 \rightarrow b_2^1 \ldots b_n^1,\ p^1),\ \ldots (b_1^m \rightarrow b_2^m \ldots b_n^m,\ p^m)$ for which the following holds: $\forall i, 1 \leq i \leq n\ \big(\text{ either } b_i^1 = b_i^2 = \ldots = b_i^m \in W, \text{ or } \{b_i^1, b_i^2, \ldots b_i^m\} \subseteq P,\ P \in \Pi_N\ \big)$.

With rules of zero probability removed, G' is now identical to the original grammar G in the example in the previous section.

2.3. Partition Search

A PCFG together with merge and split operations on the nonterminal set defines a space of derived grammars which can be searched for a new PCFG that optimises some given objective function. The disadvantage of this search space is that it is infinite, and each split operation requires the reestimation of rule probabilities from a training corpus, making it computationally much more expensive than a merge operation.

However, there is a simple way to make the search space finite, and at the same time to make split operations redundant. The resulting method, Grammar Learning by Partition Search, is described in this section. First, the merge operation that was informally introduced in the last section is generalised and defined formally. Next, search space, search task and objective function are discussed, and finally, the search algorithm is presented.

2.3.1. PCFG Partitioning

An arbitrary number of merges can be represented by a partition of the set of nonterminals. For the example presented in Section 2.2.1. above, the partition of the nonterminal set N in G that corresponds to the nonterminal set N' in G' is { {S}, {NP-SBJ, NP-OBJ}, {VP} }. The original grammar G together with a partition of its nonterminal set fully specifies the new grammar G': the new rules and probabilities, and the entire new grammar G' can be derived from the partition together with the original grammar G. The process of obtaining a new grammar G', given a base grammar G and a partition of the nonterminal set N of G will be called PCFG Partitioning[4].

In the examples in Sections 2.2.1. and 2.2.2., a notational convention was tacitly adopted which is also used in the formal definition of PCFG Partitioning (Definition 3). As a result of merging, NP-SUBJ and NP-OBJ become a single new nonterminal. This new nonterminal was represented above by the set of merged nonterminals {NP-SBJ, NP-OBJ} (in the partition), as well as by a new symbol string NP (in the definition of G'). The two representations are treated as interchangeable: the new nonterminal is represented either as a set or a nonterminal symbol[5].

The definition of PCFG Partitioning can be paraphrased as follows[6]. Given a PCFG $G = (W, N, N_S, R)$ and a partition Π_N of the set of nonterminals N, the PCFG derived from G by Π_N is $G' = (W, \Pi_N, N_S, R')$. That is, the set of terminals remains the same, and the new set of nonterminals is just the partition Π_N[7]. Ω is the partition of R in which all production rules are grouped together that become identical as a result of the nonterminal merges specified by Π_N. Then, the new set of probabilistic rules R' contains one element $(a_1 \rightarrow a_2 \ldots a_n,\ p)$ for each element $\big\{(b_1^1 \rightarrow b_2^1 \ldots b_n^1,\ p^1), \ldots (b_1^m \rightarrow b_2^m \ldots b_n^m,\ p^m)\big\}$ of Ω, such that the following holds between them: a_1 is a nonterminal from Π^N and contains all the b_1^j; for the other a_i, either a_i is a nonterminal and contains all the b_i^j, or it is a terminal and is identical to b_i^j. The new rule probability p is the sum of all probabilities $p^j, 1 \leq j \leq m$ renormalised by the size of the set a_1.

2.3.2. Search space

As stated previously, the search space for Grammar Learning by Partition Search can be made finite and search-

[4]The concept of context-free grammar partitioning in this paper is not directly related to that in (Korenjak, 1969; Weng and Stolcke, 1995), and later publications by Weng et al. In these previous approaches, a non-probabilistic CFG's *set of rules* is partitioned into subsets of rules. The partition is drawn along a specific nonterminal NT, which serves as an interface through which the subsets of rules (hence, subgrammars) can communicate after partition (one grammar calling the other). In the calling subgrammar, NT in RHSs is prefixed vt to denote that it is a 'virtual terminal'. In the following example from (Luk et al., 2000, p. +2), partitioning grammar G along the nonterminal NP yields subgrammars G_S and G_{NP} as follows:

G:	G_S:	G_{NP}:
1. S → NP VP	INPUT = {vtNP}	INPUT = ∅
2. NP → n	OUTPUT = {S}	OUTPUT = {NP}
3. NP → det n	1. S → vtNP VP	1. NP → n
4. NP → NP PP	2. VP → v vtNP	2. NP → det n
5. PP → prep NP	3. NP → prep vtNP	3. NP → NP PP
6. VP → v NP		

[5]The name assigned to the new nonterminal in the current implementation of PCFG Partitioning is the longest common prefix of the old nonterminals that are merged followed by an indexation tag (to distinguish otherwise identical names).

[6]This definition is for PCFGs with one start symbol. In the current implementation of Partition Search, PCFGs are permitted to have multiple start symbols and these can be merged with other nonterminals. The probability of a new start symbol resulting from a merge is the renormalised sum of the probabilities of only the start symbols participating in the merge.

[7]Recall previous comments about this notational convention.

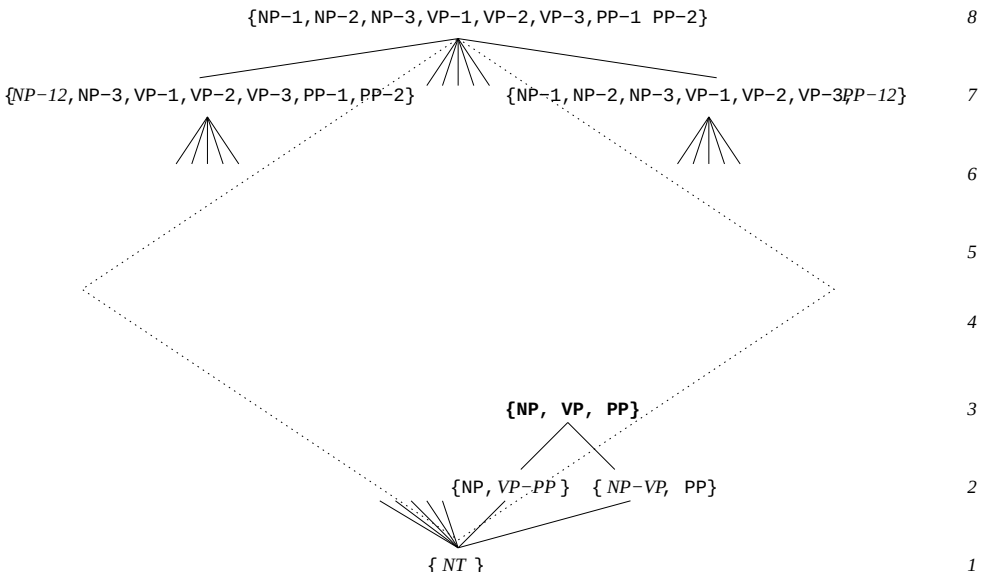

Figure 1: Simple example of a partition search space.

able entirely by merge operations (grammar partitions).

Making the search space finite: The number of merge operations that can be applied to a nonterminal set is finite, because after some finite number of merges there remains only one nonterminal. On the other hand, the number of split operations that can sensibly be applied to a nonterminal *NT* has a natural upper bound in the number of different terminal strings dominated by *NT* in a corpus of evidence (e.g. the corpus the PCFG was trained on). For example, when splitting the nonterminal NP into subjects and objects, there would be no point in creating more new nonterminals than the number of different subjects and objects found in the corpus.

Given these bounds, there is a finite number of distinct grammars derivable from the original grammar by different combinations of merge and split operations. This forms the basic space of candidate solutions for Grammar Learning by Partition Search.

Making the search space searchable by grammar partitioning only: Imposing an upper limit on the number and kind of split operations permitted not only makes the search space finite but also makes it possible to directly derive the *maximally split nonterminal set* (Max Set). Once the Max Set has been defined, the single grammar corresponding to it — the *maximally split Grammar* (Max Grammar) — can be derived and retrained on the training corpus[8].

The set of points in the search space corresponds to the set of partitions of the Max Set. Search for an optimal grammar can thus be carried out directly in the partition space of the Max Grammar.

Structuring the search space: The finite search space can be given hierarchical structure as shown in Figure 1 for an example of a very simple base nonterminal set {NP, VP, PP}, and a corpus which contains three different NPs, three different VPs and two different PPs.

At the top of the graph is the Max Set. The sets at the next level down (level 7) are created by merging pairs of nonterminals in the Max Set, and so on for subsequent levels. At the bottom is the *maximally merged nonterminal set* (Min Set) consisting of a single nonterminal *NT*. The sets at the level immediately above it can be created by splitting *NT* in different ways. The sets at level 2 are created from those at level 1 by splitting one of their elements. The original nonterminal set ends up somewhere in between the top and bottom (at level 3 in this example).

While this search space definition results in a finite search space and obviates the need for the expensive split operation, the space will still be vast for all but trivial corpora. In Section 3.3. below, alternative ways for defining the Max Set are described that result in much smaller search spaces.

2.3.3. Search task and evaluation function

The input to the Partition Search procedure consists of a base grammar G_0, a base training corpus C, and a task-specific training corpus D^T. G_0 and C are used to create the Max Grammar G. The **search task** can then be defined as follows:

> Given the maximally split PCFG $G = (W, N, N_S, R)$, a data set of sentences D, and a set of target parses D^T for D, find a partition Π_N of N that derives a grammar $G' = (W, \Pi_N, N_S, R')$, such that $|R'|$ is minimised, and $f(G', DD^T)$ is maximised, where f scores the performance of G' on D as compared to D^T.

The size of the nonterminal set and hence of the grammar decreases from the top to the bottom of the search space. Therefore, if the partition space is searched top-down, grammar size is minimised automatically and does not need to be assessed explicitly.

In the current implementation, the **evaluation function** f simply calculates the F-Score achieved by a candidate

[8] This can be done as follows: for each nonterminal *N*, count the number n of different terminal strings it dominates in the training corpus, and tag each occurrence of *NT* with a number *NT*-1, ... *NT*-n; duplicate the rules containing *NT* correspondingly, and calculate the rule probabilities.

grammar on D as compared to D^T. The F-Score is obtained by combining the standard PARSEVAL evaluation metrics *Precision* and *Recall*[9] as follows: $2 \times Precision \times Recall/(Precision + Recall)$.

An existing parser[10] was used to obtain Viterbi parses. If the parser failed to find a complete parse for a sentence, a simple grammar extension method was used to obtain partial parses instead (Schmid and Schulte im Walde (2000, p. 728) use an almost identical method).

2.3.4. Search algorithm

Since each point in the search space can be accessed directly by applying the corresponding nonterminal set partition to the Max Grammar, the search space can be searched in any direction by any search method using partitions to represent candidate grammars.

In the current implementation (see pseudo-code representation in Procedure 1), a variant of beam search is used to search the partition space top down. A list of the n current best candidate partitions is maintained (initialised to the Max Set). For each of the n current best partitions a random subset of size b of its children in the hierarchy is generated and evaluated. From the union of current best partitions and the newly generated candidate partitions, the n best elements are selected and form the new current best set. This process is iterated until either no new partitions can be generated that are better than their parents, or the lowest level of the partition tree is reached. In each iteration the size of the nonterminal set decreases by one.

The size of the search space grows exponentially with the size i of the Max Set. However, the complexity of the Partition Search algorithm is only $O(nbi)$, because only up to $n \times b$ partitions are evaluated in each of up to i iterations[11].

Procedure 1
P_SEARCH$\big((W, N, N_S, R), D, D^T, n, x, b\big)$

```
1:  Stop ← FALSE
2:  P_intermediate ← INITIALISE(N)
3:  EVALUATE(P_intermediate, G, D, D^T, x)
4:  while not Stop do
5:    P_current ← SELECT(P_intermediate)
6:    P_new ← GENERATE(P_current, b)
7:    if P_new = EMPTYLIST then
8:      Stop ← TRUE
9:    else
10:     P_intermediate ← APPEND(P_current, P_new)
11:     EVALUATE(P_intermediate, G, D, D^T, x)
12:   end if
13: end while
14: return P_current
15:
16: Subprocedure INITIALISE(N)
17: return set containing trivial partition of N
18:

32:   G' ← partition grammar G with p
33:   D^A ← parse data D with G'
34:   score of p is F-Score of D^A against D^T
35: end for
```

3. Grammar Optimisation with Partition Search

3.1. Testing and Training Data

Sections 15–18 of WSJC were used for deriving the base grammar and as the base training corpus, and different randomly selected subsets of Section 1 from the same corpus were used as task-specific training corpora during search. Section 20 was used for final performance tests.

The Brill Tagger was used for POS tagging testing data, and achieved an average accuracy of 97.5% (as evaluated by `evalb`).

3.2. Base grammar

A simple treebank grammar[12] was derived from Sections 15–18 of the WSJ corpus by the following procedure:

1. Iteratively edit the corpus by deleting (i) brackets and labels that correspond to empty category expansions; (ii) brackets and labels containing a single constituent that is not labelled with a POS-tag; (iii) cross-indexation tags; (iv) brackets that become empty through a deletion.
2. Convert each remaining bracketting in the corpus into the corresponding production rule.
3. Collect sets of terminals W, nonterminals N and start symbols N_S from the corpus. Probabilities p for rules $n \to \alpha$ are calculated from the rule frequencies C by Maximum Likelihood Estimation: $p(n \to \alpha) = \frac{C(n \to \alpha)}{\sum_i C(n \to \alpha^i)}$.

This procedure creates the base grammar *BARE* which has 10,118 rules and 147 nonterminals.

3.3. Restricting the search space further

The simple method described in Section 2.3.2. for defining the maximally split nonterminal set (Max Set) tends to result in vast search spaces. Using parent node (PN) information to create the Max Set is much more restrictive and linguistically motivated. The Max Grammar *PN* used in the experiments reported below can be seen as making use of *Local Structural Context* (Belz, 2001): the independence assumptions inherent in PCFGs are weakened by making

[9] I used the `evalb` program by Sekine and Collins (`http://cs.nyu.edu/cs/projects/proteus/evalb/`) to obtain Precision and Recall figures.

[10] LoPar (Schmid, 2000) in its non-head-lexicalised mode. Available from `http://www.ims.uni-stuttgart.de/projekte/gramotron/SOFTWARE/LoPar-en.html`.

[11] As before, n is the number of current best candidate solutions, b is the width of the beam, and i is the size of the Max Set.

[12] The term was coined by Charniak (1996).

the rules' expansion probabilities dependent on part of their immediate structural context (here, its parent node). To obtain the grammar *PN*, the base grammar's nonterminal set is maximally split on the basis of the *parent node* under which rules are found in the base training corpus[13]. Several previous investigations have demonstrated improvement in parsing results due to the inclusion of parent node information (Charniak and Carroll, 1994; Johnson, 1998b; Verdú-Mas et al., 2000).

Another possibility is to use the base grammar *BARE* itself as the Max Grammar. This is a very restrictive search space definition and amounts to an attempt to optimise the base grammar in terms of its size and its performance on a given task without adding any information. Results are given below for both *BARE* and *PN* as Max Grammars.

In the current implementation of the algorithm, the search space is reduced further by avoiding duplicate partitions, and by only allowing merges of nonterminals that have the same phrase prefix `NP-*, VP-*` etc.

The Max Grammars end up having sets of nonterminals that differ from the bracket labels used in the WSJC: while the phrase categories (e.g. `NP`) are the same, the tags (e.g. `*-S, *-3`) on the phrase category labels may differ. In the evaluation, all labels starting with the same phrase category prefix are considered equivalent.

3.4. Optimising the WSJ treebank grammar

Base grammar *BARE* achieves an F-Score of 74.09 on the full parsing task. Since the base grammar is just the treebank grammar extracted from the WSJC, and the task it is optimised for is full parsing, the most directly related research is other treebank grammar research. Over the last few years, a range of research projects — e.g. Charniak (1996), Cardie & Pierce (1998), Johnson (1998a, 2000), Krotov et al. (2000) — have looked at probabilistic grammars that have been directly derived from bracketted corpora.

Because the number of rules in treebank grammars is very large at least in the case of the WSJC, and because their parsing performance moreover tends to be not very good, some techniques are usually applied to reduce grammar size and to improve performance. All approaches edit the corpus in some way, e.g. eliminating single child rules, empty category rules, functional tags, co-indexation tags, and punctuation marks. Different compression methods (such as eliminating rules with frequency less than some n) have been investigated that reduce the size of grammars without too much loss of performance (in particular by Charniak and Krotov et al.). To improve parsing performance, e.g. Charniak relabels auxiliary verbs with a separate POS-tag and incorporates a "right-branching correction" into the parser to make it prefer right-branching structures.

Several other grammar building and training methods are similar to treebank grammar construction: Bod & Scha's Data-Oriented Parsing method which extracts tree fragments rather than rules from corpora, and Memory-Based Learning methods (Daelemans et al.) for building parsing systems from corpora.

Table 1 shows results achieved by Partition Search with grammars *BARE* and *PN* as Max Grammars. The first column shows the Max Grammar used in a given batch of experiments. The second column indicates the type of result, where the Max Grammar result is the F-Score, grammar size and number of nonterminals of the Max Grammar itself, and the remaining results are the average and single best results achieved by Partition Search. The third and fourth columns show the number of iterations and evaluations carried out before search stopped. Columns 5–8 show details of the final solution grammars: column 5 shows the evaluation score on the training data, column 6 the overall F-Score on the testing data, column 7 the size, and the last column gives the number of nonterminals.

The best size reduction result was 35 nonterminals and 8,409 rules with an increase in the F-Score to 74.54 (as compared to the baseline of 74.09). The best performance increase result was an F-Score of 78.01 (compared to the baseline of 74.09), accompanied by an increase in the number of rules to 15,608.

The best performance result reported here is better than the best results reported by Charniak (1996) and Krotov et al. (2000), even though the previous results were obtained after using ca. 10/11 of the WSJ corpus as a training set compared to 3/25 used here (UF = unlabelled F-Score, LF = labelled F-Score):

	UF	LF
Krotov et al. (2000)	79.12	76.09
Charniak (1996)	79.59	–
Optimised *PN*-Grammar	80.74	78.01

During Partition Search, only those nonterminal subsets are merged that result in an improved or unchanged F-Score. In the case of the grammar *BARE* as the Max Grammar, merging means eliminating phrase subcategories reflecting grammatical function. As can be seen from the results in Table 1, a lot of grammatical function information can be eliminated without affecting parsing results: of the 147 original phrase subcategories, only just over a third remain on average. In the case of the *PN* Max Grammar, search found it a lot harder to eliminate parent node subcategories without worsening parsing performance: just over half of the 970 parent node subcategories remain on average. The biggest part of the improvement in parsing performance is due to way the Max Grammar is defined, i.e. to the addition of parent node information (from 74.09 to 77.8 F-Score).

3.5. General comments

Partition Search is able to reduce grammar size by merging groups of nonterminals (hence groups of rules) that do not need to be distinguished for a given task. It is able to improve parsing performance firstly by grammar generalisation (a partitioned grammar parses a superset of the sentences parsed by the base grammar), and secondly by reranking parse probabilities (the most likely parse for a sentence under a partitioned grammar can differ from its most likely parse under the base grammar).

[13] The parent node of a phrase is the category of the phrase that immediately contains it.

Max Grammar		Iter.	Eval.	F-Score (subset)	F-Score (WSJC S 1)	Size (rules)	Nonterms
BARE	Max Grammar result:				74.09	10,118	147
	Average:	90.2	2,000.8	83.43	74.05	9,288.4	59.8
	Best (size and F-score):	114	2,686	86.04	74.54	8,409	35
PN	Max Grammar result:				77.8	16,480	970
	Average:	426.8	10,559.4	87.8734	77.87	15,850	545.2
	Best (size):	656	16,335	91.38	77.81	15,403	316

Table 1: Results for partition tree search on full parsing task, WSJC Section 1 (averaged over 5 runs, variable parameters: $x = 100, b = 5, n = 5$).

Automatic methods for optimising and adapting grammars for new tasks and domains are particularly useful because context-free grammars cannot be learnt from scratch from data. At the very least, an upper bound must be placed on the number of nonterminals allowed. Even when that is done, there is no likelihood that the grammars resulting from an otherwise unsupervised method will look anything like a linguistic grammar whose parses can provide a basis for semantic analysis. The present method preserves the basic phrase structures and categories of the base grammar, while reranking its parse sets and eliminating phrase distinctions not needed for a given task.

Preliminary tests revealed that results were surprisingly constant over different combinations of variable parameter values, although training subset size of less then 50 meant unpredictable results for the complete WSJC Section 1. For a random subset of size 50 and above, there is an almost complete correspondence between subset F-Score and Section 1 F-Score, i.e. higher subset F-Score almost always means higher Section 1 F-Score.

Unlike other grammar compression methods (Charniak, 1996; Krotov et al., 2000), Partition Search achieves lossless compression, in the sense that the compressed grammars are guaranteed to be able to parse all of the sentences parsed by the original grammar.

Compared to other approaches using parent node information (Charniak and Carroll, 1994; Johnson, 1998b; Verdú-Mas et al., 2000), the approach presented here has the advantage of being able to select a subset of all parent node information on the basis of its usefulness for a given parsing task. This saves on grammar complexity, hence parsing cost.

4. Conclusions and Further Research

Grammar Learning by Partition Search was shown to be an efficient method for constructing PCFGs optimised for a given parsing task. The best grammar constructed by Partition Search in the reported experiments outperforms the best existing results for nonlexicalised parsing by a significant margin. In the same experiments, grammar size was reduced by up to 16.89%. Partition Search has the advantage of reducing grammar size without loss of grammar coverage while achieving an improvement in grammar performance.

In future research, the P_SEARCH procedure will be used as a testbed for comparing the performance of different search techniques, including greedy depth-first search and genetic search (only some of the subprocedures need to be replaced for each new search type). Further research will also look at additionally incorporating lexicalisation, and testing a wider set of variable parameter combinations.

Abstract

Even if the use of the hypertext paradigm is nowadays very diffused, its potential benefits are not completely exploited by the community of the users. This is particularly evident in the case of the news agencies. The major reasons for the above limitation are the high costs for manually creating and maintaining the sets of complete links of a large-scale hypertext. This is especially true for news agencies. Therefore, in this paper we propose a method to address the problem of the automatic construction of the hyper-links based on Information Extraction techniques that enable documents (mainly news items) to be represented in a canonical form, hereafter called *objective representation* (OR). Our hyper-linking method is presented after the analysis of the traditional approaches to the same problem. We will describe the notion of objective representation and the formalism to express the linking constraints. Finally, we will sketch our future research work in the area.

1. Introduction

Even if the use of the hypertext paradigm is nowadays very diffused, its potential benefits are not completely exploited by the community of the users. This is particularly evident in the case of the news agencies. A survey, reported in (Outing, 1996), found that there were 1,115 commercial newspaper online services world-wide, 94% of which used a simplified version of hypertext which does not provide the full use of the hypertext capabilities of the WWW. The users may be able to navigate to a particular article in the current edition of an online paper by using hypertext links, but they must then read the entire article to find the information that interests them. The documents are dead ends in the hypertext, rather than offering starting points for explorations. In order to truly reflect the hypertext nature of the Web, links should to be placed within and between the documents.

The major reasons for the above limitation is, as (Westland, 1991) has pointed out, the high costs for manually creating and maintaining the sets of complete links of a large-scale hypertext. This is especially true for news agencies, given the volume of articles produced every day. Aside from the time-and-money aspects of building such large hypertexts manually, humans are inconsistent in assigning hypertext links between the paragraphs of documents (Ellis et al., April 1994; Green, 1997). That is, different linkers disagree with each other as to where to insert hypertext links into a document.

The cost and inconsistency of manually constructed hypertexts does not necessarily mean that large-scale hypertexts can never be built. It is well known in the IR community that humans are inconsistent in assigning index terms to documents, but this has not hindered the construction of automatic indexing systems intended to be used for very large collections of documents.

The taxonomy of link types given in (Allan, 1995) is very useful to understand the problem of the automatic construction of hyperlinks since it classifies links according to the abilities required for an eventual manual construction. Links are classified according the following classes:

- *Pattern Matching links*, which are easy link to discovered as they can be found through a pattern-matching algorithm. An example of these is glossary links or links between proposition.
- *Automatic links*, which can be in part captured by traditional Information Retrieval techniques. For example links among documents discussing about the same topics.
- *Manual links*, which require text analysis at level of Natural Language Understanding.

While the first two types of links have been approached successfully the third one is judged by Allan (Allan, 1995) to be inaccessible to automatic hypertext construction.

In this paper we propose a method to address the problem of the automatic construction of the "manual" links as defined in (Allan, 1995). The proposed method is based on Information Extraction techniques that enable documents (mainly news items) to be represented in a canonical form, hereafter called *objective representation* (OR). This latter describes some of the important information contained in the documents, mainly the named entities and the domain events found in the target document. Therefore, this document representation allows to draw more motivated inter-document hyper-links since a declarative language for describing linking constraints can be settled over it. Linking rules, i.e. the rules that justify a link between two documents, are in fact written as constraints over the related ORs. The detection of the domain events and of the named entities relies on a knowledge-based IE system composed by a robust parser (Basili et al., 2000b) and a discourse interpreter (Gaizauskas and Humphreys, 1997). As any IE system, this linking methodology requires a large domain knowledge base. The overall approach foresees the methods for the automatic extraction of this knowledge in an unsupervised fashion (Basili et al., 2000a; Basili et al., 2002).

Our hyper-linking method is presented in Sec. 3. after the analysis of the traditional approaches to the same problem (Sec. 2.). We will describe the notion of objective representation and the formalism to express the linking constraints. Finally, we will sketch the future work (Sec. 4.).

2. Traditional Approaches

In literature the automatic construction of hypertext is based on classical IR techniques to measure the relatedness of document couples. Only a *bag of words* are used for expressing the document contents. This results in a poor set of link type manageable in automatic way. In (Allan, 1995) is presented a reformulated taxonomy of links (Trigg, 1983) in order to identify the link type achievable with an automatic approaches. The set of link type has been divided into three major categories based upon whether or not their identification can be carried out automatically (with the IR current technology). The three categories are *Pattern-matching*, *Automatic* and *Manual*. Unfortunately, some types of links straddle the boundaries of the taxonomy, depending upon the document collection being linked.

Pattern-matching Links is a large class of link types. They can be found easily using simple pattern-matching techniques. An obvious example of such a link type is *definition* that can be found by matching words in a document to entries in a dictionary. In almost cases, these links are from a word or phrase to a small documents. They do not take into account the context of the definition so the destination document may be the same for the word or phrase searched for; no matter where the word or phrase occurs. Structural links belong to the pattern-matching category. They are those that represent layout or possibly logical structure of a document. For example, links between chapters or sections, links from a reference to a figure to the figure itself, and links from a bibliographic citation to the cited work, are all structural links. They can be discovered by mark-up codes embedded in the text. Pattern-matching links form a class that is computationally simple for automatic detection.

Automatic Links are links which cannot typically be located trivially using patterns, but which the automatic IR techniques can identify with marked success. Typical automatic links that can be identified are:

- *Revision links* are a fairly straightforward class of relationship between texts, including both ancestor and descendent relationships.
- *Summary and expansion links* are inverses of one another. A summary link type is attached to a link that starts at a discussion of a topic and has as its destination a more condensed discussion of the same topic. Equivalence links represent strongly related discussions of the same topic.
- Tangent links are equivalence links that relate topics in an unusual or tangential manner (often by comparison with other links). For example, a link from a document about *Sivlio Berlusconi* as Italy Prime Minister to one about Milan football club (whose Berlusconi is the president) would be a tangential link.
- Aggregate links are those that group together several related documents. An aggregate link may in fact have several destinations, allowing the destination documents to be treated as a whole when desirable.

Manual links are those which are judged by the IR community unable to be located without human intervention. The natural language understanding researchers have had some significant success within constrained subject areas, so some manual links could be automatically described within those limited domains. Unfortunately, those techniques are not yet extensible to a general setting, so this class of link types seems to remain inaccessible to automatic approaches. Manual links include those which connect documents which describe circumstances under which one document occurred, those which collect the various components of a debate or argument, and those that describe forms of logical implication (caused-by, purpose, warning, and so on).

2.1. A more semantic based approach

An attempt to extend the boundaries of automatic links towards the manual links has been done in (Green, 1997). In this work an automatic method for the construction of hypertext links via *lexical chains* has been carried out. Lexical chains capture the semantic relations between words that occur throughout a text. Each chain is a set of related words that captures a portion of the cohesive structure of a text. By considering the distribution of chains within an article it is possible to build links between the paragraphs. A link is activated if the similarity score of the chains contained in two different articles overcome a predefined threshold. The method comprises three steps: determining the lexical chains in a text, building links between the paragraphs of articles, and building links between articles. A comparison of this methodology with the traditional IR techniques resulted in higher user satisfaction. Lexical chains allow to retrieve a wider set of link type. As an example let us consider two documents that speak about the same fact with different words. The scalar product (a wide used IR metrics in the Vector Space Model) between the two documents would be very low as the documents have different *bag of words*. This prevents the activation of a relatedness link. On the contrary lexical chains refer to the meaning of words. They use synonyms of words in texts so their similarity between documents will be higher.

Lexical chains seems to solve some of IR problem in discovering links but some problems remain unsolved:

- The link type of two documents, which have similar lexical chains, is unknown. We could claim as an explanation that the documents contain some related semantic information. However this explanation is too generic as it is valid for each generated link.
- *Consequence links* remain unsolved. It is not possible specify the consequence relation between two documents for two main reasons: a) The lexical chains of the premised tend to be very different from the consequence. b) These links are directional while the similarity between chains is symmetric.

- Ambiguity and data sparseness affect the precision in discovering valid chains. So we can expect a lot of wrong links.

In next Section it is presented a different approach that solve the two first problems. It provides a methodology for capturing the unsolved link as well as the explanation for them. The third problem has been bound using domain knowledge for conceptualise the information.

3. A "semantic-driven" hyper-linking method

The above approaches mainly relate documents if they are enough similar according to the chosen document representation space, i.e. the bag-of-word abstraction or the lexical chain model. Therefore, according to these approaches "relatedness" is the only reason why two documents may be hyper-linked together. However, this notion of relatedness does not give the possibility of defining user-oriented hypertexts. Each user has to be exposed to the same hypertext regardless his information needs. For instance, the above approaches may relate the two news items in Fig. 1 because of the fact that in the two documents the *Intel* stem increases the relatedness of the two documents. However, the link user is not aware of the reason why the two documents are related and, while reading the first news item, he has not hints that may suggest if the related news article is of any interest to him. The justification of the link may be more easily highlighted if the domain relevant information is captured, i.e. the fact that both the first item and the second one describe an *Intel acquisition activity*.

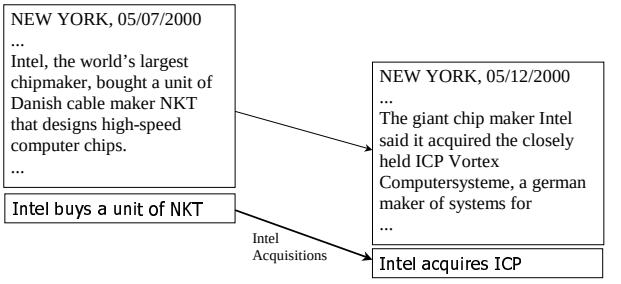

Figure 1: An example of justified link

The facts justifying the hyper-link between the two documents are respectively:

- Intel buys a unit of NKT
- Intel acquires ICP

It is worth noticing that a very precise information is needed for linking the two documents, i.e. the "equivalence" of *buy* and *acquire*. This information may be also used in an IR based hyper-linker using a query expansion technique but the justification of the link is still very difficult.

Furthermore, this notion of relatedness limits the possibility of linking documents. For instance in Fig. 2,

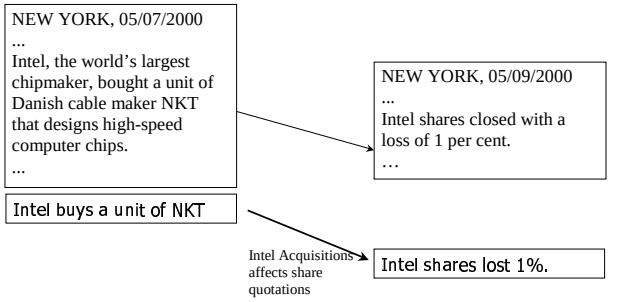

Figure 2: A complex justified link

the link between the two documents is justified by the fact that an *Intel acquisition* affects the *share prices* of a particular period of time. The facts justifying such a kind of document relation are respectively:

- Intel buys a unit of NKT
- Intel shares lost 1%

Such a kind of link is very difficult to capture if the analysis is not based on the more structured document representation.

The automatic hyper-linking method we propose is then based on an abstraction of the document, the objective representation (OR) that describes in a canonical form the salient information carried by the document. This objective representation, due to its nature, may be also considered language independent. Therefore, it enables the automatic hyper-linking between documents of different languages. Both his canonical representation, i.e. the OR, and the language for defining the linking constraints are described in the following sections.

3.1. The objective representation

The quality of the hyper-links that may be drawn in such a method strictly depends on the assumed representation of the document content. Furthermore, it is crucial that the intended information is actually captured by the IE system.

The objective representation we have defined is not too far from the actual document content and aims to represent the relevant document information with respect to a given knowledge domain. In particular, given a document *D*, its OR contains the named entities and the main events of the document *D*. These latter mainly represent particular domain relevant verb phrases that appear in the document. Both the named entities and the events are classified according to a knowledge representation scheme related to a target domain.

The objective representation is then a couple $OR(D) = (NEs, Events)$ where NEs is the set of the categorised named entities of D while the $Events$ is the set of the categorised events. Each event in $Events$ has the following form:

$$EventType(Verb, Arguments) \quad (1)$$

where $EventType$ is the type of the event, $Verb$ is the actual verb that appears in the document and $Args$ are the arguments of the verb according to the event type. Each argument representation carries its syntactic/semantic relation, the actual lexical of its semantic governor, and the type of this latter. For instance, the documents in Fig. 1 should contains respectively in their ORs the following events:

- `buy_event( agent(company,Intel), patient(object,a_unit_of_NKT))`
- `buy_event( agent(company,Intel), patient(company,ICP))`

Naturally, the efficacy of the OR strictly depends on the nature of the information that is contained in the knowledge base. The method for extracting such a knowledge and for the definition of the equivalence between different surface forms is described in (Basili et al., 2002).

3.2. Typing links using events: a declarative formalism

Once an objective representations of documents are available it is possible to write down a set of rules that can activate several links that traditional IR techniques (see Section 2.) cannot capture. However it is not possible to define general linking rules valid for each domains and for each user needs. As an example consider two documents: d_0 that speaks about Ferrari race in the grand prix of Imola and d_1 in which it is stated that FIAT market shares increase their quotation. If a user wants know all the facts which cause the event in d_1 (e.g. the document d_0) some knowledge about the correlation between FIAT and Ferrari have to be draw (i.e Ferrari is a part of FIAT and winning a race increases the share value of a Company).

Thus a systems that really wants to afford hypertext construction including links of third type (see Section 2.) should provide both a set of general rules and a set of specific rules. Moreover, the specific rules should be customisable to satisfy a wide range of user needs. These rules will be then used by the linking algorithm to draw links among documents.

3.2.1. The linking rule formalism

We have adopted a declarative formalism in which the rules and the knowledge required are easy to be written by the final user. The rules are expressed by a logical formalism.

The events in the OR are coded by means of Prolog predicates of the following type:

```
ev(EVENT_CATEGORY, EVENT_LEX,[
  arg(AGENT, AGENT_CATEGORY,
        AGENT_LEX),
  arg(DIROBJ, DIROBJ_CATEGORY,
         DIROBJ_LEX),
  arg(MODIFIER1, HANDLE1, LEX1),
  ...,
  arg(MODIFIERm, HANDLEm, LEXm)
]).
```

The first two arguments of the predicate `ev` are the category and the lexical of the *event* (i.e. the category and the lexical of the action accomplished by the object versus the direct object). The third argument is a set of participants (agent and direct object and modifiers), expressed as list of Prolog predicates. The category of the agent (AGENT_CATEGORY), the category of direct object (DIROBJ_CATEGORY) as well as their lexical form (AGENT_LEX and DIROBJ_LEX) are included in the predicative description of the event argument (`arg`).

Linking rules should therefore describe when two news items have to be linked together. These are written over the objective representation of the investigated documents. In particular, they exploit the notion of event. Linking rules are then Prolog predicates defining a linking criteria that motivates the existence of an link among the source and the target news items from which events are derived. Linking rules define all the constraints that the participants of two events must satisfied for generating a link between them. Each generated link has therefore a *LINK_TYPE* that is determined by the application of a specific rule. In order to compile a linking rule a list of pre-defined constraints, expressed as predicates, needs to be defined. The constraints act over the basic constitutes of an event (i.e. event lexical/category, subject, object and modifiers). In particular as the event category and lexical are supposed to have a different semantic from subject, object and modifier, two type of constraints have been defined. More precisely a linking rule is a Prolog predicate of the form:

```
lrule( LINK_TYPE,
       SOURCE_EVENT_CATEGORY,
       TARGET_EVENT_CATEGORY,
       SET_OF_EVENT_CONSTRAINTS,
       SET_OF_ARGUMENT_CONSTRAINTS)
```

where:

- *LINK_TYPE*, is the type of the link that is generated by such a rule.
- *SOURCE_EV._CATEGORY* and *TARGET_EV._CATEGORY* are the category of events involved in the linking rule. For example in case of an event that relates to a meeting and another event that relates to an acquisition of stocks in that meeting, it would be useful to have a linking rule characterised by MEETING_EVENT as category of source event and BUY_EVENT as category of target event.
- *SET_OF_EVENT_CONSTRAINTS* is the set of constraints to be activated on the event category/lexical information of the source and target events.
- *SET_OF_ARGUMENT_CONSTRAINTS* is the set of constraints to be activated over the arguments of the source and target events.

Given the above description a linking rules which expresses correlation between the participants of a meeting and a company acquisition in the meeting could be:

```
lrule('Acquisition during a meeting',
       MEETING_EVENT, BUY_EVENT,
```

```
        SET_OF_EVENT_CONSTRAINTS,
        SET_OF_ARGUMENT_CONSTRAINTS)
```

The *SET_OF_ARG._CONSTRAINTS* specify relation between the participants of the meeting and those that acquire something. The *SET_OF_EVENT_CONSTRAINTS* specify the relation between MEETING_EVENT and BUY_EVENT as well as the lexicals associated to them.

3.2.2. Expressing constraints in the linking rules

The aims of the constraints are to select the properties of the participants and the properties of the event categories. These constraints compositionally build linking rules. A simple set of constraints is:

- *Category Identity*: two participants must be of the same category. This implies that two entity must belong to the same class. For example IBM and INTEL are both companies so they belong to the company category. If a Category identity constraint is included inside a SET_OF_EVENT_CONSTRAINTS, it casts different events to be in the same category. If we use this constraint leaving unspecified the event category we are grouping together event of the same category.
- *Lexical Identity*: the participants must have the same lexical e.g. the participant *Bill Gates* is the same lexical in *Bill Gates buy IBM* and in *Bill Gates get married*. A rule based on the category identity constraint would not be useful in the above case as a lot person get married. The Lexical Identity for the set of event constraint is less meaningful. However it can be used to specify the relation involved in a couple of events more precisely. For example if we have the event *Bill gates sell IBM*, its category will be *acquisition*. This information would not useful if we want build a rule for capturing document about company selling.
- *Conceptual Similarity*, it is an extension of the category identity type. In this case categories are grouped in a hierarchical structures. It is possible to express a relation of parents among participants.

Given the above constraints the following events:

```
ev(MEETING_EVENT, invite,[
  arg(AGENT, Company, Intel),
  arg(DIROBJ, person, Bill Gates),
  arg(MODIFIER, in, Seattle)
]).
ev(BUY_EVENT, acquire,[
   arg(AGENT, person, Bill Gates),
   arg(DIROBJ, company, Intel)
]).
```

two sample rules for capturing the link type *Acquisition during a meeting* are:

```
lrule('Acquisition during a meeting',
       MEETING_EVENT, BUY_EVENT,
       [],
       [lex_id(AGENT,DIROBJ)]
).
```

```
lrule('Acquisition during a meeting',
       MEETING_EVENT, BUY_EVENT,
       [],
       [lex_id(DIROBJ,AGENT)]
).
```

It is worth noticing that the above rule involves general events so the information about participants has to be more specific (i.e. lexical information about participants is needed). This pushes for the use of *lex_id* constraint.

Another generic rule is that groups document speaking about a target agent doing whatever action. For example the events in which Bill Gates buy something could be captured by the following rule:

```
lrule('Same participants rule',
       _,_,
       [cat_id()],
       [lex_id(AGENT,AGENT)]
).
```

In the above rule the only requirement is the same agent in the linking documents. The agents in the target events have to do an action of the same category type (e.g. Acquisition event, Announce event, Market strategy events,...).

When is needed grouping together documents in which a target action is carried out, it is possible to use the category constraints for the agent and object (i.e. the cat_id constraint). For example a linking rule in which agents of the same category make acquisitions of object of the same category is the following:

```
lrule('Person acquire Company',
       BUY_EVENT, BUY_EVENT,
       [],
       [cat_id(AGENT,AGENT),
        cat_id(DIROBJ,DIROBJ)]
).
```

3.3. The linking algorithm

Once the linking rules formalism has been developed it is possible to design the linking algorithm. This should takes as input the ORs of two documents: the source and the target. For each couple of events in the source and in the target, the linking rule database $LRDB$ is considered. If some rule is matched a link is generated and it is stored in a link DB. The rules are composed of some basic constraints that act on the constituents of an event. In this way, if an extended list of basic constraints is available it is possible for the user to define several linking rules. The rule can be described in an external data file so new rules can be added to the similarity model without re-designing the entire architecture.

The linking algorithm takes as input two documents, one is the source S and the second is the target T, and given their sets of events, respectively $Ev(S)$ and $Ev(T)$, check if any couple $< ES, ET >$, where $ES \in Ev(S)$ and $ET \in Ev(T)$, satisfy any of the linking rules contained in $LRDB$.

The algorithm is composed of the following steps:

```
function Link(text S, text T) returns Linkset
begin
   Linkset L = ∅ ;
   Ev(S) = BuildEv(S) ;
   Ev(T) = BuildEv(T) ;
   for each (ES, ET) ∈ Ev(S) × Ev(T)
      begin
      while ((R = SelectNextRuleFor(ES, ET)) != NULL)
         begin
         R = (RuleType, SEvCat, TEvCat, CatConstr, ArgConstr);
         if ( ApplyCatConstr(CatConstr, ES, ET) == true )
         begin
         boolean sat = true;
         while (SArg, TArg) ∈ nextArg(ES, ET) AND sat )
            sat = ApplyArgConstr(ArgConstr, SArg, TArg) ;
            if (sat)
               AddLink(ES, ET, RuleType, L)
         end
      end
   end
return L ;
end
```

4. Conclusions and future work

In this paper, we have presented a methodology for the automatic hyper-linking among news items. The presented approach is based on Information Extraction techniques that give the possibility of building semantically motivated links among documents. This approach is more expressive that the traditional approaches to the problem that allows the automatic construction of links only between related documents. The approach has been used to build the Namic prototype (EU-founded project NAMIC, News Agencies Multilingual Information Categorization, IST-99 12392).

As the approach is rather different from the pre-existing the comparison is hard. We will therefore compile, according to our definition of the task, a large test set that should enable the validation of the methodology and of the implemented system.

Abstract

In this paper we present the advantages of using an ontology service for the modelling of user profiles in the EC FP5 IST project NAMIC (IST-1999-12392). By means of an ontology server people set up user profiles, which are in fact views, i.e. *specifications of queries* on the ontology. These views are constructed using a JAVA API, which forms the *commitment layer* of the ontology, built on top of an ontology base. In NAMIC an ontology server is used to establish a link between the lexical object representations, generated by the natural language processors (NLP) on the one hand and the user's interest, specified through the selection of relevant concepts and facts of the ontology on the other. This allows to specify a user profile independently of language, categorization and NLP specific "world models". Users then set up a profile consisting of events, agents participating in these events and other content information in which they are interested in. For instance, a journalist writing articles about financial issues may be interested in related documents containing a "raise event" of company shares. If he has specified those conditions in his profile he will be able to retrieve resources which contain events that are semantically related to that kind of event pattern. User profiles in NAMIC do not have to be static. The results of processing by the NLPs of a document the user is currently working on, may be used to construct a dynamic profile, which may contain events specific for that document. This way a user's profile can be dynamically adapted to his current interests. We also developed a tool which illustrates the creation of user profiles using ontological concepts and facts.

1. Introduction and Motivation

In this paper we present results derived from our work in the NAMIC project. Within the NAMIC project the main objective was to develop advanced technologies of Natural Language Processing for multilingual news customization and broadcasting throughout distributed services, which represents one of the major problems for International and National News Agencies (NA) as well as for the spread of Web technologies. Within their own business cases, NAs need to integrate in their own repositories news distributed by other NAs usually in different languages and according to different classification standards. Mismatching is at language level, since different languages are used, as well as at the conceptual, as the organization/storage of news proceeds according to diverging schemes. The volume and richness of this information has, however, a catch: it can overwhelm the pressed user-journalist that may be looking for a particular type(s) of information. This is a well-known problem in an information-rich environment, and especially in the case of (large) sets of hyperlinked documents, often referred to as the "lost-in-hyperspace syndrome".

Several aspects have been researched to improve searching, browsing and retrieval of information. In the information retrieval approach, several techniques ranging from string matching to advanced lexical analyses systems are used in order to understand the implicit semantics and thus the relevancy of the data that will be retrieved. On the other side, in the artificial intelligence and database approaches, such as for example the semantic web, the semantics (and the syntax) of the data are explicitly defined and linked with knowledge bases as ontologies, which help to make precise queries or for reasoning,. Experience shows that the accuracy of extracting the implicit semantics and the relevancy of the data is low, e.g. a search using regular search engines results in a huge amount of information, especially for large volume information resources such as the web, expanding queries to improve recall may also cause huge result sets. On the other hand, defining the semantics of the information explicitly, and reasoning about them in order to retrieve relevant information is an expensive task, and the scalability is very low. Therefore, we believe that combinations of these two approaches will be very fruitful for the improvement of information retrieval, as will be argued in the next sections of this paper.

Within the NAMIC project the User Domain Profiling System (UDPS) allows defining of user profiles for the filtering of news streams according to the specific interests of a user which for NAMIC, primarily would be journalists or other text writers. These user profiles are then used to exclude irrelevant items from a constant stream of documents before these documents are presented to the user.

As will be argued later in this paper, the use of an ontology has critical improvements: IR systems will gain from ontologies richer knowledge representation and modelling capabilities, improved recall by expanding the queries according to well-defined and consistent relationships in the ontology and improved precision by allowing the definition of personalised profile systems as queries against (an) ontologie(s) in order to include or exclude (a) certain type(s) of information.

Structure of the paper. In section 2 we give an introduction of what an ontology is and its critical added value for NLP based systems. Section 3 then gives the definition of a user profile and explains more details about the advantages of using ontology-based information filtering systems such as user profiles. Section 4 demonstrates the implementation done in the Namic Project and Section 5 draws preliminary conclusions and

maps ongoing and future work. Section 6 then places all acknowledgements.

2. Using ontology with NLPs

In this section we will illustrate the advantages of ontologies and their potential role in several aspects of information retrieval and how they can be used in defining user profiles.

Ontology[1] in computer science is a branch of knowledge engineering, where agreed semantics of a certain domain are represented formally in a computer resource, which then enables sharing of information and interoperation between systems. Representing the semantics (as a formal interpretation) of a certain domain implies the conceptualisation of the domain objects and their interrelationships in a declarative way, so that they can be processed, shared, and reused among different applications. Note that an ontology is more than a taxonomy or classification of terms, since it includes richer relationships between terms, e.g. "part-of, location-of, value-of, synonym-of…"(Figure 1). An ontology provides a higher level of knowledge[2], where the ontology terms are chosen carefully, consistently, and with a higher level of abstraction.

In the DOGMA model described summarily below, we separate relevant ontological relationship knowledge as set extensions of context-specific binary fact types called *lexons.* These express (within this assumed context) plausible relationships between concepts, using lexical terms in a given language; we implicitly assume that these terms are aligned with a lexicon ("terminology base") that is agreed among all users of the ontology (Jarrar, 2002).

Example. The following –very partial ontology (Tables 1,2,3)- could be lexons in some arbitrary hopefully self-understood syntax, the format for the purpose of textual illustration being (*#contextid*) <term1>[<role label><term2>]; details or omitted in this paper. The ontology base, which contains the set of lexons of the modelled domain, is also known by the symbol, Ω.

(*#my_company-ID*) employee

Table 2

(*#employment-ID*) salary
has amount_in-$
expressed_in currency
converted_to currency
earned_by employee

Table 3

Through the use of ontologies one is able to express semantic relations between terms, rather than is the case with ordinary categorisations. To express these meaningful relations between different terms we need advanced modelling methodologies, like the ORM conceptual modelling language. We chose ORM for its rich constraint vocabulary and well-defined semantics. Within STARLab we also developed an XML-based ORM markup language (ORM-ML) as a means of exchanging data semantics between different agents. (Demey et al, 2002)

The enormous growth of the Web causes search engines to return a large number of pages to the user for a single search. It is time consuming for the user to traverse the list of pages just to find the relevant information. We claim that information filtering systems based on ontologies will assist the user by filtering the data stream and delivering more *relevant* information to the user. Below are a few examples of how this can be achieved. We will discuss these topics in section 3 in more detail.

IR will benefit from ontologies more than terminology bases/resources since the knowledge is more formally represented than in term bases, which facilitates the representation, maintenance, and dissemination of terminological data and makes these data reusable by computer systems in various applications. Recall and precision of search operations will be improved using ontologies to model the knowledge contained in a system. Recall will be improved by exploiting the rich structure of an ontology and specifying generic queries (Guarino, 1999). The semantics in an ontology makes it quite attractive for query expansion, because there is a strong need to expand queries with relevant terms and meaningful relations which contain a lot of semantics, for instance to include subtopics or to personalize the query according to a user's personal interests. Precision will be increased through the disambiguation of terms and the ability to navigate through the ontology for the selection of more specific queries (Guarino, 1999).

While ontologies offer highly advanced modelling capabilities our experience indicates that, in the domain of Natural Language Processors (NLPs), ontologies will mostly be lighter, and therefore less expressive, than in other applications such as for example reasoning systems where the reasoning rules (defined as a logical theory in the *commitment layer*; containing for example the following constraint ORM.Mandatory(employee has_birth date)) are the most important part of the ontology, while NLP applications may see the lexons in the ontology base as canonically and linguistically structured expressions.

Furthermore, the context will provide added value to disambiguate (or approximate) the meaning of terms and relations.

Usage of an ontology also offers advantages for multilingual Information Retrieval. Since the ontology is a shared agreement about a (abstract) conceptualization it is in principle independent of a particular natural language

[1] In philosophy, Aristotle defined ontology as the science of being.

[2] The Knowledge Level is a level of description of the knowledge of an agent that is independent of the symbol-level representation used internally by the agent, (Gruber, 1995)

(Of course, one needs in general natural language to negotiate and specify such an agreement). Thus an ontology should be able to support multilingual retrieval of information by allowing the definition of conceptual queries, which are not natural language specific. Relevant information can then be retrieved through the matching of a query with the conceptual information/knowledge extracted from document corpora in other languages.

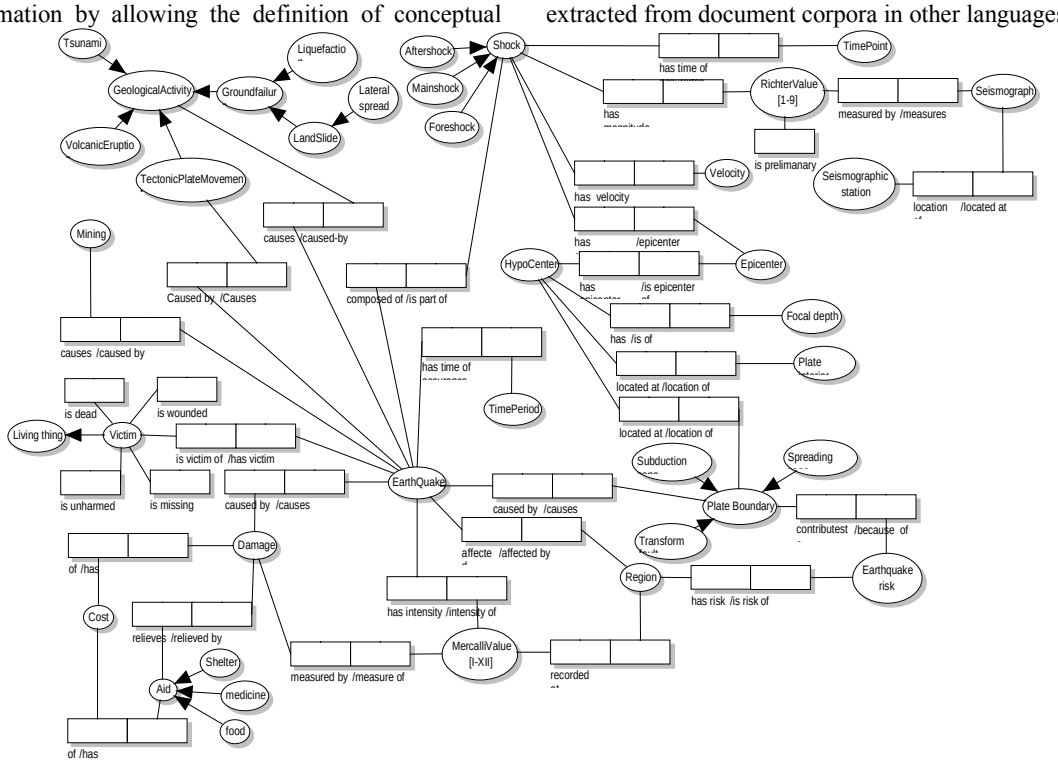

Figure. 1

3. Profiling system

While search engines find relevant items from a constant stream of documents, personalized information filtering systems generally embody one or more of a user's interests via a user profile, which ultimately improve the precision. Filtering systems are often classified into one of two categories, depending on the manner in which the documents are filtered. *Cognitive systems*, also referred to as content-based systems(Pretschner et al,1999), choose documents based on the characteristics of their contents, while *social systems*, also referred to as collaborative filtering systems, select documents based on recommendations and annotations of other users (Pretschner et al,1999; Abuzir et al,2001; Abuzir et al, 2002).

An efficient and semantics-based filtering mechanism is desirable in order to improve the precision of the results. Individual users (or a certain audience/class/social group… of users) will specify in profiles which kind of information should be included or excluded. A profile may for instance contain the following filter " 'Company acquisition event' and 'IBM' ", expressing the user is interested in all company acquisition events and in all events involving IBM.

Note that such a profile is not just a set of arbitrary keywords that may lead to inconsistent filtering, but forms a consistent and well defined filter mechanism, based on the same semantics as the query engine (or NLP). Therefore, we define a user profile as a specification of a query on the ontology. A profile enables a user to specify his interests and expresses this way what kind of documents he is interested in. A user profile is composed out of one or more filters, where each filter specifies which class(es) of information the user wishes to include or exclude. Within the NAMIC project in particular, the profile specifies those conditions that should result in "exactly" news items of interest of the journalist-user.

Defining a user profile as a query on the ontology thus implies the specification and adoption of a query language/system. Therefore, defining such profiles depends on how the relations between ontological concepts will be interpreted, e.g. one may decide to include all of a class' subclasses automatically. Within the NAMIC project we have chosen to specify a query as a composition of logic combinations using concepts and binary relations from the ontology, in which the concepts and the taxonomic relationships between them are seen as forming a kind of frame-based system (Karp, 1993).

Often queries are very broad. Consider for example the query "EU Framework 5". With a database as large as the Web, there will be thousands of documents that are related to EU Framework 5. If a query can be expanded with the user's interests, the search results are likely to be more narrowly focused. However, this is a difficult task since query reformulating needs to expand the query with relevant terms. If the expansion terms are not chosen appropriately, even more irrelevant documents will be returned to the user. By taking the semantics of the domain into account, it turns out user profiles can be an excellent source of knowledge to expand the query. By specifying an ontological concept in a user profile, a user implicitly selects all concepts from the ontology which

inherit from this concept and ignores all parent concepts (assuming the relation between the concepts is SubClassOf).

The ontology is separated from the objective representations used by the natural language processors. Since the user profile is a query on the ontology, this separation hides the user from the potentially large amount of objective representations used by the NLPs. The advantage of the independence between the underlying objective representations and the user setting up his profile is that he does not have to be aware of the different objective representations of the NLPs. The ontology can thus be seen as an intermediate level shielding the different representations of the NLPs from the user. Once the ontology is built, natural language processors will have to adapt their objective representations to it. This way a query on the ontology, can be considered to interact independently with the objective representations generated by various natural language processors.

Because of the multilingual data resources, development of different natural language processors (in NAMIC, English, Spanish and Italian) is required. This was done by the universities of Sheffield, Rome (Tor Vergata) and Catalonia (Universitat Politècnica de Catalunja). The user profiling system, introduced in NAMIC, however enables the user to specify language-independent queries, but still gives the possibility to get back related documents in all languages provided by the news agencies.

As mentioned before a user has the possibility to specify his interests in a static profile by selecting the appropriate relations and concepts from the ontology. It is however quite possible that a journalist's interests change while working on a particular news story. Therefore the user has to adapt his profile according to his current needs and interests instead of having to create an other additional profile. User profiles, developed within the NAMIC project, can be dynamically adapted. Indeed, as part of the NAMIC profile services, a journalist has the possibility to create a local profile according to the text he is currently working at, because it is likely that he will be interested in retrieving documents containing events, or knowledge related to agents participating in events which he has already entered in his text. The user is given the possibility to update his current static profile according to this new profile, making his own profile change dynamically. This prevents the user from having to manually annotate his own article of text by adding (ontologically derived) concepts and relations to his static profile, assumedly saving time and improving consistency.

4. Implementation

The ontology service in NAMIC provides the possibility to store, edit and retrieve ontological information that models (partial) semantics relevant to the project's domain and in particular the ability to define user profiles based on these semantics.

In order to satisfy the requirements mentioned above we developed a tool, with the following classical two-tier client/server architecture, illustrated in Figure 2.

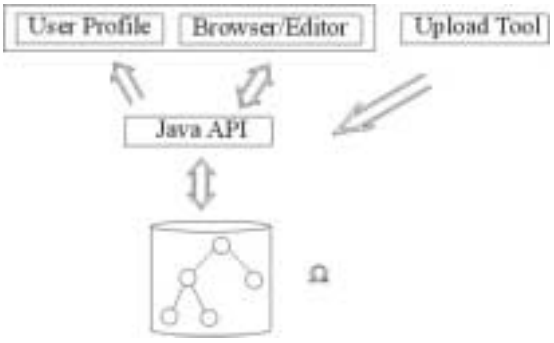

Figure 2

- At the bottom of Figure 2, there is a storage facility for the ontology (in a database)
- Above that, an intermediate API layer establishes communication between various tools and the ontology.
- At the top, support tools like browsers, editors and user profiles are implemented.

In our paper we will use the term 'objective representations' of the natural language processors to refer to Event Matching patterns, which are described in detail in (Basili et al) .The process of ontology engineering begins with the development of a base model that provides a framework for the integration of other different, individual resources. The creation of this ontology base can be viewed as a conceptual modelling task, based on ontology merging and alignment of the available resources. The result contains the fundamental concepts based upon the natural language processors' objective representations, that are generally useful for the project. For instance, consider the following verb syntactic frame: 'person – sells – attribute' as an example of an objective representation from the NLPs' event matching rules. The verb syntactic frame which is not considered to be an ontological concept, is mapped to 'Company Acquisition event'. The occurrence of this verb syntactic frame in a document then results in the detection of a 'Company Acquisition event'.

The individual resources that are considered for their incorporation into the NAMIC ontology were the following:

- The IPTC category system (IPTC)
- The EuroWordNet base concepts (EuroWordNet toplevel concepts) (Vossen, 1998)
- Named Entity lists (Stevenson et al)
- Event Types (Basili et al)

In order to integrate the natural language processors' objective representations of the different individual resources into the ontology, an alignment process needed to be performed between those different representations. Categories, events and named entities are aligned with EuroWordNet base concepts, by establishing mappings between the involved concepts of the different resources considered for integration in the ontology. This is illustrated in Figure 3; the alignment mappings are depicted as double-sided arrows.

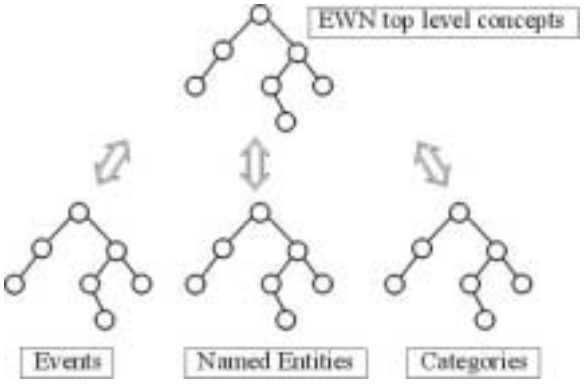

Figure.3

Because an ontology is a *shared* agreement about (a conceptualisation of) the world, aligning different ontologies with one another is required in order to obtain agreement between the concepts of the different ontologies. In order to develop tools automating this activity, good context formalisms will undoubtedly become helpful here but within the scope of NAMIC we had to align the different ontological concepts manually. At this state of the art it is as yet unrealistic to expect that merging or alignment at the semantic level could be performed completely automatically. A prototype of a tool to assist ontology merging and alignment has been built by the Stanford Medical Informatics department of Stanford University. This tool, based on the SMART algorithm, is an extension of the Protégé (Noy, 1999) ontology-development environment.

For the purposes of NAMIC we have also developed a simple custom tool (OntoNAMIC) to make the ontology available for browsing, editing and setting up user profiles.

The browser window consists out of a left pane and a right pane. The left pane is responsible for browsing through the ontology, while the content appearing in the right pane depends on whether one has selected the class view, diagram view or profile view on the toolbar of the application.

When the domain expert (i.e. typically *not* the journalist) selects the Classview, all the lexons containing the selected concept on the left will be displayed in the right pane. Choosing the Diagram view enables one to drag and drop concepts from the left pane into the right. By double-clicking on this dropped concept an ORM diagram appears, displaying all the lexons of which the concept is a part. ORM is a well-known conceptual modelling language (Halpin, 2001) here "re-used" (in part; some interesting modifications are needed that however will be the subject of a separate paper) to represent part of the ontology. In the diagram, ovals represent *entity types*, the rectangles are arbitrary (uninterpreted) relationships between them, and arrows are (interpreted) *is-a relations*. The important point is that it is possible to map such models to and from lexon-based ontologies, which provides two immediate benefits: a graphical and formally founded notation, and existing tools that already support it, such as Microsoft's VisioModeler for ORM. Because of our earlier experience with this particular method and tools for database design (De Troyer et al, 1995), we have adopted it as a prototypical research and implementation tools and techniques environment for ontology construction.

One then sets up a user profile by choosing the profile view on the toolbar. Remember a user expresses his interests in his profile by specifying a query on the ontology, i.e. as a composition of logical combinations of the desired events, EWN concepts, named entities and categories from the ontology. The resulting implied logical expression will then specify which documents satisfy the profile. This is illustrated in Figure 4.

5. Future work

Although we have now chosen to use a rather simple query language for setting up the user profiles, it is our aim for future work to develop a more sophisticated conceptual query language (for instance similar to RIDL (Verheyen et al,1982)), to specify queries on the ontology.

Abstract

Event modelling requires a good understanding of the modes used in communicating the events, including natural language, graphs and images. A case study of financial market movement, where text, or news wires, and graphical information, or a financial time series, were correlated, is described. This leads to a need for automatic text classification: a method based on unsupervised neural networks and autonomous assignment of keywords is described. These are preliminary results of an EU 5th Framework Project –GIDA (No. IST 2000-31123). Methods of corpus linguistics and terminology are used to underpin the methods.

1. Introduction

An event is defined as a significant occurrence or happening, or more specifically, as in physics, an event is a phenomenon or occurrence located at a single point in space time. In the late 20th century a tautological compound *news event* makes the meaning of the word 'event' even more explicit. A description of an event names the persons, places, things, or ideas in relation to the significant occurrence, happening or phenomenon: Osama bin Laden is frequently named in relation to terrorism; the Financial Times/Stock Exchange 100 (top companies) index (FTSE) is named in relation to the British, and possibly, EU economy; *relativity* and Einstein in relation to 20th century physics.

Reports of terrorism, stock market movements, and developments in theoretical physics, use written language, photographs, time series of financial transactions, graphs of key variables, and other symbol systems. Reports of events, political, economic, scientific or leisure, for instance, are crafted using a range of semiotic systems – from natural language to images, from time series to icons. An event, when described in natural language, involves the deliberate frequent use, and at times deliberate censoring of names related to the significant occurrence or phenomenon. For a specific event, described over a period of time in a number of texts, some persons, things or ideas are mentioned more or less frequently depending on their influence on the event. An event, perhaps at the lexical level of linguistic description, is a cluster of keywords or terms related to the specific area of human activity – terrorism, finance and commerce, physics, or football for example.

The names of (significant) persons, things or ideas act as an index to an event, an index which has linguistic rendering but can equally be referred through the use of other semes – images, graphs, mathematical symbols, circuit diagrams are some of the other indexical semes. Keywords-in-context (KWIC), largely common nouns sometimes qualified by adjectives, can be used to categorise documents related to a special subjects or, perhaps indirectly, to a specific events.

For us, event modelling requires an understanding of keywords and a collation of indexical names. For computer-based event modelling, involving information extraction and retrieval, and text understanding, it is important (a) to automatically identify and verify new keywords and indexical names, (b) to be able to note nuances of, and changes in, use of the keywords and the indexical names, and (c) to correlate the information in text and in graphs through the use of indexical names and keywords.

News streams provided by organisations like Reuters or Bloomberg comprise a range of keywords and indexical names that may change from one news item to the next; an event modeller will need to filter the news from such a diverse information resource. Specialist information providers deliver not only news texts but also supply, for example, time series of changes in value of stocks, shares, currencies, bonds and other financial instruments.

We have a narrower focus than other authors in information extraction (see for example Gaizauskas et al, 1995 and Maybury et al, 1995) in that we are looking for changes in key financial instruments that are reported in financial news-wires. The news coverage of these instruments is of two types: first, there is a daily report about changes in the value (numerical) of the instruments for instance, one can see time series comprising historic data about the changes in values of currencies; second, the manner in which the value of the instruments changes depends on the reports relating, directly or indirectly, to the instrument. The reports, for example, about war or economic uplift/downturn, affect the value of the instruments. Some authors claim that there is a correlation between 'good' or 'bad' news relating to the instrument and its potential numerical value. In Section 2 we take this discussion further.

The news report is one of the most commonly occurring linguistic expressions. Despite being a good example of open-world data, a news report is a contrived artefact: each report has a potentially attention grabbing headline; the opening few sentences generally comprise a good summary of the contents of the report; there are *slots* for the date of origin and slots for photographs and other graphic material. This contrived artefact is highly focused and highly perishable, and usually contains references to one or more persons, places, events or actions. Automatic categorisation of news stories is of substantial interest to in a range of applications (Mani 1998) to information retrieval communities, and to major news vendors

supplying *on-line news*; Section 3 takes up this story further and we conclude in Section 4.

2. Keyword and Indexical Name Correlation

Generally, information is delivered to financial market operatives via electronic mail, newspaper, or company announcement briefings or company annual reports. Whatever its source, the information in the news is an important component in making investment decisions (Figure 1). Equally important are events like natural disasters or terrorist activities for example.

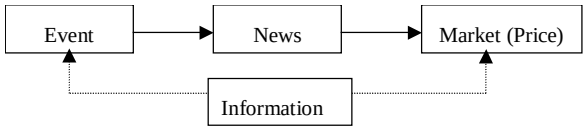

Figure 1: The relationship between Events, News and Markets (price) through Information.

For example, the terrible events of September 11, 2001, have had a catastrophic effect on financial markets world wide (See Figure 2). Various national economic indicators –indexical names – show the reaction on the date; there has been a decline in the value of these indices before that date and indeed a resurgence in the value afterwards.

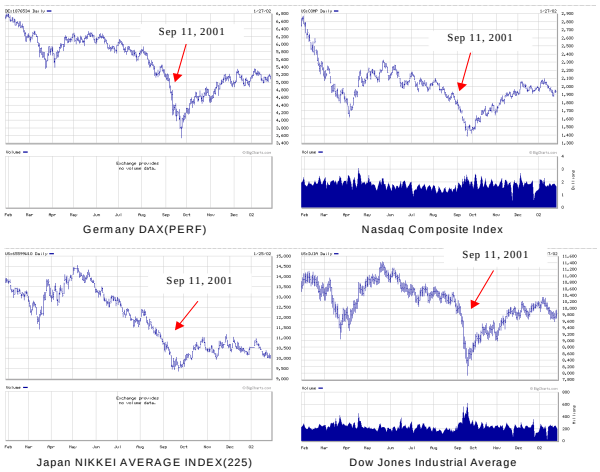

Figure 2: Movement from Feb 2002 to Jan 2002. Note the dip on and around Sep 11th 2001.

According to the Dow-Hamilton Theory (Rhea 1994), there are three kinds of price movements or market movements: (i) *Primary movement* which lasts from few months to many years and represents the broad trend within a market; (ii) *Secondary movement* last from a few weeks to few months and may sometimes be contrary to the primary movement; and, (iii) *Daily Fluctuations* can move with or against the primary trend and exist for a few hours to a few days.

2.1. Market Movement and Market Sentiment

Our work, sponsored in part by the EU-sponsored GIDA project (Project No. IST 2000-31123), focuses on primary movements. We report on some initial work that attempts to changes in an index, FTSE100, with changes in 'market sentiment' as expressed in news reports about the UK economy specifically and reports about the Wall Street indices. The later has substantial influence on the UK economy. Financial analysts use sophisticated political, economic and psychological analysis to determine the reaction of market operatives and to predict the possible trading decisions of the operatives. Reports related to the sentiment use a range of metaphors to express the state of a market and its possible movements. Francis Knowles has written about the use of *health metaphors* used in the financial news reports: markets are full of *vigour* and are *strong* or the markets are *anaemic* or are *weak* (1996); most newspapers also use *animal* metaphors – there are *bull* markets and *bear* markets, the former refer to expansion, and indirectly to fertility, and the later to shy, retiring and grizzly behaviour much like that reported about bears in popular press and in literature for children. Indeed, there are fairly literal words that express the sentiment, as reported in the news wires, about the markets: financial instruments *rise*, *fall*, markets *boom*, *go bust*, and there are *gains*, *losses* within the markets, economies *slowdown*, suffer *downturns*, whole industry sectors maybe *hardpressed*. Table 1 contains examples of good and bad news in a typical Reuters news stream:

Mainly Good News Stories	Rather Bad News Stories
Naval shipbuilder and military contractor Vosper Thornycroft has **boosted** its civil arm by buying facilities manager Merlin Communications (Nov 14, 2001)	Heavyweight banking and oil stocks have **dropped** up the leading share index as investors bet on fresh interest rate cuts.' (Nov 21, 2001).
The FTSE 100 stock index looks set to open **stronger** today after Wall Street added to **gains** seen at the London close and with U.S. stock index futures boosted by rumours that Osama bin Laden had been captured.'(Nov 15, 2001).	The European Commission has **slashed** its official growth forecasts for the euro zone [..], predicting the most serious **slowdown** since the 1990s recession, with **lower growth** in 2002 than this year.' (Nov 21, 2001).
Builder McCarthy & Stone has posted a 13 percent **rise** in annual pre-tax profits, built on **strong** sale prices for its retirement homes [..], but cautions that the **boom** may be over.(Nov 15 2001).	The FTSE 100 fell today, amid concern about how the U.S. economic **downturn** will hurt technology stocks and British Airways' operations. (Dec 10, 2001).
Leading shares are expected to **rise** again after Wall Street steamed **higher** overnight and the market basked in a feel-good glow, dealers said.' Nov 14, 2001).	Britain's economy appears to be sailing along relatively smoothly despite the global **slowdown** and a string of high-profile job **layoffs** (Oct 22, 2001).
'Leading shares have edged **higher** in early trade, **boosted** by **gains** in technology stocks in response to a Wall Street rally and **positive** expectations for the economic outlook.' (Jan 4, 2002).	'The **hard-pressed** manufacturing sector has recorded its biggest monthly production **drop** in almost a decade, **sinking deeper** into **recession**. (Nov 5, 2001).

Table 1. Examples of 'good' and 'bad' news stories in Reuters News Wires (Oct 2001-January 2002)

The above table contains examples of how the market is moving. But here we have free natural language complete with ambiguity and nuances of meaning: so there maybe a 'rise in profits' and a 'strong sale prices', in the story about builder's McCarthy & Stone above, both phrases suggesting that this is a good news story, except for the last sentence suggesting that 'boom maybe over'. Nevertheless, many of the news items do not change the nuance of the story by such highly temperate notes.

2.2. Correlating Sentiment and Market Indices

We created a corpus of 1,539 English financial texts from one source (Reuters) on the World Wide Web, published during a 3 month period (Oct 2001-January 2002) comprising over 310,000 tokens. The corpus comprised a blend of both short news stories and financial reports. Most of the news is business news from Britain with thirty percent of the news is from Europe and from the United Stages.

We found over 70 terms each for conveying good news and bad news in the above corpus. The texts in our corpus were also time stamped, and by using our text and terminology management system, System Quirk, we computed the cumulative weekly frequency of *good* words and *bad* words during one month – November 2001. The 'week' is a working week comprising 5 days, Mondays-Fridays:

Time (5 day Week)	Good Word Frequency	Bad Word Frequency
1	58	40
2	71	***75***
3	***77***	66
4	73	59
5	72	28
Total	**351**	**268**

Table 2: Frequency of Good and Bad words in Nov 2001. The underlined figures in the 2nd and 3rd columns indicate the minimum value of the frequency and the numbers in italics are the maximum value.

Table 2 shows that in November the highest frequency of 'good' words was in week 3 (77 instances) and the 'bad' words was in week 2 (75 instances). How does this correlate with the movements of the London stocks and shares as expressed by the FTSE 100? Figure 3 provides an example of the correlation between the frequency of 'good' words from news in November in our corpus and close prices of FTSE100 Index for the whole month of November.

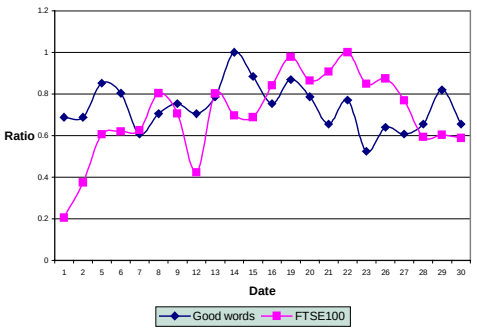

Figure 3: Market correlation between 'good' word frequency and FTSE index.

The highest value of the FTSE 100 index was on on 22 November 2001 (5345.94). There is a perhaps a correlation between the changes in the value of the index and the frequency of 'good' words: Positive gradient in the 'good' words time series correlates well with the positive gradient in the FTSE 100 index values. What will be interesting for the purposes of predicting the movement of the market, will be a correlation that suggests that a rise in the number of good words one day nudges the market . Correspondingly, that a decrease in the number the previous day will lead either to a static market or falling market the next day. The same can be said, perhaps in reverse, about the bad news words (see Figure 4).

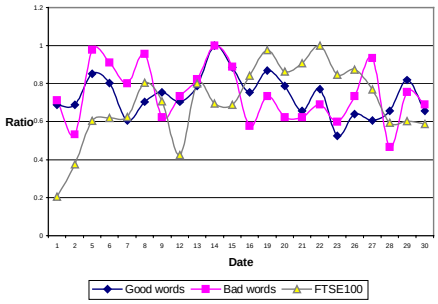

Figure 4: Good and bad word frequency correlated with FTSE 100.

Figure 4 shows 'good' word and 'bad' word frequency is perhaps correlated with FTSE100 values. For example, from 23rd to 29th November the frequency of 'bad' words increased while the FTSE100 went down over this period. After the 29th November, the FTSE100 value slightly increased as the 'good' word frequency also increased.

The above analysis and the concomitant results are of a tentative nature in that work is progressing in three major directions. First, one needs a bigger corpus, and a longer time series, to be more assertive about a correlation between an index and the corresponding sentiment-bearing terms. Second, further analysis is underway to note that the good news is sometimes tempered with bad news and vice versa – this will involve a phrasal or sentential analysis. Third, the notion of a 'time series' is a carefully defined concept for a series of cardinal numbers collected at discrete intervals of time or collected continuously; we are exploring the status of a time series made up of counts of lexical strings found in a news report that may have been produced over an approximate time. Nevertheless, Figures 3 and 4 show how a news stream, comprising subject specific texts, can be visualised especially in the context other indexical names.

3. Classifying News Wires Using Keywords

3.1. Categories of News Reports

A news stream comprises news stories that: (a) range over a whole range of subjects; (b) the news may emanate from or maybe about a nation state; and (c) the news may be focused on a certain specific area of human enterprise Reuters labels for items (a)-(c) are 'Topic', 'Country' and 'Industry'; these labels are used by Reuters' sub-editors to tag each news story with one or more Topic and Country tags, and in some cases with the Industry tags. These pre-assigned tags, about 1000 different tags in all, can, in principle, be used to categorise individual news stories in a news stream. However, the plurality of tags, that is the presence of one or more tags with either Topic, Country,

or Industry, makes such a categorisation more complex. Before we discuss how to deal with such a complex categorization task (see Section 3.5), which is possibly subjective in that the categories are based on an ontology which was created by Reuters themselves, we look at how to categorize texts based on (semi-)automatically extracted keywords.

One well-recognized way of describing news reports is to classify the texts as a distinct *register* or *genre* of writing. The term register is used to indicate that the language within a specialized field differs from that of *general language* or language of everyday use, at lexical, syntactic and semantic levels. A large collection of general language text may thus be contrasted with a set of specialist reports at various linguistic levels, including lexical and semantic.

An important use of this contrast is in a method of semi-automatically identifying the terms of a set of specialist domains. This method involves comparing the frequency of systematic terms in a collection of specialist texts sometimes called a *corpus*, with the frequency (or absence) of the terms in a carefully compiled corpus of general language texts. Each term can be construed as a dimension in a vector space and the presence or absence of a term within a text is then used to allocate the text its position within the vector space. There is some evidence from work in linguistics that word categories (nouns, verbs, adjectives, adverbs, prepositions, etc.) may be inferred from the statistical occurrences of words in different contexts. For Kohonen and his colleagues, '"*context patterns*" consist of groups of contiguous symbols'; the authors cite pairs or triplets of words in a sentence as an example of such patterns. Such *pairs* or *triplets* are then used as inputs in the training and testing of a neural network (the so-called self-organising feature maps or SOFM; details of this map is presented in the next Section 3.2). Kohonen has shown that a SOFM-trained word context pairs, derived from 10,000 random sentences, shows 'a meaningful geometric order of the various word categories'. A larger SOFM, the WEBSOM has been variously described by Kohonen as a *scheme, content-addressable memory, method* and *architecture*. WEBSOM is a two-level self-organising feature map comprising a word category map and a document category map, which has been used to classify newsgroup discussions, full-text data and articles in scientific journals (Kohonen 1997b, Kaski *et al*. 1996). Terms were pre-selected by the builders of WEBSOM. There are other neural network architectures that have been used in text categorisation, especially the widely-used supervised learning algorithms – SOFM is based on unsupervised learning algorithm – which have been discussed by Lewis (1995).

Consider a set of texts that may have been selected according to certain criteria: for instance, all texts streaming along a news wire over a short period of time comprising news related to specialist topics – like environmental news or economic news. Such a short news stream may contain may result in a text collection, or if collected systematically, a text corpus, that may be characterised the high frequency of environment – or economics – related terms. However, over a long period of time this may not be the case as the news stream may start to deliver texts in different specialist areas. So how do we extract terms from such a corpus?

Specialist texts can be distinguished from a general language text at the lexical level of linguistic descriptions by looking at the ratio of relative frequency of a linguistic token in a specialist text and its frequency in general language texts. This ratio has been termed *weirdness* to indicate how it measures the preponderance of words in specialist texts that would be unusual in general language, (see, for example, Ahmad 1995).

Typically, before text documents are represented as vectors in order to act as the input to a text categorisation system, pre-processing takes the form of filters to remove words 'low in content' from the text (see the WEBSOM method in Kaski et al 1996). We remove punctuation, numerical expressions and *closed-class words* as a precursor of generating the feature set. Vectors representing news texts were created on the basis of a lexical profile of the training set of texts. This lexical profile was determined by two measures: the frequency of a term; and, a weirdness coefficient describing the subject-specificity of a term.

The feature set was created by first selecting the top 5% most frequently occurring words, and from this set, by choosing the words with the highest weirdness coefficient. Subsequently, the 50 most frequent words are selected, excluding spelling mistakes, and numerical expressions and terms too infrequent to provide consistency within a domain are avoided. A high value for the weirdness coefficient is indicative of a word which is uncommon in general language but common in the specialist corpus under examination and is thus a good candidate for a domain term or other word specific to that genre. By disregarding words with a weirdness coefficient lower than a threshold, many *closed-class words* and other terms common in general language are automatically removed. Before we show texts can be categorised using the above method, we digress to briefly outline the Kohonen Self-organising Maps

3.2. Kohonen Self-organising Maps

A SOFM is a neural network and associated learning algorithm that is designed to produce a statistical approximation of the input space by mapping an input in to a two-dimensional output layer (see Kohonen 1997a for an extensive discussion). The approximation is achieved by selection of features that characterise the data, which are output in a topologically ordered map. The Kohonen Self-Organising Map has a close resonance with the *k-means clustering* method, with the additional constraint that cluster centres are located on a regular grid (or some other topographic structure). Furthermore their location on the grid is monotonically related to the pair-wise proximity (Murtagh & Hernández-Pajares, 1995).

The basic SOFM consists of a single layer of neurons formed into a two-dimensional lattice. Each neuron is connected to the input via a set of connections utilising connection weights, just as in a perceptron. There is no 'output' of the map, rather the values of each neuron's weight vector are used to visualise the formed topological ordering. The weight vectors form a cluster prototype that is measured against each input to determine how 'close' the vector is to a given cluster. Since the map is two-dimensional and the input typically has a high dimensionality, the SOFM acts as a dimensional squash

allowing the visualisation of features within multi-dimensional data.

Learning is achieved in the SOFM using a competitive algorithm. The Euclidean distance between each training input vector and all weight vectors is determined. The neuron with the weight vector that has the smallest Euclidean distance to the input pattern is termed the winner. To reward the winning neuron its weight vector is adjusted to be 'closer' to the input vector, with the amount of adjustment determined by the number of times the training patterns have been presented (via the learning rate). Additionally, all vectors within a defined neighbourhood of the winner are adjusted, essentially forming a cluster of similar values that are seen to be activated by the winner. The neighbourhood size decreases with the number of training cycles, typically using a bubble neighbourhood (a rectangular area) or a Gaussian neighbourhood, both centred on the winning neuron. The adjustment of the weight vector towards the input is achieved by effectively 'moving' the weight vector's direction towards that of the input. This simple process of adjusting ever-smaller neighbourhoods of winners allows the formation of clusters within the lattice. As the number of cycles increases, the clusters become more stable and can be viewed through probing to find winners using test data.

The principal way in which information about the clustering performed by the SOFM learning algorithm is visualised is through probing with a test set to find the winning neurons. The co-location of different winners from different categories highlights the similarity between clusters. The effectiveness of such clusters can be measured by comparing different versions of the map trained on the same data through a technique being developed by Ahmad et al (2001), where Fisher's Linear Discriminant Rule is used to quantify the discrimination ability of different clusters.

3.3. Limitations of a SOFM

The SOFMs strength lies in its ability to *statistically* summarise the input space. However, it has been shown that the basic SOFM does not always produce a *faithful* approximation (Ritter & Schulten, 1986). This faithful approximation is defined as the proportionality between the density of the weight vectors and the density of the input space. Lin et al (1997) has shown that the SOFM underrepresents high-density regions and overrepresents low-density regions.

3.4. Automatic Categorization of Texts Based on Keywords Using an SOFM

Our text corpus consisted of 100 Associated Press (AP) news wires selected from 10 pre-classified news categories shown in Table 3 together with their icons. The average length of the articles was 622 words.

Text Categories

1	Bioconversion		**6**	Exportation of Industry	
2	Pollution Recovery		**7**	Foreign Trade	
3	Alternative Fuels		**8**	Int. Drug Enforcement	
4	Fossil Fuels		**9**	Foreign Car Makers	
5	Rain Forests		**10**	Worldwide Tax Sources	

Table 3: Text categories used in the TIPSTER – SUMMARY program

The 100 AP news wires comprised over 56,000 words. System Quirk was used to compute frequency distribution of words in the AP News wire corpus. The System also has access to the frequency distribution of words in the British National Corpus (Aston and Burnard 1998) a carefully compiled general language corpus. Some of the high weirdness terms, e.g., *drug*, *taxes*, *pollution* and *environmental* are important keywords, but the same cannot be said for 'terms' like *billion*, *percent* and *federal*. Usually, proper nouns are also flagged as terms by this method. The feature words identified for the 100 AP News Wire texts are shown in Table 4 according to rank:

1	percent	15	congress	28	dioxide	41	corp
2	tax	16	mexico	29	marine	42	forests
3	billion	17	emissions	30	mazda	43	cocaine
4	drug	18	drugs	31	gases	44	enforcement
5	reagan	19	fuels	32	shale	45	warming
6	cars	20	senate	33	deficit	46	smog
7	taxes	21	auto	34	export	47	ozone
8	environmental	22	proposal	35	recycling	48	Massachu-setts
9	pollution	23	gasoline	36	epa	49	imports
10	fuel	24	exports	37	honda	50	automobile
12	federal	25	vehicles	38	methanol	51	trafficking
13	dukakis	26	ohio	39	automakers		
14	bush	27	green-house	40	panama		

Table 4: Feature words identified for the 100 AP News Wire Texts.

Having identified the feature set the training vectors for each of the texts could then be generated. Each vector consisted of binary values indicating the presence or not of each of the feature words determined above.

We have developed a system for creating Kohonen Feature Maps (SANC: Surrey Artificial Network Classifier). The system, after having trained an SOFM, is also capable of testing it. (There are facilities to vary the key parameters associated with the learning algorithm). The system can be used to test the trained. Furthermore, the system allows the storage of previously trained maps for reference purposes (Ahmad, Vrusias and Ledford 2001).

The results of the Kohonen classifications for full texts are shown in Figure 5. Using symbols to represent each of the locations of the 'winning node', the position of each text is indicated across the two-dimensional map (shown in Table 3). It can be seen that the quality of clustering for the full-texts is successful for a range of categories, but especially for categories 9 (FOREIGN CAR MAKERS) and 10

(WORLDWIDE TAX SOURCES). Patterns in categories 1 (BIOCONVERSION), 4 (FOSSIL FUELS), 6 (EXPORTATION OF INDUSTRY) and 8 (INTERNATIONAL DRUG ENFORCEMENT) are also effectively grouped together. The widespread distribution of Class 5 (RAIN FORESTS) shows it to be the worst class on the map.

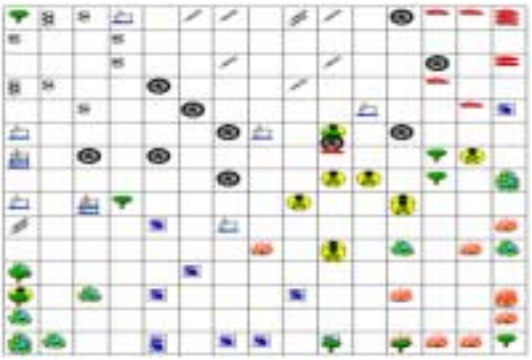

Figure 5: Results of a Full Text Map trained using exponentially decreased neighbourhood and learning rate.

These results for the trained Kohonen map were similar across a number of trials despite variations in training method and learning rate used. Some categories, for example 10 (WORLDWIDE TAX SOURCES), clustered consistently better than others for instance 5 (RAIN FORESTS). By simply counting the number of feature set words that appear in at least nine of the ten texts of each category, the best clustered categories are guaranteed to have some of these words. This reflects the tendency of these categories to cluster well. On the other hand, for a category in the 'best' case, only four of the texts share a common feature set word. This difference in classification difficulty was also seen in the TIPSTER results from two human assessors.

3.5. Multiple Categories and Text Categorization

Recall that Reuters News Agency has three categories: "Topic", "Country" and "Industry". The total number of different tags, or concepts, defined in these three categories is approximately 1000.

We have created a text corpus of 800 news stories streamed by Reuters in 1997. Each of the news stories is encoded in XML format and has clearly delineated headline, date, writer, text and code fields using XML tagset. The XML-based delineation helps in extracting keywords associated with the Topic, Country and Industry tags. The frequency of each concept was calculated within 800 documents; 80 of the keywords turned out be more frequent than other 920: the distribution of the keywords in the various fields was as follows:

Industry	**39**	***Topic***	**32**	***Country***	**19**

A SOFM was trained for categorising the 102 out of the 800 news stories. The input vector was created from the 80 most frequent keywords associated with the triple, Industry-Topic-Country: the absence and presence of a particular keyword was used to create the input vector for each of the texts. The neural network was trained 100 times. The vector thus created can, in principle, cope with upto 39 different categories of 'Industry', of 32 different 'Topics' and '19' different countries. The downside here is that documents comprising references to the 920 keywords may not get classified as well as those that may comprise the 80 categories used in the construction of the input vector.

After the training period, the pre-specified Reuters documents were visualised on the map. As can be seen in Figure 6, the documents associated with each neuron were represented by a blue square. The distribution and the similarity of the documents were based mostly on the "Topic". On the lower right side of the map, the topics related to "Government/Social" were clustered. The subtopics of "Government/Social", for example "Sports" and "Art", were also clustered near this area. The documents categorised as "Management" were found on the lower left corner of the map. "Strategy and Plans", "Comments/Forecast" and "Economy" follow this as we approach the upper left corner. "European Community" documents were found on the upper right corner of the map.

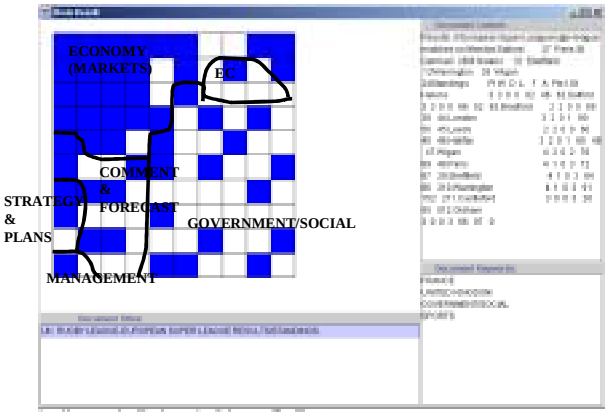

Figure 6: A Categorisation of Reuters news stories using pre-specified category information.

4. Afterword

Our current work involves evaluating the categorisation produced by the method that relies on different distribution of specialist terms in special and general language texts with that of using networks to classify texts that have pre-specified category information as was the case just described.

The pre-specified categories appear to be complex and, as mentioned above subjective in nature. We are currently examining whether a summary of text may give us some indication of the category. The reasoning is as follows: a full news story may contain extraneous material and a good summary will eliminate sentences within the text that are not directly related to the category or categories. Lexical cohesion studies have shown that keywords form the glue that helps to create a cohesive and coherent texts (Hoey 1991). In our previous work on AP news wires (Ahmad, Vrusias and Ledford 2001) we looked at three different types of text streams – headlines only, news summaries and full news items and categorised these texts using self-organising feature maps (SOFM). We found that an SOFM trained on vectors related to summaries

only provides a fairly accurate cluster when compared with vectors related to full text. This work is currently being carried out on the 102 Reuters texts mentioned above.

An analysis shows a vector for the 102 texts using our method based on the weirdness of the keywords within the news stories (Table 5).

Element	Description	Words	
1 – 25	*Single Words* Top 25 simple words with high weirdness and high frequency	inventories, yen analysts, merger cents, peso investors, exports quarterly, forecast pesos, shares dealers	analyst directive billion, soccer traded, allegations trading, stocks fiscal, tobacco nickel, earnings
26 – 30	*Compound Words:* 5 most frequent compound words	shareholder newsroom worldwide	online chairman
31 – 40	*Proper Nouns* 10 proper nouns with high weirdness and high frequency	dorfman compuserve novell aol microsoft	ec kimberly chrysler saudi netherlands
41 – 45	*Movement Indicators:* 5 most frequent downtrend words.	lost fall falling	risk losses
46 – 50	*Movement Indicators:* 5 most frequent up trend words.	up growth high	added strong

Table 5: Vector for the 102 Reuters news items (c.1997)

Note that in the above vector we have included movement indicators, proper nouns and compound words together with the single word terms. The 30 keywords and 10 proper nouns/indexical terms, together with 10 movement indicators will help us to define an event. Initial results of this analysis are encouraging in that we obtain the major clusters much like as found in Figure 6

We are currently exploring the notion that news streams will be filtered by using a trained Kohonen SOFM and the filtered text will be used to study market movement. The filter has to be 'cleaned' in that news stories are perishable items with constantly changing subjects – one idea is to re-train the network everyday, towards the end of the day perhaps, with a fixed number of stories which will exclude the very first day of the previous training set and include yesterday's news stories.

Event modelling, especially in noisy and dynamic environments, requires a careful consideration of the key concepts, expressed as keywords, and of indexicals like persons, places, things or ideas which play a crucial role in turning an occurrence, happening or phenomenon into a significant one.

Abstract

The large-scale applicability of knowledge-based information access systems such as the ones based on Information Extraction techniques strongly depends on the possibility of automatically acquiring the large amount of knowledge required. However, the basic assumption of the IE paradigm, i.e. that the information need is known in advance, limits inherently its applicability since the resulting IE pattern learning algorithms are not generally conceived for the analysis of large corpora if not driven by a specific information need. Since in the terminological studies the corpora and not the information needs already drive the extraction of the knowledge, they offer many insights and mechanisms to automatically model the knowledge content of a coherent text collection. In this paper, we will present a terminological perspective to the acquisition of IE patterns based on a novel algorithm for estimating the domain relevance of the relations among domain concepts. The algorithm and the representation space will be presented. Before starting the discussion, however, we will describe the overall process of building a domain ontology out from a extensional domain model (i.e. the collected domain corpus). Finally, the results of the application of the algorithm over a large domain corpus will be presented and the resulting ontology is discussed.

1. Introduction

The large-scale applicability of knowledge-based information access systems such as the ones based on Information Extraction techniques strongly depends on the possibility of automatically acquiring the large amount of knowledge required. The applicability of these systems over large heterogeneous text collections (e.g. the World Wide Web) may be one of the keys of success of "emerging" information access paradigm such as the Question Answering (QA) and the Automatic Summarisation (AS). In fact, the major strength of the Information Retrieval engines (typically based on the "poor" abstraction of stem) is due more to their wide applicability than to their actual retrieval performances.

A very well assessed approach to Information Access is the paradigm of Information Extraction (MUC-7, 1997; Pazienza, 1997). This latter gave the fertile area where a number of techniques for the automatic acquisition of knowledge have been proposed. However, these learning approaches are focused on the extraction of knowledge needed for the satisfaction of a particular information need (i.e. the one expressed by the template) as the IE paradigm imposes. Therefore, the resulting learning approaches are biased by the fact that they can rely on two important hypothesis limiting their search space. From the one side, the target knowledge domain is generally small and, from the other side, the target information need is very narrow (such as missile launch event in one of the MUC conference). Therefore, the size of the resulting ontology can be kept controlled and the scope of the learning algorithms is a controlled (and small) corpus. In fact, in unsupervised learning techniques as in (Yangarber, 2001; Riloff and Jones, 1999), texts are firstly classified according to their relevance with respect to the particular information need and then particular surface forms somehow related are extracted and retained. The first step narrows the corpus that is given to the second.

However, the basic assumption, i.e. that the information need is known in advance, limits the applicability of the IE paradigm and of the resulting IE pattern learning algorithms. In fact, these latter are not generally conceived for the analysis of large corpora if not driven by a specific information need. If the goal to be achieved is the applicability in large, a different approach has to be undertaken. In such a perspective, the final information needs can not drive the learning phase that should totally rely on the corpus that has to be the source of this information, i.e. it is the final source of information that should suggest the information needs that can be satisfied. This is the typical case a information access system has to face when exposed to an uncontrolled information scenario (e.g. the Web).

Since in the terminological studies the corpus is already the major source of knowledge, they offer many insights and mechanisms to automatically model the knowledge content of a coherent text collection. Here, in fact, the corpus plays the central role of extensional model for the target domain where a domain ontology (i.e. a thesaurus) is extracted from. In this latter, terms and relations among them are generally described. The "operational" notion of *term*, i.e. that the term is the surface representation of a domain concept, allows to define two different levels of analysis: the notion of *admissible surface forms* and the notion of *domain relevance*. The target is generally the extraction of concepts conveyed by nominal phrases and the investigated relations are IS-A and PART-OF. Neverthless this terminological perspective to the extraction of IE patterns can be adopted for widening the applicability. IE patterns may be considered as domain relations among specific concepts, i.e. typical concepts of the domain and named entity classes that hold by definition the special status of domain concepts.

In this paper, we will present a novel algorithm for estimating the domain relevance of the relations among domain concepts. As for the term, the application of a terminolog-

ical approach to the problem of the discovering the domain relations among concept has to establish:

- which are the surface representations of the target relations;
- which is the estimator of the "domain importance" for the discovered relations.

The algorithm and the representation space will be presented in Sec. 4.. Before starting the discussion, however, we will describe the overall process of building a domain ontology out from a extensional domain model (i.e. the collected domain corpus) in Sec. 2. Finally, the results of the application of the algorithm over a large domain corpus will be presented and the resulting ontology discussed (Sec. 5.).

2. Building an ontology for a large-scale IE system

A large-scale IE system for a news agency should be able to scan news streams. The activity of building the needed knowledge base is therefore a huge task. However, in our opinion, this may be undertaken using some insight given by the terminology extraction practice. News streams are, in fact, coupled with a news classification scheme that can be more or less complex (cf. IPTC standards (IPTC,)). This rough or fine-grained classification over the news items allows the definition of coherent knowledge areas over which terminology extraction techniques can be helpful. Each collection of news items belonging to a class is in fact the extensional model for the underlying domain according to the classifiers.

The process of the knowledge modelling is sketched in the following. Given the corpus as model for the knowledge domain (or class) under investigation, the activities that have to be carried out for building the domain ontology are the following:

1. the definition of the named entity classes
2. a first analysis of the corpus for the acquisition of the most important concepts and relations among the concepts
3. the analysis of the extracted domain knowledge for the definition of the top "event" classes
4. the extraction of all the important concepts and relations among the concepts and their clustering under the defined event classes

For the activities 2 to 4, terminology extraction practice may be very useful with the notions of *admissible surface forms* and of *domain relevance*. The latter is a key notion that helps in showing to the ontology builder only the most relevant IE patterns (a combination of the domain concepts and domain relations). These patterns sorted according the domain relevance estimated by the importance function can drive the definition of the top event classes. The event classes elsewhere referred as "template types" will represent the knowledge the final IE system is able to make explicit over the particular domain. Finally, since IE patterns are ranked according to their importance, in the activity of clustering this guarantees that the most important events (and generally the most frequent) may be captured by the resulting IE system.

The attention on the clustering activity is somehow one of the major difference between the construction of a domain ontology for an IE system and the one of a terminological knowledge base (TKB) (or thesaurus). This is mainly because of the nature of the typical target knowledge domains. Terminology extraction is mainly conceived for giving a systematic representation of scientific or technological knowledge domains where certain terms are stable and a relatively small number of surface forms are used to convey a domain concept. On the other hand, in the news streams (the areas in which IE system has to find the information) domain concepts and, more often, domain relations are generally conveyed by more than one surface form. It is the equivalence between different event prototypes, i.e. prototypes that specifies the possible instances of the "Who? Where? What? When? Why?" events, that may make the difference.

3. Domain relations among concepts as event prototypes

Event prototypes (or IE patterns) used by IE systems to perform the activity of extracting information are very similar to what a domain relation among domain concepts may look like. Given for instance the financial domain, the prototype necessary to extract a *"sell event"* from the following news items:

Example 1 *Financial news excerpts*

(a) Eon, the German utility formed by the merger of Veba and Viag, is poised to sell its electronics arm to an Anglo-American consortium for about $2.3bn.

(b) It is understood to be near a deal to sell the Longview smelter for $150m to McCook Metals.

may have the following form:

Example 2 *Sell event prototype*

```
sell(  (agent:companyNE),
       (patient:object),
       (to:companyNE),
       (for:currencyNE))
```

i.e. a company typically sells something to a company for a certain amount of money (`currencyNE`). Here, the two named entity categories, `companyNE` and `currencyNE`, are typical concepts of the financial domain and the showed event prototype is a typical domain relation among these concepts.

Due to the difference on the perspective and on the application domain, some adjustments of the techniques developed in terminology extraction are mandatory in the IE pattern extraction problem. As suggested in the example, in IE, a major role is played by named entities. They are not important as surface forms but as generalised forms (i.e. their category). This is a major difference with the general terminology extraction where named entities are important as instances. For instance, *Newton's law* and *Zipf's law* convey very different meaning and are relevant as such and not in a generalised form `personNE's law`. The adoption of TE techniques on the IE tasks requires that named entity categories are considered as typical concepts of the domain. Admissible surface forms also consider the possibility of selecting forms with named entities (e.g. `companyNE_share` where `companyNE` is a named entity category that may be used for detecting *IBM shares* in target text).

Furthermore, in the IE perspective, the definition and the extraction of the domain relations plays a major role. Such a problem is generally neglected in the TE studies because major efforts are spent in the definition of algorithm for extracting and using catalogues for the general relations among terms such as IS-A or PART-OF (Morin, 1999; CON, 1998). The resulting methods are not suitable for the extraction of domain relations.

In order to adopt an TE perspective to the IE pattern learning these two issues have to be faced. In the following section we will present our approach to the extraction of domain relations over large collection of texts.

4. Learning domain relations from large textual collections

The approach to the extraction of domain relations should be completely corpus driven since information needs are not stated in advance. Therefore, given the corpus C, all the relations have to be analysed in order to detect the more important ones. Since the corpus should suggest the typical domain relations in the first phase of the construction of the domain model (cf. Sec. 2.), the target relations should then not to be too far from the admissible surface form as happens for the concept spotting in TE. As for the concept detection, we should then define the admissible surface forms and a function for estimating the domain importance of the given form. However, a minimal abstraction is needed to take into account the relatively free order of the participants when they appear in the actual text as in the above example (Ex. 1). In the following section (Sec. 4.1.), the admissible surface forms and their equivalence are stated and the size of the problem is estimated. On the other hand, an efficient algorithm for the estimation of the importance function based on the frequency of the relations in the target corpus is presented in Sec. 4.2.

4.1. Admissible surface forms: the size of the problem

A relation $r = (rv, (ra_1, ra_2, ..., ra_n))$ (as the one of the Ex. 2) may be represented in a number of different surface forms. Due to the fact that the corpus should suggest the important relations, we will only consider the realisation of r in verbal phrases. The corpus C s then seen as a collection of verb contexts $c = (v, (a_1, a_2, ...a_n))$ where v is the governing verb and each argument a_i is a couple (g_i, c_i) representing its grammatical role g_i (e.g. subject, object, pp(for), pp(to), etc.) and the concept c_i semantically governing it. A context $c \in C$ is a positive example of the target relation $r \in R$ if $rv = v$ and r partially cover c, i.e. the arguments of r should then appear in any order in the context c.

Given the domain corpus C represented as a collection of verb contexts, the objective is to evaluate the relevance of each possible relation $(r, (ra_1, ra_2, ..., ra_n))$. The first problem is to estimate how many different relations have to be analysed. This may be obtained after partitioning the corpus C according to the verb governing the contexts. For each verb v, a subset of the corpus is then defined as:

$$C(v) = \{(a_1, ..., a_n) | (v, (a_1, ..., a_n)) \in C\} \quad (3)$$

Notice that the notion of context that we use is open to two different 'views'. A lexicalized notion of context is obtained by relying on the full definition. A context $c = (v, ((g_1, c_1), (g_2, c_2), ..., (g_n, c_n)))$ expresses the governing verb v with the lexical (c_i) and its syntactic role (g_i) for each argument found within a given corpus fragment. c_i is usually a partially generalized surface form. c_i denote thus partially generalized surface forms like `companyNE` (for fragments like *IBM*, *Financial Times*, *Apple Ltd.*) or `companyNE_shares` for structures like *IBM's shares*. If we neglect this rich $lexical$ information, and make use a generic concept (e.g. `object`) for the arguments, the remaining information is purely syntactic, making explicit only the grammatical role in the context:

$$c = (v, ((g_1, object), (g_2, object), ..., (g_n, object)))$$

As a result the following two sets of arguments in contexts of $C(v)$ remain defined:

$$A_\Lambda(v) = \{a | \exists (a_1, ..., a_n) \in C(v) \wedge \exists i . a_i = a\} \quad (4)$$

$$A_\Sigma(v) = \{ \begin{array}{l} (s, object) | \exists i . g_i = s \wedge \\ \exists ((g_1, c_1), ..., (g_n, c_n)) \in C(v)\} \end{array} \quad (5)$$

Given the above sets, $A_\Lambda(v)$ and $A_\Sigma(v)$, the set $R(v)$ of the possible relations for a given v is the following:

$$R(v) = \bigcup_{i=1...MC(v)} R_i(v) \quad (6)$$

where $R_i(v)$ are the collection of individual combinations of exactly i arguments in the set $A(v) = A_\Lambda(v) \cup A_\Sigma(v)$ that are syntactically meaningful. The distinction between lexicalised and syntactic arguments is useful to take into account the fact that some relations may have a recurrent syntactic argument whose filler concept is not recurrent.

If $R(v)$ is the set of all the relations for the investigated verb v, the domain importance of each $r(v) \in R(v)$ should be assessed. Therefore, at least the evaluation of the frequency of the relation $r(v)$ over the corpus $C(v)$ has to be used.

Given the defined sets, the size of the $R(v)$ set is, in the worst case, the following:

$$|R(v)| = \sum_{i=1...MC(v)} \left(\begin{matrix} |A(v)|+\ i-1 \\ i \end{matrix} \right)^1 \qquad (7)$$

where $MC(v)$ is the maximum context size for the verb v in $C(v)$. It is worth noticing that $|R(v)|$ values lie in a very large range, due to the size of $A(v)$. In the next section we concentrate on a measure of relevance (for the target domain) that allows to systematically reduce the size of the space where pattern selection is applied for each verb v.

4.2. Estimating the importance: Counting efficiently instances of event prototypes

Given the corpus C, the space of the possible relations is huge. This inherent complexity is the result of tackling the argument order freedom that is neglected in (Yangarber, 2001). In order to tackle with the problem, an informed exploration strategy may be settled. This strategy can not take advantage on the biasing given by the awareness of the final information need that is typical of the IE pattern extraction algorithm. However, some observations may be useful for the purpose:

- the target of the analysis is to emphasize the more important relations arising from the domain corpus
- the frequency of a specific relation strictly depends on the frequency of a more general relation

A very simple but effective domain relevance estimator is represented by the frequency of the relation in the corpus. In this perspecitive, the more important relations are the more frequent. Therefore, the above considerations may reduce the complexity of the search algorithm if only promising relation are explored, i.e. patterns whose generalisations are over a frequency threshold.

The idea is then to drive the analysis using the pattern generalisation that may be obtained projecting the patterns on their "syntactic" counterpart. The projection $\widehat{\Sigma}(r)$ of the relation r over the syntactic space Σ is defined as follows:

$$\widehat{\Sigma}(r) = (\widehat{\Sigma}(ra_1), ..., \widehat{\Sigma}(ra_m))$$

where $\widehat{\Sigma}(ra_i) = ra_i$ if ra_i is a "syntactic" argument ($ra_i \in A_\Sigma(v)$) or $\widehat{\Sigma}(ra_i) = (s_i, object)$ if $ra_i = (g_i, c_i)$ is a lexicalised argument ($ra_i \in A_\Lambda(v)$). The resulting search space $R_\Sigma(v) = \{\widehat{\Sigma}(r) | r \in R(v)\}$ is greatly smaller than $R_\Sigma(v)$ since $|A_\Lambda(v)| >> |A_\Sigma(v)| = \#preposition + 2$. This search space can be used for the extraction of the more promising generalised relations. This subset $\overline{R_\Sigma}$ can be used for narrowing the search space of the following step. In fact, when the acceptance threshold is settled, the resultant admissible relations are confined in the following set:

$$\overline{R}(v) \widehat{=} \{r | \Sigma(r) \in \overline{R_\Sigma}(v)\} \qquad (8)$$

[1]Notice that, in syntactically meaningful contexts, arguments may appear with multiplicity higher than 1, so that the factorial expression is a useful approximation.

The overall domain importance estimation procedure may take also advantage from the fact that the order of the relation arguments may be fixed after the analysis of the promising syntactic patterns. The final counting activity can be thus performed with a simple sorting algorithm with the $O(n\ log(n))$ complexity. In this case n is directly related to the number of context samples in the corpus $C(v)$. The procedure is sketched in the following:

procedure SelectAndRankRelations($R(v)$,$C(v)$)
begin
Select $\overline{R_\Sigma}(v) = \{r \in R_\Sigma(v) | hits(r, C(v)) \geq K\ \}$;
Set $L = \emptyset$;
for each $r \in \overline{R_\Sigma}(v)$
$L := L \cup proj(\ C(v), r)$;
$RankedR\ \ (v)$:= CountEquals(L);
return $RankedR(v)\ \ ;$
end

where $hits(r, C(v))$ is the number of instances of the relation r in $C(v)$ e $prj(C(v), r)$ is the projection of the contexts in $C(v)$ on the syntactic relation r. The procedure $CountEqualsl(L)$ using a standard sorting algorithm counts the repetition of each element in L. Finally, $RankedR(v)$ is the set of couples (f, r) where f the frequency of the relation $r \in \overline{R}(v)$ on the corpus.

5. A case study: IE patterns for the financial domain

The above methodology has been applied for the definition of an ontology for a financial domain. The ontology construction steps have been followed. Firstly, an homogeneous collection of texts has been prepared as the model for the target domain, namely a collection of 13,000 news stories of the *Financial Time* over a period of time ranging from 2000 to 2001. The corpus will be hereafter called $FinTimeNews$. The analysis of the corpus has been carried out with the Chaos robust parser (Basili et al., 2000).

In the tables 1 and 2, excerpts of the lists related to the complex concepts and the relations governed by the verb *to make* are respectively shown. The lists are sorted according to their frequency in the *FinTimeNews* corpus (f in the tables). A manual assessed domain relevance is then reported (DR in the tables). The rate of the complex concepts retained as useful exceeds the 60% in the presented top 50 positions. It is worth noticing that many of the complex concepts that have not been judged important for the domain are in fact relevant time indicator. These are not useful for understanding the nature of the domain knowledge but they are precious in the perspective of a IE system for the characterisation of the time stamp of the event. Some of these expression such as `first_half` are in any case typical of the financial jargon, in particular they are used in the declaration of the companies' economic performance.

In the case of the relations governed by the verb *make*, the number of domain relevant relations in the top 50 is around 28%. The other presented relations are generally phraseological use of the same verb.

The sorted lists allows the definition of the top level hierarchy of the possible events in the financial domain.

Table 2: Relations governed by the verb *to make* in $FinTimesNews$

These have been defined as follows:

1. Relationships among companies
   (a) Acquisition/Selling
   (b) Cooperation/Splitting
2. Industrial Activities
   (a) Funding/Capital
   (b) Company Assets (Financial Performances, Balance Sheet Analysis)
   (c) Staff Movement (e.g Management Succession)
   (d) External Communications
3. Company Positioning
   (a) Position vs. the competitors
   (b) Market Sector
   (c) Market Strategies
4. Governamental Activities
   (a) Tax Reduction/Increase
   (b) Anti-trust Control
5. Job Market - Mass Employment/Unemployment
6. Stock Market
   (a) Share Trends
   (b) Currencies Trends

Once the definition of the top level events has been completed, the discovered event prototypes have been manually clustered according to their class. To give the flavour of the information contained in the produced knowledge base, in the following an excerpt of the event prototypes of the *Company Assets* class are presented:

Company Assets Event Prototypes
(cut,[(subj,entityNE),(dirobj,cost)]))
(rise,[(subj,profit),(to,currencyNE)])
(rise,[(from,currencyNE),(subj,profit),(to,currencyNE)])
(issue,[(subj,entityNE),(dirobj,profit_warning)]))
(suffer,[(subj,entityNE),(dirobj,loss)])
(report,[(subj,entityNE),(dirobj,loss_of_currencyNE)])
(announce,[(subj,entityNE),(dirobj,loss_of_currencyNE)])

The analysis of $1{,}100$ patterns give rise to 229 patterns retained as useful for the definition of the event prototypes in one of the give class.

6. Conclusions and future work

In this paper we presented a terminological perspective to the extraction of IE patterns. This corpus driven method is more suitable for a wide application of IE-based systems with respect to learning methods driven by the specific information need. The presented method helps in performing the activities required for building a domain ontology since the concepts and the relations are presented according to their relevance for the target domain.

Many issues are still open and are objective of further research. First of all, a more complete evaluation of the method should be performed with respect to the task of

event recognition. The acquired ontology should be evaluated in order to understand if the level of detail of the event prototypes is deep enough for the experts to classify the event prototypes in the correct class. Therefore, we intend to study the possibility of automatically cluster the event prototypes once the domain top level hierarchy has been defined. We will try here to adopt a booting algorithm and we will study the size of the necessary booting data. Finally, domain relations (i.e. IE patterns) not headed by verbs may be an interesting area of research.

Abstract

The Topic Detection and Tracking (TDT) benchmark evaluation project embraces a variety of technical challenges for information retrieval research. The TDT topic detection task is concerned with the unsupervised grouping of news stories according to the events they discuss. A detection system must both discover new events as the incoming stories are processed and associate incoming stories with the story clusters created so far. The TNO topic detection system is based on a language modeling approach. The system has been evaluated on a multilingual corpus of approximately 80.000 stories from multiple new sources. For the grouping of stories we combined a simple single pass method to establish an initial clustering and a reallocation method to stabilize the clusters within a certain allowed deferral period. The similarity of an incoming story S_n to an existing cluster C is defined as the average of the similarities of S_n to each story $S_i \in C$. These individual similarities are computed by taking the sum of the generative probabilities $P(S_n|S_i)$ and $P(S_i|S_n)$ where S_i and S_n are modeled as unigram language models. Because these story language models are based on extremely sparse statistics, the word probabilities are smoothed using a background model.

1. Introduction

This paper describes the design and development of a system for the unsupervised grouping of news stories according to the events they discuss. The system has been evaluated on an augmented version of the TDT3 corpus which contains approximately 80.000 stories from multiple news sources, including both text and speech. These sources are newswires, radio and television broadcasts, and internet sites. The source languages are English and Mandarin. The TDT3 corpus is annotated for 120 events, each of which spans both English and Mandarin sources.

The TNO topic detection system is based on a language modeling approach. We had good experience with the application of language models for different IR-related tasks, like ad hoc, cross language, web and spoken document retrieval (Hiemstra and Kraaij, 1999; Kraaij et al., 2000; Hiemstra et al., 2001; Kraaij et al., 2002), filtering (Ekkelenkamp et al., 1999), and multi-document summarization (Kraaij et al., 2001). We also successfully applied language models for topic tracking (Spitters and Kraaij, 2001). However, due to the substantially higher computational complexity of topic detection, it was not trivial to convert our tracking approach into a detection algorithm. In the topic tracking task, events are to be followed individually. Each target event is defined by a small set of training stories that discuss it. Our tracking system estimates a single unigram language model based on the union of these on-topic stories and computes for each incoming story the likelihood according to this topic model. The computational complexity of this process is linear to the input. However, the topic detection task is a highly dynamic process. The topic models are constructed on the fly from the incoming stories. Each incoming story is added to a cluster, and thus changes the corresponding topic model. Experiments showed that reclustering the already processed stories (within the allowed deferral window) is important for a good performance. Reclustering is a computationally demanding process, since every change in cluster membership lists is reflected in changes in the cluster models, which form the basis for the similarity computation. Therefore we have chosen for a clustering approach which is independent of the (global) cluster models and instead is based on the similarities between individual stories. The advantage of this approach is that the inter-story similarities can be cached, resulting in a significant speed-up of the clustering process.

The remainder of this paper is organized as follows. To familiarize the reader with the TDT framework, section 2 elaborates on the TDT corpora, the TDT research tasks, and the TDT evaluation method. In section 3 we describe in detail our language model-based approach to topic detection. This section also contains a short study into the influence of two different smoothing methods for language models on the detection performance of our system. In section 4 we try to draw some conclusions.

2. The TDT benchmark test

The topic detection and tracking (TDT) benchmark evaluation project[1] was initiated by DARPA in 1996. After a pilot study in 1997, TDT has continued with annual evaluations conducted by the National Institute of Standards and Technology (NIST). Main purpose of the TDT project is to advance the state-of-the-art in determining the topical structure of multilingual news streams from various sources. See (Wayne, 2000) for a detailed overview of the TDT project.

2.1. TDT corpora

Currently, the Linguistic Data Consortium (LDC) has three corpora available to support TDT research[2] (Cieri et al., 2000). The TDT-Pilot corpus contains newswire and

[1] http://www.nist.gov/speech/tests/tdt

[2] http://www.ldc.upenn.edu/Projects/TDT

transcripts of news broadcasts, all in English, and is annotated for 25 news events. The TDT2 and TDT3 corpora are multilingual (Chinese and English) and contain both audio and text. ASR transcriptions and close captions of the audio data as well as Systran translations of the Chinese data are also provided. TDT2 and TDT3 are completely annotated for 100 and 120 events respectively. Currently, LDC is developing a new TDT corpus (TDT4) which will include Arabic news.

In the TDT evaluation, there are three alternative choices for the form of the audio sources to be processed, namely manual transcriptions, ASR transcriptions, or the sampled audio signal. Three story boundary conditions are supported: reference story boundaries (manually determined correct boundaries), automatic story boundaries (automatically determined errorful boundaries), or no story boundaries (the system must provide its own boundaries). Sites that participate in one of the TDT tasks are required to perform at least one evaluation under shared conditions. See (Doddington and Fiscus, 2001) for the TDT evaluation details.

2.2. TDT research tasks

The TDT benchmark evaluation project embraces a variety of technical challenges for information retrieval research. The goal of *story segmentation* is to segment a stream of data into homogeneous regions, discussing certain events. Given a small number of stories that discuss a certain event, a *tracking* system has the task to detect which stories in the data stream are related to this event and which are not. In *topic detection* there is no knowledge of the events to be detected. A detection system must both discover new events as the incoming stories are processed and associate incoming stories with the event-based story clusters created so far. A task which is very similar to topic detection is *first-story detection*. The goal of this task is to detect, in a chronologically ordered stream of stories, the first story that discusses a certain event. Finally, in *link detection*, the question to be answered is whether or not two stories discuss the same event.

2.3. TDT evaluation method

Topic detection systems are evaluated in terms of their ability to cluster together stories that discuss the same event (or events and activities that are directly connected to the cluster's seminal event). Detection performance is characterized in terms of the probability of miss and false alarm errors (P_{Miss} and P_{FA}). To speak in terms of the more established and well-known precision and recall measures: a low P_{Miss} corresponds to high recall, while a low P_{FA} corresponds to high precision.

These two error probabilities are combined into a single detection cost C_{Det}, by assigning costs to miss and false alarm errors (Doddington and Fiscus, 2001):

$$C_{Det} = C_{Miss} \cdot P_{Miss} \cdot P_{target} + C_{FA} \cdot P_{FA} \cdot P_{\neg target} \quad (1)$$

where C_{Miss} and C_{FA} are the costs of a miss and a false alarm respectively; P_{Miss} and P_{FA} are the conditional probabilities of a miss and a false alarm respectively; P_{target} and $P_{\neg target}$ are the a priori target probabilities ($P_{\neg target} = 1 - P_{target}$).

Then C_{Det} is normalized to:

$$(C_{Det})_{Norm} = \frac{C_{Det}}{min(C_{Miss} \cdot P_{target}, C_{FA} \cdot P_{\neg target})} \quad (2)$$

Detection error probability is estimated by accumulating errors seperately for each topic and by taking the average of the error probabilities over topics, with equal weight assigned to each topic. A set of predefined topics is automatically mapped to the system output topics by choosing for each reference topic the system output topic which produces the lowest evaluation cost.

3. Design of a probabilistic topic detection system

This section describes in detail the design of the TNO topic detection system. 3.1. describes our clustering approach. We combined a simple single pass method to establish an initial clustering and a reallocation method to stabilize the clusters within a certain allowed deferral period. In 3.2. we describe our story-cluster similarity measure. An incoming story is compared to an existing cluster by averaging the similarities of the new story S_n to each story in the cluster S_i. These individual similarities are defined as the sum of the generative probabilities $P(S_n|S_i)$ and $P(S_i|S_n)$ where S_i and S_n are modeled as unigram language models. Because these story language models are based on extremely sparse statistics, the word probabilities are smoothed using a background model. Section 3.3. reports on our experiments concerning the application of two different smoothing methods for language models and some contrastive tests with automatic versus manually determined story boundaries.

3.1. Clustering method

Our clustering procedure combines a simple single pass method and a reallocation method. Because the clusters formed by the single pass method are dependent of the order in which the stories are processed, they are merely used to initiate reallocation clustering. However, because in the TDT evaluation a topic detection system may defer its assignment of stories until a limited amount of subsequent source data (10 source files) is processed, the reallocation is restricted to the stories within that deferral period. More specifically, our clustering process involves the following steps:

1. For each new story within the deferral window, compute its similarity to each cluster the system has created so far. There are two options for a story:
   (a) if the similarity of the story to the closest cluster exceeds a certain threshold, assign the story to that cluster
   (b) else create a new cluster with the concerning story as its seed

2. When the end of the deferral window is reached, loop through the window stories again and compare each story to each existing cluster. There are three options for a story:

   (a) a story may switch to another cluster if the similarity to that cluster exceeds both the similarity to its current cluster and the threshold

   (b) if neither the similarity to its current cluster nor the similarity to any other cluster exceeds the threshold, create a new cluster with the concerning story as its seed

   (c) if the similarity to its current cluster exceeds the threshold as well as the similarities to all other clusters, the story stays in its current cluster

   Step 2 is repeated until all clusters are stable, that is, when 2c is true for each story.

The combination of a cluster initialization step and a reallocation step has previously (successfully) been used for topic detection by a.o. BBN (Walls et al., 1999) and Dragon (Yamron et al., 2000).

The reclustering step is important for a good performance of the detection system. However, the fact that every change in a cluster membership list means that the cluster language model would have to be reestimated, makes it a computationally demanding process. Therefore we have chosen for an approach which does not use the global cluster language models (contrary to our topic tracking approach) but instead is based on the similarities between individual stories. The similarity of an incoming story S_n to an existing cluster C is defined as the average of the similarities of S_n to each story $S_i \in C$. The advantage of this approach is that the inter-story similarities can be cached, resulting in a significant acceleration of the clustering process. These inter-story similarities are computed using a two-way language modeling approach, which is discussed in detail in the following section.

A cluster which has not changed for an uninterrupted period of fifteen days is frozen, which means that it is no longer considered an 'active event'. The cluster is removed from the list of candidate clusters for new stories. This cluster evolution monitoring has two advantages. First of all it limits the computational complexity, because the number of clusters a story has to be compared with stays within certain bounds. Second, it can be argued that restricting the temporal extent of an event is beneficial for detection performance because it prevents different events with similar vocabulary (like different attacks or political elections) to be grouped together (Yang et al., 1999).

3.2. Language model-based similarity

The basic idea behind the language modeling approach to information retrieval is to estimate a (usually unigram) language model for each document and to rank documents by the probability that the document model generated the query. Absolute probabilities are not important for ranking in the IR situation. For other applications, i.e. topic tracking and also topic detection, scores have to be comparable on an absolute scale. For tracking, we found that modeling similarity as a likelihood ratio and normalizing this likelihood ratio by the (test) story length was adequate (Spitters and Kraaij, 2001). This normalized likelihood ratio is presented in equation (3), where $\mathrm{LLR}_{Norm}(T_1, T_2, ..., T_n|S_k)$ denotes the normalized log likelihood ratio of a story consisting of the terms $T_1, ..T_n$ given the story S_k in comparison with background model $\mathcal{B}$.

$$\mathrm{LLR}_{Norm}(T_1, T_2, ..., T_n|S_k) = \frac{1}{n} \log \sum_{i=1}^{n} \frac{P(T_i|S_k)}{P(T_i|\mathcal{B})} \quad (3)$$

In our clustering approach, the similarity between two stories S_n and S_i is based on a combination of the probability that the language model representing S_n generated story S_i and the reverse: the probability that the language model representing S_i generated story S_n. This approach results in the symmetrical similarity measure, presented in the following equation:

$$Sim(S_n, S_i) = \mathrm{LLR}_{Norm}(S_n|S_i) + \mathrm{LLR}_{Norm}(S_i|S_n) \quad (4)$$

Because the language models are estimated based on very limited amounts of text (single stories), it is very important that the word probabilities are smoothed using some background model. We performed a short study into the influence of two different smoothing methods on the performance of our detection system: Bayesian smoothing using Dirichlet priors and Jelinek-Mercer smoothing. The details of these smoothing methods and the results of our experiments are described in the following section.

3.3. Smoothing

Recent experiments at CMU have shown that different smoothing methods have different characteristics (Zhai and Lafferty, 2001a). For title ad hoc queries, Zhai and Lafferty found Dirichlet smoothing to be more effective than linear interpolation (Jelinek-Mercer smoothing). Both methods start from the idea that the probability estimate for unseen terms: $P_u(T_i|S_k)$ is modeled as a coefficient α_s times the background collection based estimate: $P_u(T_i|S_k) = \alpha_s \cdot P(T_i|\mathcal{B})$. A crucial difference between Dirichlet and Jelinek-Mercer smoothing is that the smoothing coefficient is dependent on the story length for Dirichlet, reflecting the fact that probability estimates are more reliable for longer stories. Formula (5) shows the weighting formula for Dirichlet smoothing, where $c(T_i|S_k)$ is the term frequency of term T_i in story S_k , $\sum_w c(T_i; S_k)$ is the length of story S_k and μ is a constant. The smoothing coefficient α_s is in this case $\frac{\mu}{\sum_w c(T_i;S_k)+\mu}$, whereas the smoothing coefficient is λ in the Jelinek-Mercer based model (formula (6)).

$$P(T_1, T_2, \cdots, T_n|S_k) = \prod_{i=1}^{n} \frac{c(T_i; S_k) + \mu P(T_i|\mathcal{B})}{\sum_w c(T_i; S_k) + \mu} \quad (5)$$

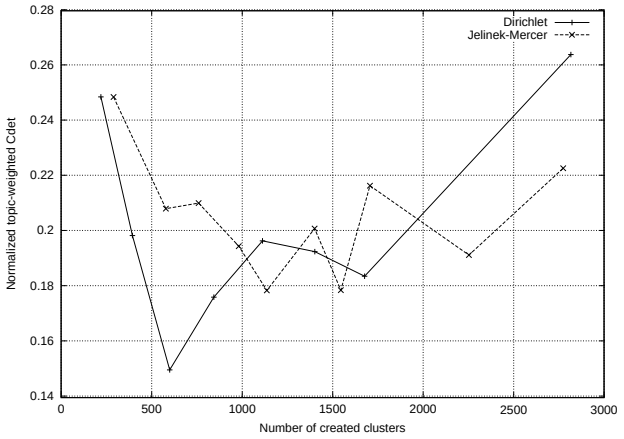

Figure 1: C_{Det} at different decision thresholds for two smoothing methods (Dirichlet and Jelinek-Mercer), performed on the TDT2 stories from April 1998, using automatic boundaries.

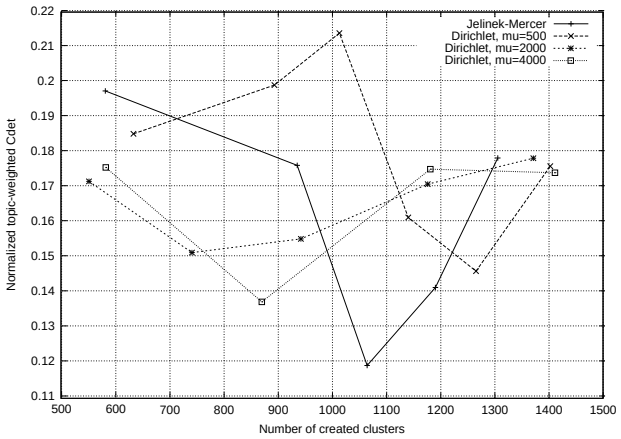

Figure 2: C_{Det} at different decision thresholds for two smoothing methods (Dirichlet and Jelinek-Mercer), performed on the TDT2 stories from April 1998, using reference boundaries.

$$P(T_1, T_2, \cdots, T_n|S_k) \;=\; \prod_{i=1}^{n} \lambda P(T_i|\mathcal{B}) + (1-\lambda) P(T_i|S_k) \tag{6}$$

For our official TDT2001 detection run, we applied Dirichlet smoothing with $\mu = 2000$. Our hypothesis was that Dirichlet smoothing would lead to improved performance, since story lengths vary considerably in the TDT corpus, and Dirichlet performed better than Jelinek-Mercer smoothing on a small test corpus (one month of stories from the TDT2 corpus) using the automatic story boundaries and ASR transcriptions of the audio (the primary topic detection evaluation requires these conditions). The results of this experiment are plotted in Figure (1).

We performed some post-hoc experiments on this same test set using reference story boundaries instead of automatic story boundaries and were surprised to find that Jelinek-Mercer performed better than Dirichlet under that condition, even when we varied μ (see equation (5)). Figure (2) shows the results. It is too early to draw conclusions from these experiments, since the test set was small and we did not explore the complete parameter space. However, one explanation could be the observation from Zhai and Lafferty (Zhai and Lafferty, 2001b; Zhai and Lafferty, 2001a) that smoothing has two functions: i) improving the maximum likelihood estimates ii) generate common words in the query. The latter function is especially important for longer queries since they contain more common words.

In the topic detection task we use language models to generate stories instead of queries. Since stories are considerably longer than TREC title queries, it is probably important that the smoothed model generates common words with proper "idf"-like probabilities. The TREC experiments show that the two roles of smoothing have an inverse interaction with the query length. Dirichlet is a good strategy for the first smoothing role (avoiding the assignment of a zero probability to an unseen word) while Jelinek-Mercer is better for the second role (weighting query terms in an idf-like fashion) (Zhai and Lafferty, 2001a). The longer the "queries" are, the more important the second function will become. This phenomenenon might be an explanation for the fact that Dirichlet performs best under the automatic story boundary condition, and Jelinek-Mercer under the reference story boundary condition, since the former has shorter stories than the latter (median: 62 versus 114). Further experiments are needed, including a validation of a combined Dirichlet/Jelinek-Mercer smoothing scheme for the TDT tasks.

4. Conclusions and future work

We think that the choice to use normalized likelihood ratios as the basis of a similarity measure was the key for the good performance of our system. Like in the tracking task, a proper normalized similarity measure is of utmost importance. Simply adding the generative probabilities $P(S_n|S_i)$ and $P(S_i|S_n)$ proved to work well to "symmetrize" the similarity measure. The accuracy of a language model-based clustering approach which is independent of the (global) cluster models and instead is based on the similarities between individual stories surpassed our expectations. However, we intend to check whether a similarity measure based on the global cluster model would enhance the results. The results of some initial post-hoc experiments indicate that the Jelinek-Mercer smoothing method works better than Dirichlet smoothing for manually segmented data, while the Dirichlet method yields better performance than Jelinek-Mercer on automatically segmented data. Further investigation is necessary to draw definite conclusions.

1. Current Situation in Stochastic Parsing

The earliest corpus-based approaches to stochastic parsing (e.g. Sampson et al. (1989), Fujisaki et al. (1989), Sharman et al. (1990), Black (1992)) used a variety of data resources and evaluation techniques. With the creation of the Penn Treebank of English (Marcus et al., 1993) and the parser evaluation measures established by the PARSEVAL initiative (Black, 1992), new approaches to stochastic parsing and uniform evaluation regimes emerged (Magerman (1995), Charniak (1996), Collins (1996)), leading to impressive improvements in parser accuracy (Collins (1997), Charniak (2000), Bod (2001)).

In the meantime, annotated corpora have been built for several other languages, most notably the Prague Dependency Treebank for Czech (Hajic, 1998), and the NEGRA corpus for German (Skut et al., 1997). Well-known, but smaller corpora for English are the ATIS Corpus and SUSANNE. Many more corpora are available or under construction, e.g. the Penn treebanks for Chinese and Korean, the TIGER corpus for German, as well as corpora for Bulgarian, French, Italian, Portugese, Spanish, Turkish, etc. Annotation schemes in these treebanks vary, often motivated by language-specific characteristics. For example, dependency-based annotation is generally preferred for languages with relatively free word order.

More recently, in line with increasing interest in more fine-grained syntactic and semantic representations, stochastic parsing has been applied to several higher-order syntactic frameworks, such as unification-based grammars (Johnson et al., 1999), tree-adjoining grammars (Chen et al., 1999) and combinatory categorial grammars (Hockenmaier, 2001). In parallel, due to the lack of appropriate large-scale annotated training corpora, unsupervised methods have been investigated, i.e. training of manually written (context-free or unification-based) grammars on free text (Beil et al. (1999), Riezler et al. (2000), Bouma et al. (2001)).

As opposed to the PARSEVAL measures — which are based on phrase structure tree match — most of these novel parsing approaches use other evaluation measures, such as dependency-based, valence-based, exact, or selective category match.

2. Challenges for Parser Evaluation

Despite the emergence of stochastic parsing approaches using alternative syntactic frameworks, the currently established paradigm for evaluating stochastic parsing still consists of the combination of Penn Treebank English (Section 23) with PARSEVAL measures.

However, in practice (especially if we count industrial labs) parsing systems using treebank grammars are not representative of the field. Moreover, a strong trend in stochastic parsing is away from treebank grammars and towards higher-level syntactic frameworks and hand-built grammars.

Research in stochastic parsing with higher-order syntactic frameworks is therefore confronted with a lack of a common evaluation metrics: neither do the PARSEVAL measures straightforwardly correspond to dependency structures or other valence-based representations, nor have these alternative approaches come up with a common, agreed-on standard for evaluation. Furthermore, no common evaluation corpora exist for many alternative languages. To some extent, this problem has been circumvented by building small theory-specific treebanks (with the obvious drawbacks for supervised training and inter-comparability). In sum, the growing field in stochastic parsing with alternative syntactic models or languages other than English faces problems in benchmarking against the established Gold Standard.

As a consequence, the best-known stochastic parsers are trained for Penn Treebank English. Yet, to validate these parsers on a broader basis, it has to be evaluated how well these stochastic models carry over to languages with e.g. free word order, intricate long-distance phenomena, pro-drop properties, and agglutinative or clitic languages. Again, this presupposes the availability of annotated corpora and evaluation schemes appropriate to cover a broad range of diverse language types.

3. Towards a New Gold Standard

The current situation in stochastic parsing, as well as prospects for its future development, calls for a new and uniform scheme for parser evaluation which covers both shallow and deep grammars, different syntactic frameworks, and different language types.

What is needed is an annotation scheme bridging structural differences across diverse languages and frameworks. In practice, many researchers have been using their own evaluation metrics which, despite divergences, bear some common ground, namely higher-level syntactic annotations such as grammatical relations, dependencies, or subcategorization frames (Beil et al. (1999), Carroll et al. (2000), Collins et al. (1999), Hockenmaier (2001), etc). Such basic syntactic relations build on crucial, but underlying structural constraints, yet provide more abstract, functional information.

This information is not only an appropriate level of abstraction to bridge structural differences between languages and higher-level syntactic theories, but moreover, provides a basis for evaluation of partial, more shallow analysis systems, at a higher level of representation. For example, if the evaluation is against grammatical relation rather than phrase structure information, partial parsers extracting functional relations can be evaluated within the same setup as full parsers.

Starting from this state of affairs, one of the aims of the workshop will be to provide a forum for researchers in the field to discuss (define and agree on) a new, uniform evaluation metric which provides a basis for comparison between different parsing systems, syntactic frameworks and stochastic models, and how well they extend to languages of different types.

Definition of a new evaluation standard could be restrictive and flexible at the same time: flexible in that training can exploit fine-grained annotations of richer syntactic frameworks; and restrictive in that diverging analyses are then to be mapped to uniform (more coarse-grained) annotations for standardized evaluation.

4. Starting an Initiative

A previous LREC-hosted workshop on parser evaluation in 1998 in Granada brought together a number of people advocating parser evaluation based on dependencies or grammatical relations (Carroll and Briscoe (1998), Lin (1998), Bangalore et al. (1998)). The consensus of the concluding discussion at that workshop was that there is much common ground between these approaches, and that they constitute a viable alternative to the PARSEVAL measures.

In the meantime, as described above, many more corpora are under construction and novel stochastic parsing schemes are being developed, which call for an initiative for establishing a new, agreed-on evaluation standard for parsing which allows for comparison and benchmarking across alternative models and different language types.

The workshop is intended to bring together four parties: researchers in stochastic parsing, builders of annotated corpora, representatives from different syntactic frameworks, and groups with interests in and proposals for parser evaluation. As a kick-off initiative, the workshop should lead to collaborative efforts to work out a new evaluation metric, and to start initiatives for building or deriving sufficiently large evaluation corpora, and possibly, large training corpora according to the new metric.

In conclusion, stochastic parsing has now developed to a stage where new methods are emerging, both in terms of underlying frameworks and languages covered. These need to be brought together by means of a new evaluation metric to prepare the new generation of stochastic parsing.

5. Workshop Programme

The workshop comprises thematic papers focussing on benchmarking of stochastic parsing, parser evaluation, design of annotation schemes covering different languages, and different frameworks, as well as creation of high-quality evaluation corpora.

Intended as a forum for discussion, the workshop programme consists of paper presentations with discussion sessions and a panel, where important results of the workshop are summarized and discussed.

In the final session we intend to wrap-up, and plan a kick-off initiative leading to concrete action plans and the creation of working groups, as well as planning for future coordination. To maintain the momentum of this initiative we will work towards setting up a parsing competition based on new standard evaluation corpora and evaluation metric.

Abstract

We describe extensions to a scheme for evaluating parse selection accuracy based on named grammatical relations between lemmatised lexical heads. The scheme is intended to directly reflect the task of recovering grammatical and logical relations, rather than more arbitrary details of tree topology. There is a manually annotated test suite of 500 sentences which has been used by several groups to perform evaluations. We are developing software to create larger test suites automatically from existing treebanks. We are considering alternative relational annotations which draw a clearer distinction between grammatical and logical relations in order to overcome limitations of the current proposal.

1. Introduction

We have developed a scheme for evaluating parse selection accuracy based on named grammatical relations between lemmatised lexical heads. The scheme is intended to directly reflect the task of recovering semantic relations, rather than more arbitrary details of tree topology—as with the PARSEVAL scheme, which has been criticised frequently for the opaque relationship between its measures and such relations (Carroll *et al.*, 1998; Magerman, 1995; Srinivas, 1997). Carroll *et al.* (1998) provide more detailed motivation and comparison with other extant schemes.

Carroll *et al.* (1999, 2002 in press) report the development of a test suite of 500 sentences annotated with grammatical relations, the specification of the relations, and their criteria of application. The set of named relations are organised as a subsumption hierarchy in which, for example, subj(ect) underspecifies n(on)c(lausal)subj(ect). There are a total of 15 fully specified relations, however, many of these can be further subclassified; for example, subj relations have an initial-gr slot used to encode whether the syntactic subject is logical object (as in passive) and for other marked subjects (such as in locative inversion). Thus a fully specified GR might look like (ncsubj marry couple obj) to encode the subj relation in *The couple were married in August*, and the GR annotation of each sentence of the test suite consists of a set of GR *n*-tuples. Figure 1 gives the full set of named relations represented as a subsumption hierarchy. The most generic relation between a head and a dependent is dependent. Where the relationship between the two is known more precisely, relations further down the hierarchy can be used, for example mod(ifier) or arg(ument). Relations mod, arg_mod, aux, clausal, and their descendants have slots filled by a type, a head, and its dependent; arg_mod has an additional fourth slot initial_gr. Descendants of subj, and also dobj have the three slots head, dependent, and initial_gr. Relation conj has a type slot and one or more head slots. The x and c prefixes to relation names differentiate clausal control alternatives.

When the proprietor dies, the establishment should become a corporation until it is either acquired by another proprietor or the government decides to drop it.

```
(ncsubj die proprietor _)
(ncsubj become establishment _)
(xcomp _ become corporation)
(ncsubj acquire it obj)
(arg_mod by acquire proprietor subj)
(ncmod _ acquire either)
(ncsubj decide government _)
(xcomp to decide drop)
(ncsubj drop government _)
(dobj drop it _)
(cmod when become die)
(cmod until become acquire)
(cmod until become decide)
(detmod _ proprietor the)
(detmod _ establishment the)
(detmod _ corporation a)
(detmod _ proprietor another)
(detmod _ government the)
(aux _ become shall)
(aux _ acquire be)
(conj or acquire decide)
```

Figure 2: Grammatical relation sample annotation.

Figure 2 shows the GR encoding of a sentence from the Susanne corpus.

The evaluation metric uses the standard precision and recall and F_α measures over sets of such GRs. Carroll and Briscoe (2001) also make use of weighted recall and precision (as implemented in the PARSEVAL software) to evaluate systems capable of returning *n*-best sets of weighted GRs. The software makes provision for both averaged scores over all relations as well as scores by named relation. It also supports partial scoring in terms of non-leaf named relations which underspecify leaf relations. The current specification of the

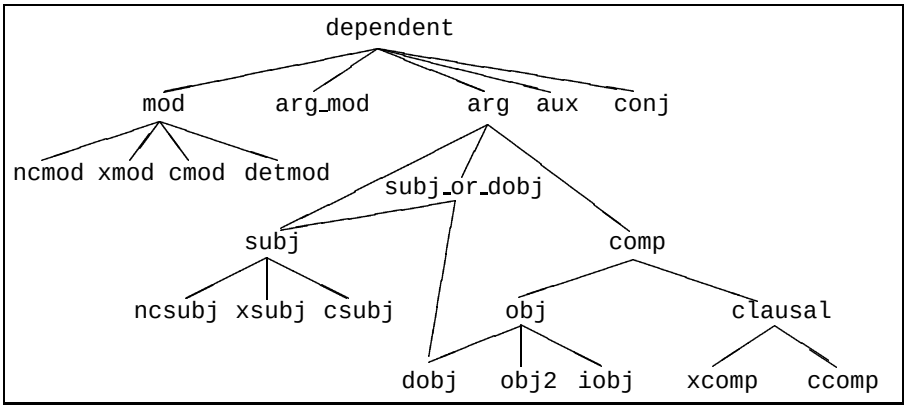

Figure 1: Grammatical relation hierarchy.

scheme along with the test suite and evaluation software (implemented in Common Lisp) is available from http://www.cogs.susx.ac.uk/lab/nlp/carroll/greval.html

Evaluation of stochastic parsers using relational schemes similar to our proposal is becoming more common (e.g. Collins, 1999; Lin, 1998; Srinivas, 2000). However, comparison across such results is hampered by the fact that the set of relations extracted is not standardised across these schemes, and it is clear that some relations (e.g. that between determiners and head nouns) are much easier to extract than others (e.g. control relations in predicative complements), as can be seen, for example, from the separate and divergent precision / recall results by named relation reported by Carroll *et al.* (1999). This makes meaningful comparison of 'headline results' such as mean overall F_1 measures very hard. Our scheme attempts to ameliorate these problems by supporting different levels of granularity within named relations (ncsubj / csub / xsubj $\subset$ subj) and encouraging not only the reporting of overall mean precision / recall scores, but also separate scores for each named relation.

In the rest of this paper we describe ongoing efforts to improve the evaluation scheme and enlarge the annotated test suite(s).

2. Divergent system output representations

There remain several infelicities in the current scheme that are a consequence of the method of factoring information into distinct relations which, in fact, still encode composites of information. For example, a system which clearly separates categorial constituency and functional information, such as one based on LFG, might choose to map F-structure SUBJ relations to subj in our scheme. A more constituency based parser might map NPs immediately dominated by S and preceding a VP to ncsubj, and Ss in the same configuration to csubj. Superficially the latter system is extracting more information because the relation name encodes categorial as well as relational information. The current scoring metric also assigns a penalty to systems that do not recover fully-specified (leaf) relations. However, for either system to score in the evaluation the subj relation most hold between lemmatised heads of the appropriate type, so the distinction between clausal and non-clausal subjects is maintained in both, since clausal subjects have verbal heads. On the other hand a system which systematically returned subj-or-dobj relations, as opposed to a leaf subj or obj one, would clearly be losing significant information pertinent to recovery of underlying logical relations.

There are many other cases of divergent encoding of aspects of categorial and functional information: for example, a LFG system will clearly distinguish clausal and predicative complements at F-structure corresponding directly to the xcomp / ccomp distinction in our relational scheme. However, a parser that represents such complements as clauses (S nodes) with or without an empty (PRO) NP subject, as in the Penn WSJ Treebank, would need to utilise a more complex (non-local) mapping from tree topology and node labels to named relations in order to maintain the xcomp / ccomp distinction. However, in this case, the easier underspecification to comp is genuinely significant since in either case the relation will hold between the same lexical (verbal) heads.

There are, in principle, two ways of dealing with such divergences. The first is to complicate the mapping from system output to named relations so that the specific set of leaf relations identified in the current scheme is recovered, if it is deducible from the total system output. The second is to modify the scoring metric so that informationally insignificant underspecification is not penalised. In some cases, such as the LFG system SUBJ case described above, the latter step will be much easier. In the new version of the specification and evaluation measure, we will attempt to identify such cases and parameterise the evaluation software to compute scores appropriately, as well as provide more specific guidance on mapping of named relations to the output of extant systems. This should improve the validity of cross-system evaluation. However, problems of this type are likely to emerge for each new system representation considered, so this is likely to be an ongoing process requiring judgement on the part of evaluators coupled with explicit description of decisions made alongside reported socres.

Provision of a flexible software system for mapping from parser output representations to factored relational ones may also ameliorate this class of problems (see section 5.). In particular, where a specific choice of system output representation necessitates a more complex mapping to leaf relations in our scheme, it would facilitate fair and

feasible cross-system comparison if the evaluation scheme provided software that would recover the named leaf relations from the system output. Once again, each new system representation is likely to throw up new problems of this type, so flexible and easily parameterisable software will be more useful.

3. Surface / logical form divergence

The current annotation scheme attempts to stay close to surface grammatical structure, while also encoding divergence from predicate-argument structure / logical form. Divergence is currently encoded using two distinct mechanisms for different types of cases. Extra slots in named relations are used to indicate surface / underlying logical relation divergences, as with subj discussed in section 1. An additional relation is used for coordination (conj) to indicate how the conjunction scopes over the individual conjuncts.

One conspicuous area where the current scheme is inadequate is with equative and comparative constructions, which occur quite frequently in the 500 sentence test suite. Semantically, it is standard to treat *more* and *as*, etc as generalised quantifiers over propositions so that an example like

> *GR evaluation is more / as attractive than / as PARSEVAL*

is represented (very crudely) as

> more′(is-attr′(GReval′), is-attr′(PARSEVAL′))

This example, however, is annotated by the GRs

> (ncmod _ attractive more)
> (ncmod than attractive PARSEVAL)

However, in general, the GR annotation of such constructions is variable because of the varied surface syntactic location of *more* and *as* and also because of the optionality of and degree of ellipsis in the *than / as* constituent. Furthermore, because of the divergence between surface form and logical form the current annotations give little indication of whether a system would be capable of outputting an appropriate logical form. Replacing the current annotation with one close to the target logical form would undermine the scheme, since most extant stochastic parsers would be unable to generate such a representation.

One alternative is to additionally annotate such constructions with construction-specific named relations. This could be based on the approach to coordination, where the named relation

> (conj conj-type conjunct-heads+)

is used in addition to distributing the conjunct heads over multiple occurrences of the relation over the coordinate construction. For comparatives and equatives, we could add a relation like

> (compequ as/more/... attractive GReval PARSEVAL)

encoding the type of comparison, the predicate of comparison, and the arguments to this predicate.

There are undoubtedly further constructions, beyond coordination and comparatives / equatives that merit some such treatment. The advantage of adding additional construction-specific named relations that encode the same phenomena from different perspectives is that the resulting annotation will support a graded and fine-grained evaluation of the extent to which a specific system can support recovery of underlying logical form / predicate-argument structure in addition to surface grammatical relations. The disadvantage of this approach is that the scheme is likely to become more complex, and thus its recovery from any specific parser representation more time-consuming. In addition, the encoding of the underlying logical relations in the GR scheme has already spawned two divergent mechanisms, and may well require more.

4. MRS-style annotation scheme

A second and more complex but potentially more thorough approach to the issue of surface / logical form divergence is to bleach the current GR scheme of all attempts to represent such mismatches and instead define a factored and underspecified semantic annotation scheme to be used in tandem with GR annotation. The approach to underspecified logical representation developed by Copestake *et al.* (2001) can be extended to allow semantics to be underspecified to a much greater degree. In this extension of minimal recursion semantics (MRS), a Parsons-style notation (Parsons, 1990) is used, with explicit equalities representing variable bindings. For instance, from

> *The couple were married.*

a particular parsing system might return

> (ARGN u1 u2)
> (marry u3)
> (couple u4)

However, the fully specified test suite annotation would be

> (ARG2 e1 x4)
> (marry e2)
> (couple x3)
> e1 = e2
> x3 = x4

where ARG2 is formally a specialisation of ARGN, and the equalities and variable sorts also add information.

Potentially, this would allow us to dispense with complications like init-gr fields in the GR annotation and provide a principled basis for a graded evaluation of the recovery of logical form. The disadvantage over the further extension of the existing scheme is that two stages of extraction from specific system output are now required, the matching operations and scoring metrics become more complex, and the ability to do a graded evaluation of recovery of both grammatical and logical relations may be somewhat undermined.

```
try
  {
   while (dd)
    {
     String s = readWord(W);
     setS += 1;

     if (c==0) dd = false;

     if (s.equals("S"))
      {
       if (domprecedes("S", "NP",
                       "VP", setS))
        { String head = mainverb(setvp);
          String dependent =
            righthead("NP", "N-", setnp);
          String objslot =
            ispassive(setvp);
          System.out.println(
                   "(ncsubj " + head + "
                   " + dependent + "
                   " + objslot + ")");
        }
       }
    }
  }
```

5. Enlarging and improving the test suite(s)

The current test suite of 500 sentences is too small, but was still labour-intensive to create semi-automatically. Consequently, it contains a number of inadequacies: tokenisation of multiwords is somewhat arbitrary, some relations which should be included are systematically omitted (e.g. predicative XP complements of *be* have not been annotated with their controlled subjects), quotation marks have been systematically removed, and so forth. The next release will attempt to remove these inadequacies. However, it is clear that we also need a method for annotating much more data efficiently. To this end we have been developing a generic system, implemented in JAVA, that can be applied to existing treebanks to extract relational information (Graham, 2002). This system can, in principle, extract GRs in the current or related schemes, or even (possibly underspecified) MRSs. It can be parameterised for different extant treebanks, such as Penn Treebank-II or Susanne, and requires a set of declarative rules expressed in terms of tree topology and node labels for each named relation. The system has been designed to process labelled trees looking for relations defined ultimately in terms of (immediate) dominance and (immediate) precedence efficiently. It has been tested on a subset of GRs, concentrating particularly on the subj sub-hierarchy. A fragment of the class for ncsubj encoding relevant constraints is shown in Figure 3, giving a sense of the degree of parameterisation required for different representations. Running a first prototype of the GR extractor on the 30 million word automatically annotated WSJ BLLIP corpus distributed by the LDC results in estimated recovery of 86% of ncsubj and dobj relations with a precision of 84%, taking around 3 hours CPU time on standard hardware.

This system will facilitate rapid automatic construction of relational annotation according to specified input and output scheme(s) up to the limit of what is currently represented in treebanks and system output. Our longer term plan is to make this software, and a number of rule sets implemented in it, available as part of the evaluation scheme. This should facilitate both the construction of test data and the mapping of system output to the required format.

6. Conclusions

Relational schemes for parser evaluation are gaining in popularity over the exclusive use of PARSEVAL or similar tree topology based measures. We hope that the ongoing work reported here will facilitate further cross-system and within-system relational evaluation. To this end, we are developing test suites and software to support flexible mapping from system and treebank output to relational encodings of grammatical and underlying logical relations, and actively seeking feedback from the community on weaknesses of our current encoding scheme and evaluation measures and errors in our current test set.

Acknowledgements

We would like to thank Ron Kaplan for carefully documenting many errors and inconsistencies in our semi-automatic annotation of the 500 word test suite. The GR encoding scheme was heavily influenced by the EAGLES encoding scheme, primarily developed by Antonio Sanfilippo. We would also like to thank Anne Abeillé and Srinivas Bangalore for useful discussions. This work was partially supported by the EPSRC-funded RASP project (grants GR/N36462 and GR/N36493).

Abstract

Quantitative evaluation of parsers has traditionally centered around the PARSEVAL measures of *crossing brackets, (labeled) precision,* and *(labeled) recall*. However, it is well known that these measures do not give an accurate picture of the quality of the parser's output. Furthermore, we will show that they are especially unsuited for partial parsers. In recent years, research has concentrated on dependency-based evaluation measures. We will show in this paper that such a dependency-based evaluation scheme is particularly suitable for partial parsers. TüBa-D, the treebank used here for evaluation, contains all the necessary dependency information so that the conversion of trees into a dependency structure does not have to rely on heuristics. Therefore, the dependency representations are not only reliable, they are also linguistically motivated and can be used for linguistic purposes.

1. Introduction

Quantitative evaluation of parsers has traditionally centered around the PARSEVAL measures of *crossing brackets, (labeled) precision,* and *(labeled) recall* (Black et al., 1991). However, it is well known that these measures do not give an accurate picture of the quality of the parser's output (cf. Manning and Schütze (1999)), e.g. in cases of attachment errors. Additionally, many phenomena like negation or unary branches are ignored in the original measures in order to allow a comparison between parsers that use incompatible grammars. For this reason, research in recent years has concentrated on dependency-based evaluation measures (cf. e.g. Lin (1995), Lin (1998)). We will show in this paper that such a dependency-based evaluation scheme is particularly suitable for partial parsers since it does not lead to disproportionately high losses in precision and recall for partial parses. Furthermore, the dependency representations are not only reliable, they are also linguistically motivated and can be used for linguistic purposes since the treebank used here for evaluation contains all the necessary dependency information.

2. Deficiencies of Constituency-Based Precision and Recall

It is a well known fact that the PARSEVAL measures do not always give an accurate picture of the quality of a parser's output. Carroll and Brisoce (1996), for example, note that the *crossing brackets* measure is too lenient in case of errors involving the disambiguation of arguments and adjuncts, which in some cases are not recognized as errors. The failure to attach a constituent which should be embedded n levels deep leads to n crossing errors, while this constituent may not be very important to the overall structure. Manning and Schütze (1999) show that this behavior is mirrored in *precision* and *recall*: If a constituent is attached very high in a complex right branching structure, but the parser attached it at a lower point in the structure, both precision and recall will be greatly diminished. An example of such a parsing error for the sentence "ich nehme den Zug nach Frankfurt an der Oder" (I will take the train to Frankfort on the Oder) is shown in Figure 1[1]. There the prepositional phrase "an der Oder" is erroneously grouped as an adjunct of the verb instead of being attached as a postmodifier to the noun phrase "nach Frankfurt" (cf. the following section for a description of the annotation scheme). The correct tree is shown in Figure 2. When using the PARSEVAL measures, the output of the parser shown in Figure 1 results in $10/13 = 76.92\%$ recall[2] and $10/12 = 83.33\%$ precision, the only error being the wrong attachment of the last prepositional phrase.

The same behavior can be observed when the parser attaches a constituent very high in a complex right branching structure instead of very low, or if the constituent is not attached at all. The latter is often the case for chunk parsers (Abney, 1991; Abney, 1996) or partial parsers (cf. e.g. Aït-Mokhtar and Chanod (1997)). These parsers generally aim at annotating only partial, reliably discoverable tree structures, i.e. base phrases and clausal structures. Postmodifications are generally not attached since this decision cannot be taken reliably based on very limited local context. TüSBL (Kübler and Hinrichs, 2001a; Kübler and Hinrichs, 2001b), e.g., a similarity-based parser for German, annotates syntactic structures including function-argument structure in a two-level architecture: in the first phase, a deterministic chunk parser (Abney, 1996) is used to anal-

[1] All syntactic trees shown in this paper follow the data format for trees defined by the NEGRA project of the Sonderforschungsbereich 378 at the University of the Saarland, Saarbrücken. They were printed by the NEGRA graphical annotation tool *Annotate* (Brants and Skut, 1998; Plaehn, 1998).

[2] Contrary to the original PARSEVAL measures, we do count the root node as well since there exist different root nodes in the annotation scheme, and there are cases when a sentence in the treebank is annotated with more than one tree (e.g. interjective utterances).

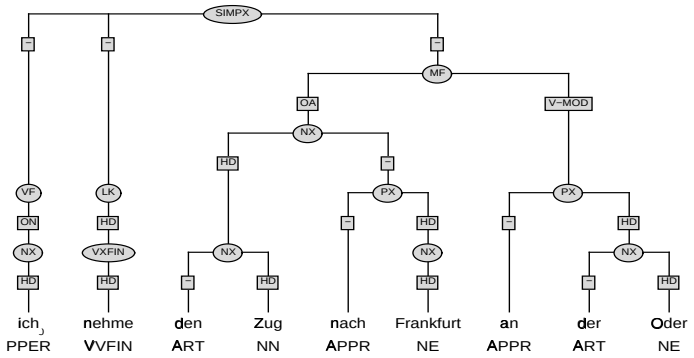

Figure 1: Wrong attachment of the prepositional phrase “an der Oder”.

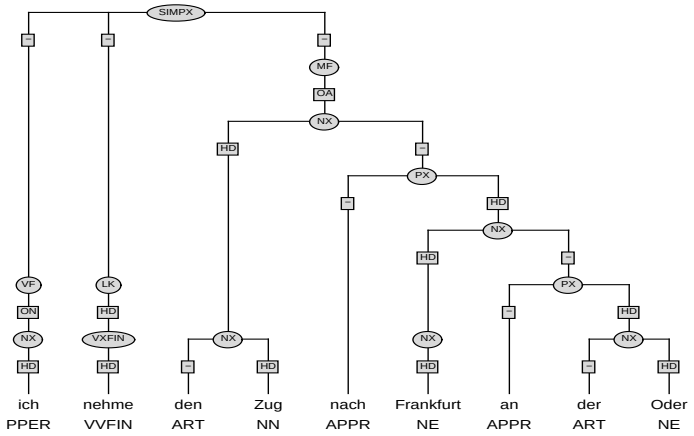

Figure 2: Correct attachment of the prepositional phrase “an der Oder”.

yse major syntactic constituents such as non-recursive base phrases and simplex clauses. As a consequence, dependency relations between individual chunks, such as grammatical functions or modification relations, within a clause remain unspecified. In the second step, the attachment ambiguities are resolved, and the partial annotation of the first step are enriched by dependency information. A typical output of this phase is shown in Figure 3. The second phase of analysis is based on a similarity-based machine learning approach, which uses a similarity metric to retrieve the most similar sentence to the input sentence from the instance base and adapts the respective tree to the input sentence. (For a more detailed description of the algorithm cf. Kübler and Hinrichs (2001a) and Kübler and Hinrichs (2001b).) The parser is designed to prefer partial analyses over uncertain ones. In some cases, this strategy leads to unattached phrases, mostly at the end of sentences, which results in high losses in precision and recall. We therefore propose to use a dependency-based evaluation as described by Lin (1995) and Lin (1998), in which both the gold standard and the parser’s output are transformed into dependencies and then compared on the basis of dependencies rather than on the basis of the constituent structure.

3. The TüBA-D Treebank

The dependency-based evaluation was based on the German corpus TüBa-D (Stegmann et al., 2000; Hinrichs et al., 2000a; Hinrichs et al., 2000b), which consists of approximately 38,000 syntactically annotated sentences. For this treebank, a theory-neutral and surface-oriented annotation scheme has been adopted that is inspired by the notion of topological fields – in the sense of Herling (1821), Erdmann (1886), Drach (1937), Reis (1980), and Höhle (1985) – and enriched by a level of predicate-argument structure, which guides the conversion into dependencies. The linguistic annotations pertain to the levels of morpho-syntax (part-of-speech tagging) (Schiller et al., 1995), syntactic phrase structure, and function-argument structure.

The tree structure contains different types of syntactic information in the following way: As the primary clustering principle the theory of topological fields (Höhle, 1985) is adopted, which captures the fundamental word order regularities of German sentence structure. In verb-second sentences, the finite verb constitutes the left sentence bracket (LK) and the verb complex the right sentence bracket (VC). This sentence bracket divides the sentence into the following topological order of fields: initial field (VF), LK, middle field (MF), VC, final field (NF). This structuring concept in addition favors bracketings that do not rely on crossing branches and traces to describe discontinuous dependencies.

Below this level of annotation, i.e. strictly within the bounds of topological fields, a phrase level of predicate-argument structure is established with its own descriptive

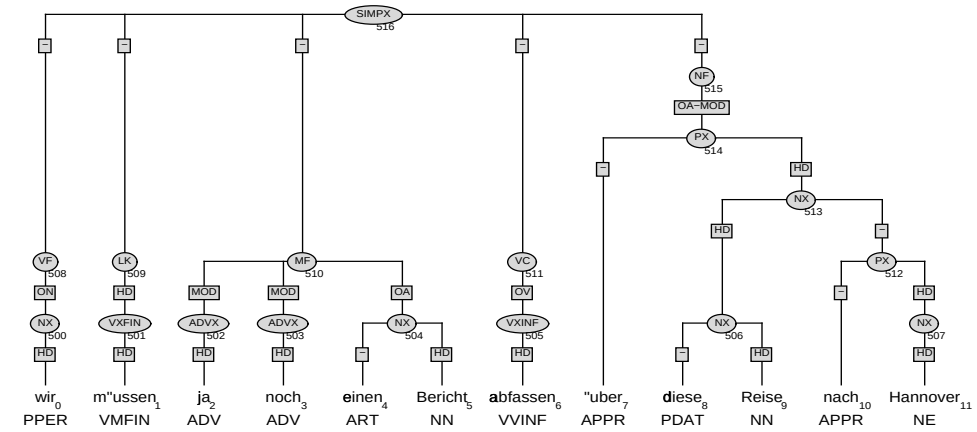

Figure 3: A tree annotated according to the TüBa-D treebank annotation scheme.

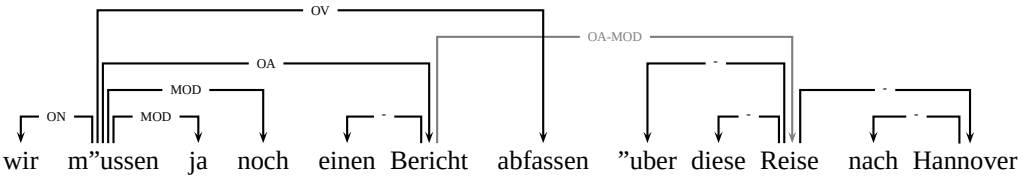

Figure 4: The dependency structure of the tree in Figure 3. The crossing dependency is shown in gray.

inventory based on a minimal set of assumptions concerning constituenthood, phrase attachment, and grammatical functions that have to be captured by any syntactic theory: nodes are labeled with syntactic categories on four different levels of annotation (sentence level, field level, phrase level, and lexical level), edges denote grammatical functions on the phrase level (i.e. immediately below the topological fields) and head/non-head distinctions within phrases. The integrated constituent analysis with its information about grammatical functions ensures that the resulting dependency structures are linguistically motivated and can also be used for linguistic purposes.

An example of such a tree for the sentence "wir müssen ja noch einen Bericht abfassen über diese Reise nach Hannover" (we still need to write a report on this journey to Hanover) is shown in Figure 3 (for more information about the annotation scheme cf. Stegmann et al. (2000)).

Two specific edge labels denote whether a constituent has the function of a head (HD), e.g. a phrase (NX, PX, ADJX, ADVX, VXFIN, VXINF), or a non-head (-), e.g. a determiner or a modifier attached to a phrase. On any annotation level, there is at most one head. The head of a sentence structure (e.g. SIMPX) is always the finite verb, which can be found in the left sentence bracket (LK). If there is no LK, the head is represented by the finite verb in the verb complex (VC). In coordinations, each conjunct depends on the head of the whole construction. Therefore, conjuncts are denoted with the non-head edge label.

The constituents below the topological fields are assigned grammatical functions. A subset of the edge label set consists of labels denoting the grammatical function of complements and modifiers, which depend on the head of the sentence. Another subset consists of labels determining long distance dependencies among these complements or modifiers as well as between conjuncts of split-up coordinations.

In Figure 3, e.g., the first constituent is marked as subject (ON), the finite verb is the head (HD), the two adverbs are modifiers (MOD), and the second noun phrase represents the direct object (OA). The constituent following the verb complex modifies the direct object (OA-MOD). Since the annotation scheme for the TüBa-D treebank facilitates a theory-neutral and surface-oriented representation of syntactic trees, this long distance relation is marked by the label OA-MOD (modifier of the accusative object) which refers to OA (accusative object) in the same tree; instead of using crossing branches and traces. This shows that long distance dependencies, which can even go beyond the border of topological fields, are encoded by special naming conventions for edge labels. Unambiguous edge labels, referring to exactly one non-adjacent constituent in the same tree, are used either for long distance modifications (*X*-MOD) like in the example above or for the rightmost conjunct of split-up coordinations (*X*K) (for an example cf. Figure 5). In both patterns, *X* is a variable for the grammatical function of the constituent to which it refers.

4. Converting TüBa-D into Dependencies

For TüBa-D, the conversion of the constituent structure into dependencies is in general determined by the head/non-head distinction in the tree. The dependency relations are labeled with the functional labels of the governed constituents. Using these strategies, the tree shown in Figure 3 is converted into the dependency structure in Figure 4. Here, the noun phrase "einen Bericht" is converted into one dependency relation, which denotes that the noun "Bericht"

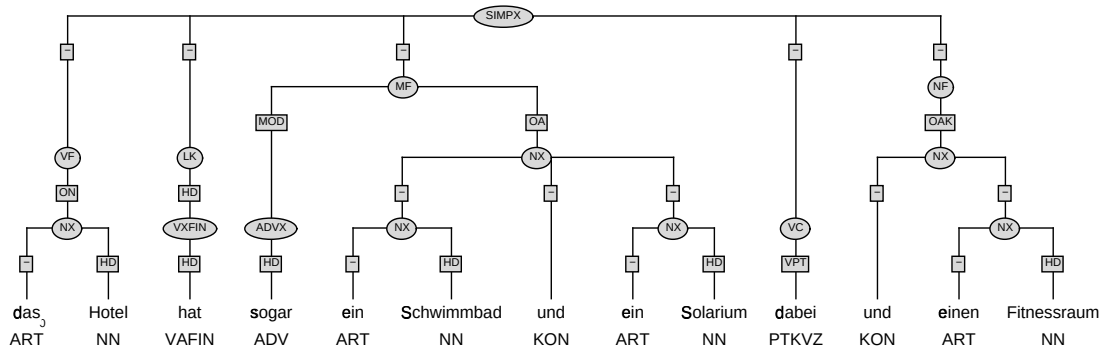

Figure 5: A complex coordination of noun phrases.

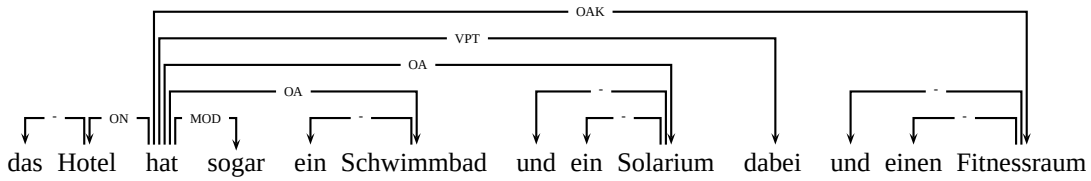

Figure 6: The dependency structure of the tree in Figure 5.

governs the article “den”.

It is evident that the dependency structure contains two different types of dependencies: head/non-head dependencies within phrases (-) and dependencies from the finite verb, i.e. from the head of the clause, to its complements and adjuncts, which are labeled by the grammatical functions of the governed constituents (ON, MOD, OA, OV). This is why e.g. the direct object “einen Bericht” is represented as a dependent of the modal verb “müssen” although it constitutes an argument of the embedded main verb “abfassen”. However, the dependency relations among the finite verb and the (possibly multiple) infinite verbs is explicitly annotated in the syntactic and therefore in the dependency structure. And since information about clausal boundaries is present in the trees, even in this surface-oriented structure, the predicate-argument structure can be recovered.

The long-distance dependency between the direct object and its modifying prepositional phrase was modeled in the syntactic tree by the function label “OA-MOD” instead of by the attachment of the prepositional phrase to the direct object because the latter would have resulted in a *crossing branch*. In the dependency structure, this restriction is suspended, and the dependency is explicitly marked and has now resulted in crossing dependencies. Note that this is the only type of phrase-internal dependency that is not labeled by the head/non-head distinction but by unambiguous labels which denote their specific reference.

Since head information is present on all levels for the majority of constituents, specific decisions for determining dependency have to be taken only in the few cases when dependency relations are not clearly defined in the tree structure, i.e. for the following syntactic phenomena:

1. Conjunctions within coordinations do not depend on the head of the whole construction. Therefore, they are attached to the conjunct on their right hand side. An example of such a coordination is shown in Figure 5, the corresponding dependency structure in Figure 6. Here, the third conjunct is positioned after the verb complex and thus is assigned the label “OAK”.
   Similar constructions with a preposition instead of a conjunction like “der achte bis neunte” (the eighth until the ninth) are treated in the same way. In order to stress the identical syntactic status of conjuncts, all conjuncts depend on the head governing the coordination. This analysis is in contrast to Lin (1998), who relies on the *Single Head Assumption* and proposes a dependency relation between the first and the second conjunct.

2. Sentence-initial coordinative particles such as “und” (and) or “oder” (or) in the KOORD-field depend on the head of the sentence.

3. The annotation of prepositional phrases in the syntactic trees is based on the principles of Dependency Grammar (Heringer, 1996); therefore, the noun phrase constitutes the head. For an example of the dependency structure of a prepositional phrase cf. the phrase “nach Hannover” in Figure 4. Circumpositions and postpositions are treated similarly.

4. The single elements of proper names, split cardinal numbers, the spelling of words, and complex conjunctions in the C-field, e.g. “so daß” (so that), are attached on the same level carrying a non-head edge label to indicate that there is no obvious dependency relation between them. Therefore, they are treated like conjuncts in coordinations.

5. A heuristic analysis has to be applied when long distance relations are underspecified – a MOD-MOD la-

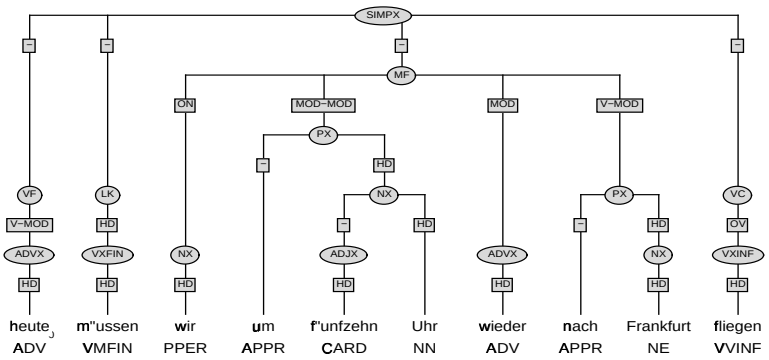

Figure 7: An ambiguous long-distance modifier: MOD-MOD.

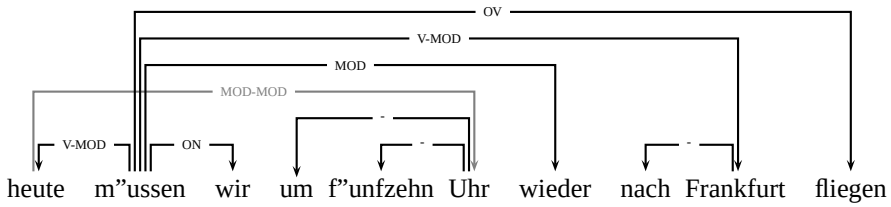

Figure 8: Resolved dependencies for ambiguous long-distance modifiers. The crossing dependency is shown in gray.

bel (modifier of a modifier), e.g., may refer to one of several modifiers in the sentence, such as for the sentence “heute müssen wir um fünfzehn Uhr wieder nach Frankfurt fliegen” (today we need to fly again to Frankfort) in Figure 7. Here, the long-distance modifier MOD-MOD might modify the V-MOD “heute” or the V-MOD “nach Franfurt”. A close inspection of such ambiguous sentences in TüBa-D revealed that in a majority of all cases, the MOD-MOD label refers to the first V-MOD in the clause, or the first MOD if there is no V-MOD present. Exceptions to this rule are MOD-MODs in resumptive constructions, which generally refer to the modifier in the VF. Ambiguous OA-MODs generally refer to the closest OA in the clause. By applying these heuristics, the ambiguities are resolved in the dependency structure, as shown in Figure 8 for the syntactic tree in Figure 7.

5. Dependency-Based Parser Evaluation

Lin (1998) proposed a procedure for converting syntactic trees from the gold standard and from the parser into dependency structures. From these structures, precision and recall are calculated.

Another similar evaluation procedure was suggested by Srinivas et al. (1996), they first convert hierarchical phrasal constituents into chunks, and then compute the dependencies between these chunks. This is a valid approach for the Penn treebank annotation style, which assumes a complete flat annotation of complex noun phrases such as noun compounds. Parsers based on manually developed rules tend to assign more internal structure to such noun phrases, which leads to decreased precision. Reducing such phrases to flat chunks alleviates this problem of comparing these different structures. The TüBa-D annotations, however, assign more complex, non-trivial structures to complex noun phrases. Using the method of Srinivas et al. (1996) would therefore lead to a significant loss in information. Additionally, the flattening of phrases into chunks might introduce errors in the data in such cases, in which the conversion into chunks is not obvious, such as for the noun phrase “wichtige Konferenzen und Besprechungen” in the sentence “da haben wir noch wichtige Konferenzen und Besprechungen” (we still have important conferences and business meetings) shown in Figure 9.

Basili et al. (1998) developed a similar approach for the Italian language. But instead of parsing a sentence completely and then reducing this parse to chunks and dependencies between chunks, Basili et al. apply a chunk parser combined with a module that calculates dependencies between these chunks. For this approach, the same restrictions hold as for the evaluation procedure of Srinivas et al. (1996).

The evaluation method presented here is based on Lin’s (Lin, 1998) approach. Following Lin’s procedure, we first convert both the gold standard tree and the parser’s output into dependency structures and compare these by applying (labeled) precision and (labeled) recall to these dependency structures.

TüSBL’s analyses depend heavily on the syntactically annotated sentences contained in the instance base. It is therefore difficult to give examples of errors for specific sentences or linguistic phenomena. It is, however, possible to characterize the typical behavior of the parser and give typical examples of errors.

Attachment errors. Attachment errors as described in Section 1. are not very common for TüSBL. Since TüSBL uses the complete sentence as context to retrieve the most similar tree, it either finds the correct spanning analysis or it does not attach all constituents. In the few cases

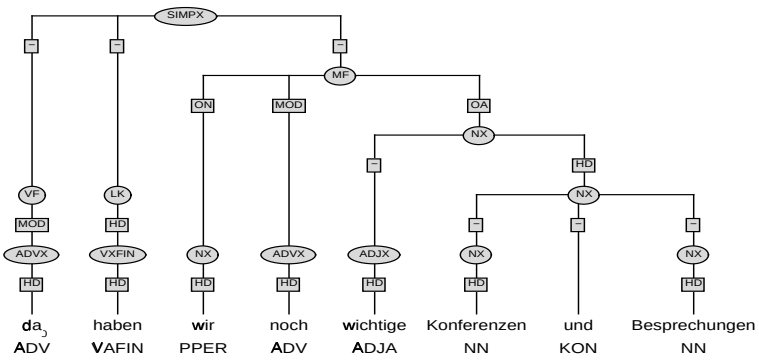

Figure 9: A complex noun phrase in the TüBa-D annotation scheme.

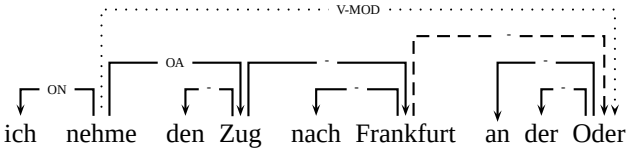

Figure 10: The dependency structure of the trees in Figure 1 and 2. The wrong attachment is shown as a dotted arc whereas the correct attachment is shown as a dashed arc.

where attachment errors are introduced by incorrect adaptations of the retrieved trees or in cases when a wrong tree is found as the most similar one, the parsers evaluation based on constituents suffers from the same problems as decribed in Section 2. above. The parser's output containing the wrong attachment in Figure 1 would result in $10/13 = 76.92\%$ recall and $10/12 = 83.33\%$ precision when using a constituent-based evaluation scheme. The dependency structure of the wrong and the correct attachment is shown in Figure 10. With the dependency-based evaluation, both precision and recall would be calculated as $7/8 = 87.50\%$.

Coordination. Coordination phenomena are in general very difficult to treat with deterministic partial parsers since this type of parsers needs to make the decision on the scope of a coordination early on when there is not enough information available. Two examples of coordination can be found in Figure 11. For both cases, TüSBL would typically retrieve these trees but not be able to attach the conjunction and the second conjunct, as shown in Figure 12 for the second example. For the first example, "am siebten und achten" (on the seventh and the eighth), this would lead to $2/4 = 50.00\%$ recall and $2/3 = 66.67\%$ precision. For the second example, "das wäre Mittwoch der dritte und Donnerstag der vierte August" (that would be Wednesday the third and Thursday the fourth of August), recall would be $9/12 = 75.00\%$ and precision $9/11 = 81.82\%$. If the evaluation is based on dependencies, TüSBL's analysis would deviate from the gold standard by the missing dependencies of the conjunction and the second conjunct. Therefore, recall would be $1/3 = 33.33\%$, for the first example, and $7/9 = 77.78\%$ for the second example. Precision would be $1/1 = 100\%$ for the first example and $7/7 = 100\%$ for the second example.

Another problematic coordination phenomenon constitute split-up coordinations such as in the sentence "das Hotel hat sogar ein Schwimmbad und ein Solarium dabei und einen Fitnessraum" (the hotel even has a swimming pool and a tanning booth – and a fitness room) in Figure 5. A typical error that might occur when parsing such sentences with TüSBL is that the split-up conjunct "und einen Fitnessraum" would not be attached. This would result in $12/14 = 85.71\%$ recall and $12/13 = 92.31\%$ precision. The evaluation based on the dependency structure shown in Figure 6 leads to $11/12 = 91.67\%$ recall and $11/11 = 100\%$ precision.

The comparison shows that dependency-based recall tends to suffer less than constituent-based recall since the unattached part of the coordination does not contribute to errors on higher levels, such as the MF and SIMPX in the second example, which are in principle correct. Dependency-based precision, on the other hand, does not depend on the level of embedding of the coordinations but only on the number of conjuncts that were correctly attached.

Unattached phrases. The failure to attach constituents at the end of an input sentence is the most common error type when evaluating partial parsers. It is generally part of the design decisions to prefer partial analyses which can be gained with a small amount of effort but which will be correct in a majority of cases to complete analyses which involve a high degree of manual labor and a higher error rate for attachment decisions. A typical analysis of TüSBL for the input sentence "wir müssen ja noch einen Bericht abfassen über diese Reise nach Hannover" would be similar to the tree in Figure 3; one possible error might be that the last PX ("nach Hannover") could not be attached to the NX ("diese Reise"). Thus, the NX node 513 would be missing, and the PX node 514 would then immediately dominate the NX node 506. Using the PARSEVAL measures, this

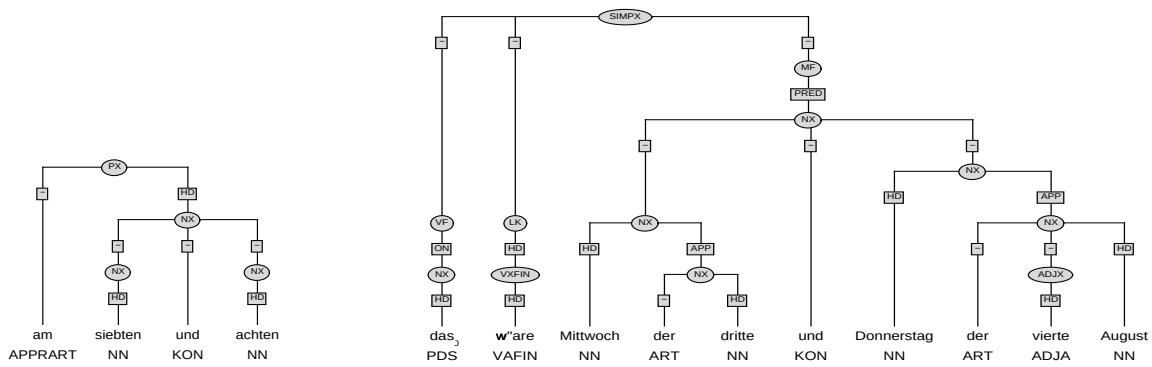

Figure 11: Two trees containing coordination.

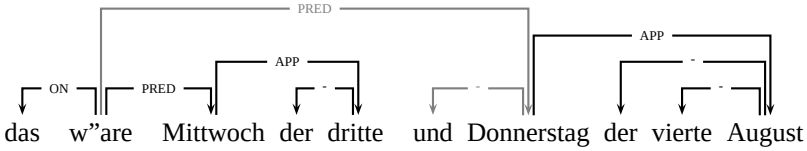

Figure 12: The dependency-based representation of the second example in Figure 11. TüSBL's analysis is shown in black, the missing dependencies in gray.

error would result in $13/17 = 76.47\%$ labeled recall and $13/16 = 81.25\%$ labeled precision. The evaluation based on the dependency structure would give $10/11 = 90.90\%$ labeled recall and $10/10 = 100\%$ labeled precision. Considering that only the attachment of the final PX is missing and that the analysis of the sentence is otherwise correct and complete, the latter figures give a better picture of the quality of the partial parse.

6. Conclusion

We have shown that the PARSEVAL measures do not allow a suitable evaluation of partial parsers. If the evaluation is based on constituency, missing information in the partial parses leads to precision and recall errors in several constituents, and the losses in both measures are disproportionately high. We therefore proposed a dependency-based evaluation. TüBa-D, the treebank used here, contains all the necessary dependency information so that the conversion of trees into a dependency structure does not have to rely on heuristics. Therefore, the dependency representations are not only reliable, they are also linguistically motivated and can be used for linguistic purposes. Using these structures for evaluation ensures that missing information will not decrease the evaluation measures disproportionately, which allows a more suitable evaluation of partial information.

7. Acknowledgments

The research reported here was supported by the German Research Council (DFG) as part of the Sonderforschungsbereich 441 "Linguistische Datenstrukturen" (Linguistic Data Structures). The authors are grateful to Steven Abney, who made the chunk parser available, and to Prof. Hans Uszkoreit and his colleagues at the Universität des Saarlandes, who kindly provided us with the graphical annotation tool *Annotate*. The authors are also grateful to the anonymous reviewers for their helpful comments.

LinGO Redwoods

A Rich and Dynamic Treebank for HPSG

Abstract

The LinGO Redwoods initiative is a seed activity in the design and development of a new type of treebank. A treebank is a (typically hand-built) collection of natural language utterances and associated linguistic analyses; typical treebanks—as for example the widely recognized Penn Treebank (Marcus, Santorini, & Marcinkiewicz, 1993), the Prague Dependency Treebank (Hajic, 1998), or the German TiGer Corpus (Skut, Krenn, Brants, & Uszkoreit, 1997)—assign syntactic phrase structure or tectogrammatical dependency trees over sentences taken from a naturally-occuring source, often newspaper text. Applications of existing treebanks fall into two broad categories: (i) use of an annotated corpus in empirical linguistics as a source of structured language data and distributional patterns and (ii) use of the treebank for the acquisition (e.g. using stochastic or machine learning approaches) and evaluation of parsing systems.

While several medium- to large-scale treebanks exist for English (and some for other major languages), all pre-existing publicly available resources exhibit the following limitations: (i) the depth of linguistic information recorded in these treebanks is comparatively shallow, (ii) the design and format of linguistic representation in the treebank hard-wires a small, predefined range of ways in which information can be extracted from the treebank, and (iii) representations in existing treebanks are static and over the (often year- or decade-long) evolution of a large-scale treebank tend to fall behind theoretical advances in formal linguistics and grammatical representation.

LinGO Redwoods aims at the development of a novel treebanking methodology, (i) *rich* in nature and *dynamic* in both (ii) the ways linguistic data can be retrieved from the treebank in varying granularity and (iii) the constant evolution and regular updating of the treebank itself, synchronized to the development of ideas in syntactic theory. Starting in October 2001, the project is aiming to build the foundations for this new type of treebank, develop a basic set of tools required for treebank construction and maintenance, and construct an initial set of 10,000 annotated trees to be distributed together with the tools under an open-source license. Building a large-scale treebank, disseminating it, and positioning the corpus as a widely-accepted resource is a multi-year effort; the results of this seeding activity will serve as a proof of concept for the novel approach that is expected to enable the LinGO group at CSLI both to disseminate the approach to the wider academic and industrial audience and to secure appropriate funding for the realization and exploitation of a larger treebank. The purpose of publication at this early stage is three-fold: (i) to encourage feedback on the Redwoods approach from a broader academic audience, (ii) to facilitate exchange with related work at other sites, and (iii) to invite additional collaborators to contribute to the construction of the Redwoods treebank or start its exploitation as early-access versions become available.

1. Why Another (Type of) Treebank?

For the past decade or more, symbolic, linguistically oriented methods (like those pursued within the HPSG framework; see below) and statistical or machine learning approaches to NLP have typically been perceived as incompatible or even competing paradigms; the former, more traditional approaches are often referred to as 'deep' NLP, in contrast to the comparatively recent branch of language technology focussing on 'shallow' (text) processing methods. Shallow processing techniques have produced useful results in many classes of applications, but have not met the full range of needs for NLP, particularly where precise interpretation is important, or where the variety of linguistic expression is large relative to the amount of training data available. On the other hand, deep approaches to NLP have only recently achieved broad enough grammatical coverage *and* sufficient processing efficiency to allow the use of HPSG-type systems in certain types of real-world applications. Fully-automated, deep grammatical analysis of unrestricted text remains an unresolved challenge.

In particular, applications of analytical grammars for natural language parsing or generation require the use of sophisticated statistical techniques for resolving ambiguities. We observe general consensus on the necessity for bridging activities, combining symbolic and stochastic approaches to NLP; also, the transfer of HPSG resources into industry has amplified the need for general parse ranking, disambiguation, and robust recovery techniques which all require suitable stochastic models for HPSG processing. While we find promising research in stochastic parsing in an number of frameworks, there is a lack of appropriately rich and dynamic language corpora for HPSG. Likewise, stochastic parsing has so far been focussed on IE-type applications and lacks any depth of semantic interpretation. The Redwoods initiative is designed to fill in this gap.

Most probabilistic parsing research—including, for example, work by by Collins (1997), Charniak (1997), and Manning and Carpenter (2000)—is based on branching process models (Harris, 1963). An important recent advance in this area has been the application of log-linear models (Agresti, 1990) to modeling linguistic systems. These models can deal with the many interacting dependencies and the structural complexity found in constraint-based or unification-based theories of syntax (Johnson, Geman, Canon, Chi, & Riezler, 1999). The availability of even a medium-size treebank would allow us to begin exploring

the use of these models for probabilistic disambiguation of HPSG grammars. At the same time, other researchers have started work on stochastic HPSG (or are about to), some pursuing unsupervised approaches, but in many cases using the same grammar or at least the same descriptive formalism and grammar engineering environment. The availability of a reasonably large, hand-disambiguated HPSG treebank is expected to greatly facilitate comparability of results and models obtained by various groups and, eventually, to help define a common evaluation metric.

2. Background

The LinGO Project at CSLI has been conducting research and development in Head-Driven Phrase Structure Grammar (HPSG; Pollard & Sag, 1994) since 1994. In close collaboration with international partners—primarily from Saarbrücken (Germany), Cambridge, Edinburgh, and Sussex (UK), and Tokyo (Japan)—the LinGO Project has developed a broad-coverage, precise HPSG implementation of English (the LinGO English Resource Grammar, ERG; Flickinger, 2000), a framework for semantic composition in large-scale computational grammars (Minimal Recursion Semantics, MRS; Copestake, Lascarides, & Flickinger, 2001), and an advanced grammar development environment (the LKB system; Copestake, 1992, 1999). Through contributions from collaborating partners, a pool of open-source HPSG resources has developed that now includes broad-coverage grammars for several languages, a common profiling and benchmarking environment (Oepen & Callmeier, 2000), and an industrial-strength C^{++} run-time engine for HPSG grammars (Callmeier, 2000). LinGO resources are in use world-wide for teaching, research, and application building. Because of the wide distribution and common acceptance, the HPSG framework and LinGO resources present an excellent anchor point for the Stanford treebanking initiative.

3. A Rich and Dynamic Treebank

The key innovative aspect of the Redwoods approach to treebanking is the anchoring of all linguistic data captured in the treebank to the HPSG framework and a generally-available broad-coverage grammar of English, viz. the LinGO English Resource Grammar, combined with tools for the extraction of various, user-defined representations and a software environment to continuously update the treebank as part of the on-going grammar maintenance and extension. Unlike existing treebanks, there will be no need to define a (new) form of grammatical representation specific to the treebank. Instead, the treebank will record complete syntacto-semantic analyses as defined by the LinGO ERG and provide tools to extract many different types of linguistic information at greatly varying granularity.

In particular, the project centrally draws on the [incr tsdb()] profiling environment (essentially a specialized database recording fine-grained parsing results obtained from diverse HPSG systems; Oepen & Carroll, 2000), constructing the treebank as an extension of the existing data model and tools. In turn building on a pre-existing tree comparison tool in the LKB (similar in kind to the SRI Cambridge TreeBanker; Carter, 1997), the treebanking environment presents annotators, one sentence at a time, with the full set of analyses produced by the grammar. Using the tree comparison tool, annotators can quickly navigate through the parse forest and identify the correct or preferred analysis in the current context (or, in rare cases, reject all analyses proposed by the grammar). The tree selection tools persents users, who need little expert knowledge of the underlying grammar, with a range of properties that distinguish competing analyses and that are relatively easy to judge. Each such property corresponds to the usage of a particular lexical item, semantic relation, or grammar rule applied to a specific substring to form a constituent; unlike the LFG packed f-structure representations discussed by King, Dipper, Frank, Kuhn, and Maxwell (2000), the set of basic discriminating properties reduces the information presented to annotators to the minimal amount of structure required to completely disambiguate a sentence. All disambiguating decisions made by annotators are recorded in the [incr tsdb()] database and thus become available for (i) later dynamic extraction from the annotated profile or (ii) dynamic propagation into a more recent profile obtained from re-running an extended version of the grammar on the same corpus.

Important innovative research aspects pertaining to this approach to treebanking are (i) enabling users of the treebank to extract information of the type they need and to transform the available representation into a form suited for their needs and (ii) updating the treebank for an enhanced version of the grammar underlying the recorded analyses in an automated fashion, viz. by re-applying the disambiguating decisions to an updated version of the corpus.

Depth of Representation and Transformation of Information Internally, the [incr tsdb()] database records analyses in three different formats, viz. (i) as a derivation tree composed of identifiers of lexical items and constructions used to construct the analysis, (ii) as a traditional phrase structure tree labeled with an inventory of some fifty atomic labels (of the type 'S', 'NP', 'VP' et al.), and (iii) as an underspecified MRS meaning representation. While (ii) will in many cases be similar to the representation found in the Penn Treebank, (iii) subsumses the functor – argument (or tectogrammatical) structure as it is advocated in the Prague Dependency Treebank or the German TiGer corpus. Most importantly, however, representation (i) provides all the information required to replay the full HPSG analysis (e.g. using the original HPSG grammar and one of the open-source HPSG processing environments, e.g. the LKB or PET, which already have been interfaced to [incr tsdb()]). Using the latter approach, users of the treebank are enabled to extract information in whatever representation they require, simply by reconstructing the full analysis and adapting the existing mappings (e.g. the inventory of node labels used for phrase structure trees) to their needs. Figure 1 depicts the internal Redwoods encoding and two export representations derived from existing conversion routines. Labeled phrase structure trees result from reconstructing a derivation (using the original grammar) and matching a user-defined set of underspecified feature structure 'templates'

Table 1: Redwoods development status as of February 2002: four sets of transcribed and hand-segmented VerbMobil dialogues have been annotated. The columns are, from left to right, the total number of sentences (excluding fragments) for which the LinGO grammar has at least one analysis ('♯'), average length ('‖'), lexical and structural ambiguity ('⊙' and '×', respectively), followed by the last four metrics broken down for the following subsets: sentences (i) for which the annotator rejected all analyses (no active trees), (ii) where annotation resulted in exactly one preferred analysis (one active tree), (iii) those where full disambiguation was not accomplished through the first round of annotation (more than one active tree), and (iv) massively ambiguous sentences that have yet to be annotated.

corpus	total				active = 0				active = 1				active > 1				unannotated			
	♯	‖	⊙	×	♯	‖	⊙	×	♯	‖	⊙	×	♯	‖	⊙	×	♯	‖	⊙	×

VM32	608	7·4	4·3	25·6	46	9·8	4·1	18·3	516	7·5	4·4	9·2	21	10·4	3·9	29·6	25	16·6	4·8	375·4

against the HPSG feature structure at each node in the tree. The elementary dependency graph, on the other hand, is an abstraction from the full MRS meaning representation associated to each full analysis; informally, elementary dependencies correspond to the type of tectogrammatical representations found in the Prague Dependency Treebank or the German TiGer corpus and, likewise, resemble the basic relations suggested for parser evaluation by Carroll, Briscoe, and Sanfilippo (1998). Given a rich body of MRS manipuation and conversion software, it is relatively straightforward to adapt the type and form of elementary dependencies to user needs.

For evaluation purposes, the existing [incr tsdb()] facilities for comparing across competence and performance profiles can be deployed to gauge results of a (stochastic) parse disambiguation system, essentially using the preferences recorded in the treebank as a 'gold standard' target for comparison. While the concept of a meta-treebank of the type proposed here has been explored in earlier research (e.g. the AMALGAM project at Leeds University in the UK; Atwell, 1996), previous approaches to the dynamic mapping of treebank representations have built on a static, finite set of hand-constructed mappings.

Automating Treebank Construction Although a precise HPSG grammar like the LinGO ERG will typically assign a small number of analyses to a given sentence, choosing among a handful or sometimes a few dozens of readings is time-consuming and error-prone. The project will explore two approaches to automating the disambigutation task, viz. (i) seeding lexical selection from a part-of-speech (POS) tagger and (ii) automated inter-annotator comparison and assisted resolution of conflicts. Ranking lexical ambiguity on the basis of tagger-assigned POS probabilities requires research into generalizations over the rather fine-grained hierarchy of HPSG lexical types and identifying many-to-many correspondences in a standard POS tagset. Conversely, detecting mismatches (i.e. conflicts) between disambiguating decisions made for the same input sentence by two independent annotators will facilitate research into the linguistic nature of the discriminating properties used and existing logical relations (inclusion, implication, inconsistency et al.) among subsets of discriminators. To exemplify the nature of these properties, consider the sentence

(1) *Have her report on my desk by Friday!*

which is (correctly) assigned thirty two readings by the HPSG grammar; while human language users (and correspondingly human annotators) will typically not note most of the alternative analyses, one can contextualize the sentence to emphasize either one of the following ambiguities: the causative vs. possessive *have*, the determiner vs. personal pronoun *her*, the noun vs. verb *report*, the temporal vs. locative preposition *by*, and *Friday* as a day of the week vs. as a proper noun (e.g. the name of a bar). Using the tree comparison tool and our notion of elementary discriminators, annotators can reduce the set of analyses quickly (where full disambiguation requires minimally four decisions for this example); yet, a POS tagger will reliably assign high probability to the pairings ⟨*her* , determiner⟩ and ⟨*report* , noun⟩ which could be used to bias the presentation to annotators.

Treebank Maintenance and Evolution Perhaps the most challenging research aspect of the Redwoods initiative is about developing a methodology for automated updates of the treebank to reflect the continuous evolution of the underlying linguistic framework and of the LinGO grammar. Again building on the notion of elementary linguistic discriminators, it is expected to explore the semi-automatic propagation of recorded disambiguating decisions into newer versions of the parsed corpus. While it can be assumed that the basic phrase structure inventory and granularity of lexical distinctions have stabilized to a certain degree, it is not guaranteed that one set of discriminators will always fully disambiguate a more recent set of analyses for the same utterance (as the grammar may introduce additional distinctions), nor that re-playing a history of disambiguating decisions will necessarily identify the correct, preferred analysis for all sentences. Once more, a better understanding into the nature of discriminators and relations holding among them is expected to provide the foundations for an update procedure that, ultimately, should be fully automated or at least require minimal manual inspection.

Scope and Current State of Seeding Initiative The first 10,000 trees to be hand-annotated as part of the kick-off initiative are taken from a domain for which the English Resource Grammar is known to exhibit broad and accurate

coverage, viz. transcribed face-to-face dialogues in an appointment scheduling and travel arrangement domain. Corpora of some 50,000 such utterances are readily available from the VerbMobil project (Wahlster, 2000) and have already been studied extensively among researchers worldwide in the field. For the follow-up phase of the project, it is expected to move into a second domain and text genre, presumably more formal, edited text taken from newspaper text or another widely available on-line source. As of April 2002, the seeding initiative is well underway. The integrated treebanking environment, combining [incr tsdb()] and the LKB tree selection tool, has been established and has been deployed in a first iteration of annotating a corpus of 10,000 VerbMobil utterances. For a second-year Stanford undergraduate in linguistics, the approach to parse selection through minimal discriminators turned out to be not at all hard to learn and required less training in specifics of the grammatical analyses delivered by the LinGO grammar than could have been expected.

Table 1 summarizes the current Redwoods development status; while annotation of a residual fraction of highly ambiguous sentences and inter-annotator cross-validation continue, the current development snapshot of the treebank can be made available upon request. We have just started work on stochastic parse selection models for the Redwoods treebank, so far obtaining a parse selection accuracy of around eighty per cent from a combination of existing methods applied to the Redwoods derivation trees and elementary dependency graphs (see Figure 1); details on Redwoods parse selection results will be reported in separate publications.

4. Related Work

To our best knowledge, no prior research has been conducted exploring both the linguistic depth, flexibility in available information, and dynamic nature of treebanks as proposed presently. Earlier work on building corpora of hand-selected analyses relative to an existing broad-coverage grammar was carried out at Xerox PARC, SRI Cambridge, and Microsoft Research; as all these resources are tuned to proprietary grammars and analysis engines, the resulting treebanks are not publicly available, nor have research results reported been reproducible. Yet, especially in the light of the successful LinGO open-source repository, it seems vital that both the treebank and associated processing schemes and stochastic models be made available to the general (academic) public.

An on-going initiative at Rijksuniversiteit Groningen (NL) is developing a treebank of dependency structures (Mullen, Malouf, & Noord, 2001), as they are derived from an HPSG-like grammar of Dutch (Bouma, Noord, & Malouf, 2001). While the general approach resembles the Redwoods initiative (specifically the discriminator-based method used in selecting trees from the set of analyses proposed by the grammar; the LKB tree selection tool was originally developed by Malouf, after all), there are three important differences. Firstly, the Groningen decision to compose the treebank from dependency structures commits the resulting resource to a single stratum of representation, tectogrammatical structure essentially, and thus eliminates some of the flexibility in extracting various types of linguistic structure that the Stanford initiative foresees. Secondly, and in a similar vein, recording dependency structures means that the (stochastic) disambiguation component has to consider two syntactically different analyses equivalent whenever they project identical dependency structures; hence, there is a mismatch of granularity between the disambiguated treebank structures and the primary structures (i.e. derivation trees) constructed by the grammar. Finally, the Groningen initiative is making the assumption that the dependency structures, once they are stored in the treebank, are correct and do not change over time (or as an effect of grammar evolution); from the available publications, at least, there is no evidence that the disambiguating decisions made by annotators are recorded in the treebank or that the project expects to dynamically update the treebank with future revisions of the underlying grammar.

Another closely related approach is the work reported by Dipper (2000), essentially the application of a broad-coverage LFG grammar for German to constructing tectogrammatical structures for the TiGer corpus. While many of the basic assumptions about the value of a systematic, broad-coverage grammar for the treebank construction are shared, the strategy followed by Dipper (2000) exhibits the same limitations as the Groningen initiative: the TiGer target representation, still, is mono-stratal and the approach to hand-disambiguation and subsequent transfer of result structures into the TiGer corpus looses the linkage to the original analyses and basic properties used in the disambiugation, hence the potential for dynamic adaptation of the data or automatic updates.

Acknowledgements

The Redwoods initiative is part of the LinGO Laboratory at CSLI and many people, both at Stanford and at partner sites, have contributed to its design and (given small amounts of resources) relative success so far. Ivan A. Sag, Tom Wasow, Emily M. Bender, Tim Baldwin, John Beavers, and Kathryn Campbell-Kibler all have participated in our regular tree conferences, helping annotators select parses and offering productive critiques on analyses provided by the LinGO grammar. Ann Copestake, John Carroll, Rob Malouf, and Stephan Oepen are the main developers of the LKB and [incr tsdb()] software packages from which the Redwoods treebanking environment has been built and, in various capacities, have influenced the Redwoods approach significantly. During a three-month visit to Stanford, Stuart Shieber has been among the driving forces for applications of the existing development version of the treebank, helping us develop and fine-tune suitable stochastic parse selection models. The Redwoods initiative has been partially funded by an internal opportunity grant from CSLI Stanford and by a donation from YY Technologies.

A Test of the Leaf-Ancestor Metric for Parse Accuracy

Abstract

The GEIG metric for quantifying accuracy of parsing became influential through the Parseval programme, but many researchers have seen it as unsatisfactory. The LA metric, first developed in the 1980s, arguably comes closer to formalizing our intuitive concept of relative parse accuracy. We support this claim via an experiment which contrasts the performance of alternative metrics on the same body of automatically-parsed examples. The LA metric has the further virtue of providing straightforward indications of the location of parsing errors.

1. Introduction

One of us (Sampson 2000) has argued that what we call the "leaf-ancestor" (LA) metric is better than the Grammar Evaluation Interest Group (GEIG) metric used in the Parseval competition series (e.g. Black et al. 1991) as a way of quantifying the accuracy of automatic parses, in a context where gold-standard parses using a known scheme of node labelling are available. This paper presents an experiment comparing the performance of the two metrics on a sample of automatic-parser output.

The GEIG metric, which counts the numbers of tagmas (multi-word grammatical units) correctly and incorrectly identified, from our point of view lays excessive weight on locating the exact boundaries of constructions.

As originally defined by Black et al. and as it is often applied, the GEIG metric takes no account of node labels at all: it only considers the location of brackets. And in consequence, this metric includes no concept of approximate correctness in identifying tagmas: a pair of brackets either enclose a sequence of words (or other terminal elements) exactly corresponding to a sequence bracketed off in the gold-standard parse, or not. The result is that "it is unclear as to how the score on [the GEIG] metric relates to success in parsing" (Bangalore et al. 1998).

More recently (Magerman 1995, Collins 1997) a refined variant of the GEIG metric has been used which does check label identity as well as wordspan identity in matching tagmas between gold-standard and candidate parses. We shall argue that even this variant of the GEIG metric is inferior to the LA metric. We shall refer to the Black et al. (1991) and Collins (1997) variants of the GEIG metric as GEIG/unlabelled and GEIG/labelled respectively.

We think of "parsing" as determining what kind of larger elements are constituted by the small elements of a string that are open to direct observation. Identifying the exact boundaries of the larger elements is a part, but only one part, of that task. If, for instance, in the gold standard, words 5 to 14 are identified as a noun phrase, then a candidate parse which identifies a noun phrase as beginning at word 5 but ending at word 13, or word 15, should in our view be given substantial though not full credit; under the GEIG metric it is given no credit. The LA metric quantifies accuracy of parsing in this sense.

Incidentally, we believe that the LA metric was the earliest parse-assessment metric in the field, having been used, and briefly described in print, in the 1980s (Sampson, Haigh, & Atwell 1989: 278), though it was later eclipsed by the influential Parseval programme.

2. The Essence of Leaf-Ancestor Assessment

The LA metric evaluates the parsing of an individual terminal element in terms of the similarity of the "lineages" of that element in candidate and gold-standard parse trees, where a lineage is essentially the sequence of node-labels for nodes on the unique path between the terminal element and the root node. The LA value for the parsing of an entire sentence or other many-word unit is simply the average of the values for the individual words. Apart from (we claim) yielding figures for parsing accuracy of complete sentences which succeed better than the GEIG metric in quantifying our intuitions about parse accuracy, the LA metric has the further practical virtue of identifying the location of parsing errors in a straightforward way.

We illustrate the general concept of LA assessment using one of the shortest sentences in our experimental data-set. (The nature of that data-set, and the gold-standard parsing scheme, will be discussed below.) The sentence runs *two tax revision bills were passed.* (Certain typographic details, including capitalization, inverted commas, and sentence-final punctuation marks, have been eliminated from the examples.) The gold-standard analysis, and the candidate analysis produced by an automatic parser, are respectively:

1G [S [N1 *two* [N1 *tax revision*] *bills*] *were passed*]
1C [S [NP *two tax revision bills*] *were passed*]

(Here and below, "nG" and "nC" label gold-standard and candidate analyses for an example *n*.)

The automatic parser has failed to identify *tax revision* as a unit within the tagma headed by *bills*, and it has labelled that tagma NP rather than N1. Lineages for these tree structures are as follows, where for each terminal element the gold-standard lineage is shown to the left and the candidate lineage to the right of the colon, and within each of the paired lineages the Leaf end is to the Left and the Root end to the Right:

two	N1 [S : NP [S
tax	[N1 N1 S : NP S
revision	N1] N1 S : NP S
bills	N1] S : NP] S
were	S : S
passed	S] : S]

The only aspect of the relationship between this notation and the tree structures which is not self-explanatory is the inclusion of boundary markers (left and right square brackets) in many of the lineages. These are included in accordance with the following rules:

- a left-boundary symbol is inserted in the lineage of a terminal element immediately before the label of the highest nonterminal beginning with that element, if there is such a nonterminal

- a right-boundary symbol is inserted in the lineage of a terminal element immediately after the label of the highest nonterminal ending with that element, if there is such a nonterminal

The reason for including these elements in lineages is that, without them, a set of lineages would not always uniquely determine a tree structure; for instance the structures ÒP [Q *a b*] [Q *c*]]Óand ÒP [Q *a b c*]]Ó would not be distinguishable, since the lineage for each terminal element in both cases would consist of the sequence Q P. A set of lineages in which boundary markers have been inserted by these rules uniquely determines the tree structure from which it is derived.

Thus, in the example above, the LA metric equates the accuracy with which the word *two* has been parsed with the degree of similarity between the two strings NP˚[S and N1 [S, it equates the parse-accuracy for *tax* with the degree of similarity between NP S and [˚N1˚N1˚S, and so forth; for the last two words the lineages are identical, so the metric says that they have been parsed perfectly. We postpone discussion of our method for calculating string similarity until after we have discussed our experimental material.

3. The Experimental Material

Our experiment used a set of sentences from genre sections A and G of the SUSANNE Treebank (Sampson 1992) parsed by an automatic treebanker developed at the Universities of Cambridge and Sussex by Ted Briscoe and John Carroll; of those sentences for which the treebanker was able to produce a structure, a set of 500 was randomly chosen. For the purposes of illustrating the performance of the LA metric and comparing it with the GEIG metric, we wanted material parsed by a system that used a simple parsing scheme with a smallish vocabulary of nonterminal labels, and which made plenty of mistakes in applying the scheme to real-life data; there is no suggestion that the parses in our experimental data-set represent the Ò*state of the art*Ófor automatic parsing.

The parsing scheme which the automatic parser was intended to apply used seven nonterminal labels, which we gloss with our own rather than Briscoe and Carroll's labels:

S	finite clause
VP	nonfinite clause
NP	noun phrase containing specifier
N1	noun phrase without specifier
PP	prepositional phrase
AP	adjectival or adverbial phrase
T	Òtextual constituentÓ, defined by Briscoe and Carroll as a tagma enclosing Òa sequence of sub-constituents whose relationship is syntactically indeterminate due to the presence of intervening, delimiting punctuationÓ

The use of these seven categories is defined in greater detail in documentation supplied to us, but for present purposes it is unnecessary to burden the reader with this material. The automatic-parser output occasionally included node-labels not on the above list (e.g. V, N2), but these were always regarded by the developers of the parser as mistakes.

Briscoe and Carroll's original data included GEIG/unlabelled precision and recall scores for each automatic parse, assessed against the SUSANNE bracketing as gold standard. For the purposes of this experiment, the Evalb program (Sekine & Collins 1997) was used to produce GEIG/labelled precision and recall figures for the same data. In order to be able to compare our LA scores with single GEIG/labelled and GEIG/unlabelled scores for each sentence, we converted pairs of precision (P) and recall (R) figures to F-scores (van Rijsbergen 1979) by the formula $F = 2PR/(P + R)$, there being no reason to include a weighting factor to make precision accuracy count more than recall accuracy or *vice versa*.

One of us (Babarczy) constructed a set of gold-standard trees that could be compared with the trees output by the automatic parser, by manually adding labels from the seven-element Briscoe and Carroll label vocabulary to the SUSANNE bracketing, in conformity with the documentation on that seven-element vocabulary. Because the parsing scheme which the automatic parser was intended to apply was very different from the SUSANNE scheme, to a degree this was an artificial exercise. In some cases, none of the seven labels was genuinely suitable for a particular SUSANNE tagma; but one of them was assigned anyway, and such assignments were made as consistently as possible across the 500-sentence data-set. The admitted artificiality of this procedure did not seem unduly harmful, in the context of an investigation into the performance of a metric (as opposed to an investigation into the substantive problem of automatic parsing).

4. Calculation of Lineage Similarity

Leaf-ancestor assessment depends on quantifying the similarity between pairs of strings, which is done in terms of a variant of Levenshtein distance (Levenshtein 1966), also called edit distance. The Levenshtein distance between two strings is the minimum cost for a set of insert, delete, and replace operations to transform one string into the other, where each individual operation has a cost of one. For instance, the Levenshtein distance between A B C B D and A D C B is two: the latter string can obtained from the former by replacing the second character with D and deleting the last character.

We define similarity between candidate and gold-standard lineages in terms of a variant of Levenshtein distance, in which the cost of a replace operation is not fixed but varies over the interval (0, 2) depending on an application-defined concept of similarity between the two symbols involved in a replacement. In the present experiment, replacement of a symbol by an unrelated symbol costs 2; replacement of a symbol by a different symbol sharing the same first character (e.g. NP for N1 or *vice versa*) costs 1.5. The intuition here is that if two grammatical categories are entirely dissimilar, then for a parser to mistake one for the other amounts to two separate errors of failing to recognize the existence of a tagma of one kind, and falsely positing the existence of another type of tagma (a delete and an insert); but partial credit ought to be given for mistaking, say, a noun phrase for an N-bar. (When LA assessment is deployed in practice, the symbol-replacement cost function should be chosen by reference to the nature of the particular scheme of parsing categories, and to the goals of the application for which parsing is needed.)

If len(*s*) is the length of a string *s*, and ML(*s*, *t*) is the modified Levenshtein distance (under some chosen symbol-replacement cost function) between string *s* and string *t*, then the similarity between candidate and gold-standard lineages *c*, *g* for a given terminal element is computed as 1 — ML(*c*, *g*)/(len(*c*) + len(*g*)), which for any *c*, *g* must fall on the interval (0, 1). The accuracy of a candidate parse is defined as the mean similarities of the lineage-pairs for the various words or other terminal elements of the string.

Applied to our short example sentence, this metric gives the scores for successive terminal elements shown in the left-hand column below:

0.917	*two*	`N1 [ S : NP [ S`
0.583	*tax*	`[ N1 N1 S : NP S`
0.583	*revision*	`N1 ] N1 S : NP S`
0.917	*bills*	`N1 ] S : NP ] S`
1.000	*were*	`S : S`
1.000	*passed*	`S ] : S ]`

The average for the whole sentence is 0.833. For comparison, the GEIG/unlabelled and GEIG/labelled *F*-scores are 0.800 and 0.400.

5. Are the Metrics Equivalent?

The figure for the LA metric just quoted happens to be very similar to one of the two GEIG figures. An obvious initial question about the performance of the metrics over the data-set as a whole is whether, although the metrics are calculated differently, they perhaps turn out to impose much the same ranking on the candidate parses.

To this the answer is a clear no. An extreme case is (2):

2G [S *it is not* [NP *a mess* [S *you can make sense of*]]] G12:0520.27
2C [S *it is not* [NP *a mess* [S *you can make sense*]] *of*] (0.333, 0.333, 0.952)

(Here and below, gold-standard analyses are followed by the SUSANNE location code of the first word — omitting the last three characters, this is the same as the Brown Corpus text and line number. The location for example (1) was A02:0790.51. Candidate parses are followed in brackets by their GEIG/unlabelled, GEIG/labelled, and LA scores, in that order.)

The LA and GEIG numerical scores are very different; but more important than the raw scores are the rankings assigned by the respective metrics, relative to the range of 500 examples. For both GEIG/labelled and GEIG/unlabelled, the parse of (2) is in the tenth (i.e. the lowest) decile; for LA, it is in the second decile. (The ònthÓ decile for any of the metrics, refers to the set of examples occuping ranks 50(*n* — 1) + 1 to 50*n*, when the 500 candidate parses are ordered from best to worst in terms of score on that metric; for instance the second decile is the set of examples ranked 51 to 100. Where a group of examples share identical scores on a metric, for purposes of dividing the examples into deciles an arbitrary order was imposed on members of the group.)

The difference between the low GEIG scores and the high LA score for example (2) is a classic illustration of one of the standard objections to the GEIG metric. The parser has correctly discovered that the sentence consists of an S within NP within S structure, and almost every word has been given its proper place within that structure; just one word has been attached at the wrong level, but because this leads to the right-hand boundary of two of the three tagmas being slightly misplaced, the GEIG score is very low. We believe that most linguistsÕ intuitive assessment of example (2) would treat it as a largely-correct parse with one smallish mistake, not as one of the worst parses in the data-set — that is, the intuition would agree much better with the LA metric than with the GEIG metrics in this case.

An extreme case in the opposite direction (LA score lower than GEIG score) is (3):

3G [S *yes* , [S *for they deal* [PP *with distress*]]] G12:1340.42
3C [T *yes* , [PP *for they deal* [PP *with distress*]]] (1.0, 0.333, 0.262)

The GEIG/unlabelled metric gives 3C a perfect mark — all brackets are in the right place; but its LA score is very low, because two of the three tagmas are wrongly labelled — 0.262 is in fact by a clear margin the lowest LA score for any of the 500 examples. One might of course debate about whether, in terms of the Briscoe/Carroll labelling scheme, the root tagma *should* be labelled S rather than T, but that is not to the point here. The relevant point is that, *if* the target is the gold-standard parse shown, then a metric which gives a poor score to 3C is performing better than a metric which gives it a perfect score.

For example (3), GEIG/labelled performs much better than GEIG/unlabelled. Where parsing errors relate wholly or mainly to labelling rather than to structure, that will be so. But we have seen in the case of (2), and shall see again, that there are other kinds of parsing error where GEIG/labelled is no more, or little more, satisfactory than GEIG/unlabelled.

6. Performance Systematically Compared

In order systematically to contrast the performance of the metrics, we need to focus on examples for which the ranking of the candidate parse is very different under the

different metrics, which implies checking cases whose parses are among the lowest-ranked by one of the metrics. It would be little use to check the highest-ranked parses by either metric. Many candidates are given perfect marks by the LA metric, because they are completely accurate, in which case they will also receive perfect GEIG marks. Some candidates receive perfect GEIG/unlabelled marks but lower LA (and GEIG/labelled) marks, however this merely reflects the fact that GEIG/unlabelled ignores labelling errors.

We have checked how many examples from the lowest GEIG/unlabelled and GEIG/labelled deciles fall into the various LA deciles, and how many examples from the lowest LA decile fall into the various GEIG/unlabelled and GEIG/labelled deciles. These are the results:

LA deciles for GEIG/unlabelled 10th decile:

1st	0
2nd	1
3rd	3
4th	2
5th	2
6th	4
7th	8
8th	7
9th	11
10th	12

LA deciles for GEIG/labelled 10th decile:

1st	0
2nd	1
3rd	1
4th	0
5th	0
6th	1
7th	7
8th	8
9th	13
10th	19

GEIG/unlabelled deciles for LA 10th decile:

1st	1
2nd	0
3rd	4

9th	8
10th	19

Clearly there is a tendency for parses assigned poor LA scores also to be assigned poor GEIG scores, and *vice versa*. If there were not, at least one of the metrics could never have been taken seriously by anyone. But there are many exceptions.

The GEIG/unlabelled and GEIG/labelled 10th-decile, LA 2nd-decile example is (2), already discussed above. The GEIG/labelled 10th-decile, LA 3rd-decile example (and this is also one of the GEIG/unlabelled 10th-decile, LA 3rd-decile examples) is (4):

4G [S *then he began* [VP *to speak* [PP *about* [NP *the tension* [PP *in art*] [PP *between* [NP *the mess* [N1 *and form*]]]]]]] G12:0610.27
4C [S *then he began* [VP *to speak* [PP *about* [NP *the tension*]] [PP *in* [N1 *art* [PP *between* [NP *the mess*]] [N1 *and form*]]]]] (0.353, 0.353, 0.921)

The two further GEIG/unlabelled 10th-decile, LA 3rd-decile cases are:

5G [S *Alusik then moved Cooke across* [PP *with* [NP *a line drive* [PP *to left*]]]] A13:0150.30
5C [S *Alusik then moved Cooke across* [PP *with* [NP *a line drive*]] [PP *to left*]] (0.500, 0.500, 0.942)

6G [S [NP *their heads*] *were* [PP *in* [NP *the air*]] *sniffing*] G04:0030.18
6C [S [NP *their heads*] *were* [PP *in* [NP *the air sniffing*]]] (0.500, 0.500, 0.932)

Examples (5) and (6) are essentially similar to (2) above, since all three concern errors about the level at which a sentence-final element should be attached. The LA scores are marginally lower than for (2), because the misattached elements comprise a higher proportion of total words in the respective examples. In (5) a two-word phrase rather than a single word is misattached, and in (6) the misattached element is a single word but the sentence as a whole is only seven words long while example (2) contains ten words. Intuitively it is surely appropriate for a misattachment error involving a higher proportion of total words to be given a lower mark, but for these candidates nevertheless to be treated as largely correct. (Notice that the candidate parse for (5) verges on being a plausible alternative interpretation of the sentence, i.e. not mistaken at all. It is only the absence of *the* before *left* which, to a human analyst, makes it rather certain that our gold-standard parse is the structure corresponding to the writerÕs intended meaning.)

The candidate parse for (4) contains a greater variety of errors, and we would not claim that in this case it is so

intuitively clear that the candidate should be ranked among the above-average parses. Notice, though, that although several words and tagmas have been misattached, nothing has been identified as a quite different kind of tagma from what it really is (as *for they deal with distress* in (3) above was identified as a prepositional phrase rather than subordinate clause). Therefore our intuitions do not clearly suggest that the candidate should be ranked as worse than average, either; our intuitions are rather indecisive in this case. In other cases, where we have clear intuitions, the LA ranking agrees with them much better than the GEIG ranking.

Turning to cases where LA gives a much lower ranking than GEIG: the most extreme case is (3), already discussed. The LA 10th-decile, GEIG/labelled 3rd decile case (which is also one of the GEIG/unlabelled 3rd-decile cases) is (7):

7G [S [NP *its ribs*] *showed* , [S *it was* [NP *a yellow nondescript color*]] , [S *it suffered* [PP *from* [NP *a variety* [PP *of sores*]]]] , [S *hair had scabbed* [PP *off* [NP *its body*]] [PP *in patches*]]] G04:1030.15

7C [T [S [NP *its ribs*] *showed*] , [S *it was* [NP *a yellow nondescript color*]] , [S *it suffered* [PP *from* [NP *a variety* [PP *of sores*]]]] , [S *hair had scabbed off* [NP *its body*] [PP *in patches*]]] (0.917, 0.833, 0.589)

There are large conflicts between candidate and gold-structure parses here: the candidate treats the successive clauses as sisters below a T node, whereas under the SUSANNE analytic scheme the gold-standard treats the second and subsequent clauses as subordinate to the first, with no T node above it; and the candidate fails to recognize *off* as introducing a PP. The presence v. absence of the T node, because it occurs at the very top of the tree, affects the lineages of all words and hence has a particularly large impact on LA score (Sampson 2000: 66 discussed this property of the LA metric).

The three other LA 10th-decile, GEIG/unlabelled 3rd-decile cases are:

8G [S [S *when* [NP *the crowd*] *was asked* [S *whether it wanted* [VP *to wait* [NP *one more term*] [VP *to make* [NP *the race*]]]]] , *it voted no* —[S *and there were* [NP *no dissents*]]] A01:0980.06

8C [T [S [PP *when* [NP *the crowd*] *was asked* [PP *whether it wanted* [VP *to wait* [NP *one more term*] [VP *to make* [NP *the race*]]]]] , *it voted no*] — [S *and there were* [NP *no dissents*]]] (0.952, 0.667, 0.543)

9G [S [S *we wo +n't know* [NP *the full amount*] [S *until we get* [NP *a full report*]]] , *Wagner said*] A09:0520.12

9C [T [S *we wo +n't know* [NP *the full amount*] [PP *until we get* [NP *a full report*]]] , [S *Wagner said*]] (0.909, 0.545, 0.531)

10G [S [S [NP *her husband*] *was lying* [PP *on* [NP *the kitchen floor*]]] , *police said*] A19:1270.48

10C [T [S [NP *her husband*] *was lying* [PP *on* [NP *the kitchen floor*]]] , [S *police said*]] (0.909, 0.727, 0.627)

Each of these involves the same problems as (7) of presence v. absence of a root T node and co-ordinate v. subordinate relationships between successive clauses. Example (8) includes further large discrepancies: *when* and *whether* are both treated as initiating prepositional phrases rather than clauses (though neither word has a standard prepositional use). Example (9) has a similar error involving *until* (this is more understandable, since *until* can be a preposition). Intuitively, to the present authors, the LA metric seems correct in characterizing (8) and (9) as two of the cases where the candidate parse deviates furthest from the gold standard, rather than as two of the best parses. The case of (10) is admittedly less clearcut.

Some readers may find this section unduly concerned with analysts' intuitions as opposed to objective facts. But, if the question is which of two metrics better quantifies parsing success, the only basis for comparison is people's intuitive concept of what ought to count as good or bad parsing. Both metrics give perfect scores to perfect matches between candidate and gold-standard structure; which departures from perfect matching ought to be penalized heavily can only be decided in terms of "educated intuition", that is intuition supported by knowledge and discussion of the issues. It would not be appropriate to lend such intuitions the appearance of objectivity and theory-independence by "counting votes" from a large number of subjects. (Since the GEIG metric is widely known, raw numbers from an exercise like that could have as much to do with the extent to which individual informants were aware of that metric as with pre-theoretical responses to parse errors.) Deciding such an issue in terms of averaged subject responses would be as inappropriate as choosing between alternative scientific theories by democratic voting. Rather, the discussion should proceed as we have conducted it here, by appealing to readers' and writers' individual intuitions with discussion of particular examples.

7. Local Error Information

Different accuracy rankings assigned to complete parses are not the only reason for preferring the LA to the GEIG metric. Another important difference is the ability of the LA metric to give detailed information about the location and nature of parse errors.

Consider, for instance, example (11), whose gold-standard and candidate analyses are:

11G [S *however* , [NP *the jury*] *said* [S *it believes* [S [NP *these two offices*] *should be combined* [VP *to achieve* [N1 *greater efficiency*] [VP *and reduce* [NP *the cost* [PP *of administration*]]]]]]] A01:0210.15

11C [S *however* , [NP *the jury*] *said* [S *it believes* [NP *these two*] [S *offices should be combined* [VP *to* [VP *achieve* [N1 *greater efficiency*] [VP *and reduce* [NP *the cost* [PP *of administration*]]]]]]]] (0.762, 0.667, 0.889)

The score of 0.889 assigned by the LA metric to this candidate analysis, like any LA score, is the mean of scores for the individual words. For this example, those are as follows:

```
1.000  however [ S : [ S
1.000  ,       S : S
1.000  the     [ NP S : [ NP S
1.000  jury    NP ] S : NP ] S
1.000  said    S : S
1.000  it      [ S S : [ S S
1.000  believes S S : S S
0.667  these   NP [ S S S : [ NP S S
0.750  two     NP S S S : NP ] S S
0.667  offices NP ] S S S : [ S S S
1.000  should  S S S : S S S
1.000  be      S S S : S S S
1.000  combined S S S : S S S
1.000  to      [ VP S S S : [ VP S S S
0.800  achieve VP S S S : [ VP VP S S S
0.923  greater [ N1 VP S S S : [ N1 VP VP
   S S S
0.923  efficiency N1 ] VP S S S : N1 ] VP VP
   S S S
0.769  and     [ S VP S S S : [ VP VP VP
0.727  reduce  S VP S S S : VP VP VP S S S
0.800  the     [ NP S VP S S S : [ NP VP
   VP VP S S S
0.769  cost    NP S VP S S S : NP VP VP VP
   S S S
0.824  of      [ PP NP S VP S S S : [ PP
   NP VP VP VP S S S
0.824  administration    PP NP S VP S S S ] :
   PP NP VP VP VP S S S ]
```

The display shows that, according to the LA metric, the early part of the sentence is parsed perfectly, and that the worst-parsed part is *these two offices*. That seems exactly right; in the correct analysis, these three words are a NP, subject of the clause which forms the object of *believe*, but the automatic parser has interpreted *believe* as a ditransitive verb with *these two* as indirect object, and has treated *offices* as grammatically unrelated to *these two*. Intuitively, these are gross mistakes. The next stretch of erroneous parsing is from *achieve* to the end, where each wordÕs mark is pulled down by the error of taking *achieve* to open a subordinate VP within the VP initiated by the preceding *to*. Relative to the SUSANNE scheme used here as gold standard, this also seems a bad error. It is an understandable consequence of the fact that the Briscoe/Carroll automatic parser was based on a parsing scheme that made different theoretical assumptions about grammar, but in the present target scheme no English construction ought to be analysed as ÒVP *to* [VP ...Ó

We would not pretend that our intuitions are so refined that they positively justify a score for *reduce* which is marginally lower than those for the surrounding words, or positively justify the small difference between 0.727 as the lowest score in the second bad stretch and 0.667 in the earlier stretch; the present authorsÕ intuitions are vaguer than that. But notice that, as it stands, the GEIG metric offers no comparable technique for identifying the locations of bad parsing performance within parsed units; it deals in global scores, not local scores. True, one can envisage ways in which the GEIG metric might be developed to yield similar data; it remains to be seen how well that would work. (Likewise, the GEIG/labelled metric could be further developed to incorporate the LA concept of partial matching between label pairs. On the other hand, there is no way that GEIG could be adapted to avoid the unsatisfactory performance exemplified by (2) above.)

Using the LA metric, researchers developing an automatic parser in a situation where large quantities of gold-standard analyses are available for testing should easily be able to identify configurations (e.g. particular grammatical words, or particular structures) which are regularly associated with low scores, in order to focus parser development on areas where further work is most needed. If the parsing scheme used a larger variety of nonterminal labels, one would expect that individual nonterminals might regularly be associated with low scores, though with the very austere nonterminal vocabulary of the Briscoe/Carroll scheme that is perhaps less likely to be so. Even with a small-vocabulary scheme like this, though, one might expect to find generalizations such as ÒWhen a subordinate S begins with a multi-word NP, the parser tends to failÓ Note that we are not saying that this is a true generalization about the particular automatic parser used to generate the data under discussion; one such mistake occurs in the example above, but we do not know whether this is a frequent error or a one-off. Any automatic parser is likely to make errors in *some* recurring patterns, though; the LA metric is potentially an efficient tool for identifying these, whatever they happen to be.

8. Conclusion

From these results, we would argue that the leaf-ancestor metric comes much closer than the GEIG metric to operationalizing our intuitive concepts of accurate and inaccurate parsing.

Someone looking for reasons to reject the LA metric might complain, correctly, that the algorithm for calculating it is much more computation-intensive than that for the GEIG metric. But intensive computation is not a problem in modern circumstances.

More important: there is no virtue in a metric that is easy to calculate, if it measures the wrong thing.

9. Acknowledgment

The research reported here was supported in part by the Economic and Social Research Council (UK) under grant R000 23 8746. We are very grateful to John Carroll for supplying us with the experimental material, generating the GEIG/labelled data, and discussing the material with us.

Evaluating parser accuracy using edit distance

Abstract

This paper examines parser evaluation in terms of edit distance, rather than precision and recall. We demonstrate the potential efficacy of edit distance as an evaluation metric with an example, and compare several edit distance scores to labeled precision and recall scores for several statistical parsers from the literature. We suggest a simple schema that has some nice properties. Finally, we discuss the applicability of edit distance metrics for comparing heterogeneous output.

1. Introduction

The dominant metrics in parsing accuracy evaluation are precision and recall, which might suggest that parsing is a classification task, since these metrics are intended to measure classification accuracy. Another way to view parsing is as a recognition task, more analogous to something like speech recognition – recovering hidden structure over an unlabeled, temporally sequenced signal – than classification. From this perspective, we propose adopting the evaluation metric most widely used for speech recognition, namely string edit distance (Wagner and Fischer, 1974). While there is a literature on tree edit distance (Tai, 1979; Zhang and Shasha, 1989), which involves expanding and contracting labeled edges in a tree structure, we will not approach parser evaluation from this perspective. Rather, we will use the simpler string edit distance between string representations of parses. String edit distance as a general framework is very flexible, which will allow us to score parses on more than simply constituent label and span, and to tailor the edit costs to particular needs. We will use it to evaluate how well a parse matches to gold standard, in terms of (i) a sequence of context-free rules corresponding to the tree; (ii) a sequence of constituents with span information; or (iii) the labeled bracketing itself. We will show that the specific distance metrics we will present have some nice properties: they make similar distinctions between parsers to those of standard labeled precision and recall, when the new measures are applied to statistical parsers trained to produce the same kind of annotation; and they provide a conceptually clean way to encode both partial matches and matches across labeling schemas. This paper is not intended to present a specific approach to evaluating specific parsers; rather a general approach that, in our opinion, has the best chance to provide a unified evaluation framework for the parsing community.

Before continuing further, let us define the terms and metrics that we are going to be using in the course of this paper. A parse can be represented as a labeled bracketing[1], e.g.

```
(S  (NP (DT The) (NN dog) )
    (VP (VBD barked) ) )
```

Each left parenthesis, which we will also refer to as an open bracket, is associated with a label and a right parenthesis, which we will also call a close bracket. Each open and close bracket pair denotes a constituent in the parse tree. Each constituent has a span, which is the part of the string that is at the leaves of the sub-tree rooted at the constituent. For example, the NP constituent in the example spans the words "The" and "dog". Each local tree in the structure, i.e. the constituent label and the labels of its children, constitutes a context-free rule instance. For example, the highest local tree in the above labeled bracketing is an instance of the rule S $\rightarrow$ NP VP.

A parser returns a labeled bracketing of a string, which is evaluated with respect to a hand-labeled "gold standard" annotation. The most widely used metrics to evaluate the accuracy of the parser come from the PARSEVAL recommendations (Black et al., 1991); among these, labeled precision and recall are principal. The labeled measures do not count part-of-speech (POS, also known as pre-terminal) labels, which are those non-terminals with one and only one terminal child. In the above example, the accuracy of the DT, NN, and VBD labels would not be included in the labeled precision and recall scores. Of the other constituents in the labeled bracketing (S, NP, and VP), each would be compared with the constituents in the gold standard parse. If they match the label and the span of an otherwise unmatched constituent in the gold standard parse, then they are counted as correct, otherwise incorrect. Labeled precision (LP) is the number of correct constituents divided by the total number of constituents in the parser's labeled bracketing (excluding, of course, POS). Labeled recall (LR) is the number of correct constituents divided by the total number of constituents in the gold standard labeled bracketing. Often these are combined into a single measure, called the F-measure, according to the following formula:

$$2(\mathrm{LR})(\mathrm{LP})/(\mathrm{LR} + \mathrm{LP}) \quad (1)$$

[1] The labeled bracketing convention that will be used for examples in this paper are those from the Penn Treebank (Marcus et al., 1993), but that is not intended to restrict the scope of this paper to these annotations.

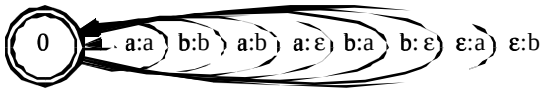

Figure 1: Example edit distance transducer.

The E-measure is 100 minus the F-measure. This will come in handy when comparing precision and recall based measures with error rates based on edit distance. There are other measures in the PARSEVAL recommendations, such as the crossing brackets scores, but for the purpose of this paper, we will focus on labeled precision and recall.

We will present string edit distance as weighted finite-state transduction[2]. Let Σ_0 be the alphabet of the input string $S_0 \in \Sigma_0$*, and Σ_1 be the alphabet of the output string $S_1 \in \Sigma_1$*. Let T be a finite state transducer that maps (i) all $a \in \Sigma_0 \bigcap \Sigma_1$ to themselves at no cost; (ii) all $a \in \Sigma_0$ to $b \in \Sigma_1$ at cost 1 (substitution); (iii) all $a \in \Sigma_0$ to the empty string at cost 1 (deletion); and (iv) the empty string to all $b \in \Sigma_1$ at cost 1 (insertion). Then the edit distance between S_0 and S_1 is the least cost path in $S_0 \circ T \circ S_1$.

Figure 1 presents a transducer for (a+b)*, which, when used according to the previous paragraph, returns the edit distance between two strings. Each arc is labeled with an input symbol i, and output symbol o and a cost c, as follows: $i{:}o/c$. The empty string has label ϵ. Only those arcs which map characters to themselves are cost free. All other arcs – substitution (a:b), deletion (a:ϵ), and insertion (ϵ:b) – have cost 1. Thus, for example, the edit distance between an input string "abab" and an output string "aabb" is two[3].

Of course, it is up to us what the alphabets and strings are. In the case of speech recognition, where edit distance is used to calculate the word error rate (WER), the strings are strings of words in the lexicon, and the transduction maps words to words or the empty string. For the case of parser evaluation, we might consider strings of rules, strings of constituents with span, or strings consisting of pieces of the labeled bracketing. It is also up to us what cost to put on the arcs. In the above figure, all edit costs are one, but there may be cases where the cost of an edit might be judged to be less than one.

The rest of the paper will be structured as follows. First we will motivate the use of edit distance with an example where precision and recall give scores that fail to correspond to intuitive notions of similarity, which an edit distance score is closer to. Then we will present three edit distance measures, and how they perform on four parser implementations from the statistical parsing literature. Finally, we will discuss how this approach can handle more complicated schemas that might address some of the cross-system issues.

[2] For an introduction to finite-state transducers, see, e.g. Jurafsky and Martin (2000).

[3] Note that there is more than one derivation here with the same cost, e.g. a:a b:a a:b b:b (two substitutions) and a:a b:ϵ a:a b:b ϵ:b (one deletion and one insertion).

2. Motivation

One perceived failure of precision and recall measures was presented in Bangalore et al. (1998), namely that shallow parses that do not make strong attachment choices are penalized less than parses that are quite close to the gold standard, but that make some wrong attachment decisions. Their example is repeated here, with node labels on the bracketing.

```

The gold standard parse (1) has the final prepositional phrase modifying the verb phrase, while parse 2 mistakenly attaches the PP to the lowest noun phrase. Other than this, though, parse 2 is quite close to the gold standard. Parse 3 is a much shallower parse, with much of the hierarchy in the gold standard left out. Using standard labeled precision and recall against the gold standard parse (1), parse 2 achieves 72.73 labeled recall and 66.67 labeled precision, or 69.56 F-measure. In contrast, parse 3, which is much farther from the gold standard, achieves 72.73 labeled recall and 100.0 labeled precision, or 84.21 F-measure. The clear reason for this is that judging correctness based on span ignores dominance relationships, so that parse 3 identifies many correct constituents, despite getting the immediate dominance relationships quite wrong (according to the gold standard).

One way to include the dominance relationships is to encode the parse as a sequence of rules (top-down, left-most). This uniquely identifies the tree, and serves as a string for input into the simple edit distance approach outlined in the previous section. We will uniformly give a cost of 1 for each insertion, deletion, and substitution, without giving credit for substitutions between more or less similar

Gold parse rules	parse (2) rules	(2) edits	edit type	parse (3) rules	(3) edits	edit type

Table 1: Edits from gold standard for aligned rule sequences.

Figure 2: Labeled bracketing encoded as a string

rules. This may appear somewhat coarse, but it is merely a starting point. If it is felt that certain rules are, in some sense, closer than others, then this can be represented in the amount of cost that is associated with that arc in the transducer. The approach is general enough to allow for different costs. To begin, we will count each deletion, substitution, and insertion as one edit, and present the error rate, i.e. the total edit cost per 100 rules of gold standard. This is the same measure that is used for accuracy in the speech recognition community (word error rate).

One note about the encoding: because every left-hand side category (except S at the root) also occurs on a right-hand side, we omit the left-hand side category (except the initial S), so as to avoid doubling errors. Because of the rule ordering, there is no ambiguity with respect to the left-hand sides.

Table 1 shows the aligned sequences of rules, and the edit cost accumulated by both parse 2 and parse 3 under the standard cost. Recall that the symbols that are being compared are entire rules, not individual non-terminals within the rules. Hence each candidate parse has a single substitution for the verb phase expansion, despite the fact that the parse 2 VP expansion is in some sense closer to the original than that of parse 3. In this sense, as was stated above, the metric is somewhat coarse. Nevertheless, we can see that parse 2 accrues one substitution and one insertion, for an error rate of 18.2 (2 edits for 11 rules), whereas parse 3 accrues one substitution and three deletions for a 36.4 error rate. These scores better correspond to our intuition, and the one stated in Bangalore et al. (1998), that parse 2 is closer to the gold standard than parse 3.

What this example demonstrates is that there are circumstances where precision and recall can unduly penalize parses, and others where they do not penalize parses enough. Edit distance between sequences of rules does the right thing, at least in these cases. Note, however, that edit distance does not need to be over sequences of rules. In fact, we can calculate edit distance over constituent spans, by replacing the rules in the table above with the left-hand side and word span positions. In the next section, we will present a third edit distance approach, which treats the labeled bracketing itself as a string. This will be followed by some parser evaluations using all three of our proposed edit distance approaches.

3. Labeled bracketing edit distance

Before presenting our method for calculating edit distance between labeled bracketings, let us first discuss how to encode them as strings, i.e. what are the tokens? We will adopt what was used in Roark (2001b) for storing automatically generated treebanks. Every open bracket has a label, so an open bracket plus its label is one token. Terminal items (i.e. lexical items) are always followed by a close bracket (at least in Penn Treebank annotation), so terminal plus close bracket is one token. Finally, close brackets for non-POS constituents, which do not have an associated terminal item, are each tokens. In this way, the labeled bracketing can be encoded as a string. Figure 2 shows our original labeled bracketing encoded as a string with this tokenization.

To calculate the edit distance between labeled bracketings of the same string, we are going to exploit some characteristics of the bracketing. First, we know that the terminal items are the same in the input and the gold standard. Hence there is no need to provide any arcs for terminal items other than those mapping them to themselves. Next, we assume that both the input and the gold standard are balanced, i.e. there are the same number of right and left parentheses. What this means is that, for every successful mapping between one parse to the other, every deleted open bracket must be matched with either an inserted open bracket or a deleted close bracket, to maintain balanced bracketing. Indeed, any bracket insertion or deletion must be paired with another edit.

	Open Bracket	Close Bracket
Delete	(X:ϵ/0.5	):ϵ/0.5
Insert	ϵ:(X/0.5	ϵ:)/0.5

Table 2: Labeled bracketing edit cost table

If we used a standard edit cost of 1, then we would get a double count for every deleted or inserted constituent. If, however, we make the cost of deleting or inserting open (labeled) brackets or close (non-terminal) brackets one half, we can rely on the balanced brackets property to ensure that we ultimately get a cost of one for the error. Table 2 presents this cost schema. One nice side effect of this is that substitution can be considered simply as a deletion plus an insertion, and hence automatically given an edit cost of 1, without having to explicitly put substitution arcs into the transducer, since deleting a labeled bracket and inserting an alternatively labeled bracket has cost 1 under this schema. We can, however, if we wish, allow substitution at no cost. For example, if we do not wish to include POS tags in the evaluation, we can allow any POS tag to rewrite as any other POS tag with no cost. Since the close brackets for POS tags are terminals, which cannot be inserted or deleted, and since the yield for the two parses are identical, this free substitution means that no POS tagger error will result in any cost for the least cost transduction. Let us refer to as the *basic labeled bracketing edit transducer* that which maps (i) all symbols to themselves at no cost, (ii) all non-POS open bracket non-terminals to epsilon and vice versa at cost 0.5, (iii) the close bracket symbol to epsilon and vice versa at cost 0.5, and (iv) all POS open bracket non-terminals to all other POS open bracket non-terminals at no cost.

There does remain one serious problem with this approach, however. Referring back to our motivating example in the previous section, one can see by inspection that the least cost path under this approach between the gold standard (parse 1) and parse 2 will involve deleting one NP constituent (one open and one close bracket) and inserting and deleting three close brackets. In other words, the misattachment of the PP is costing just as much as it would under precision and recall evaluation. A better solution is to allow certain kinds of constituent movement to count as just one edit. Deleting and inserting consecutive close brackets in effect allows constituents to be moved higher or lower in the hierarchy. Thus, in parse 2, the deletion of the three close brackets from their current location and their insertion into the correct location – how the movement of the constituent is effected – should count as a single edit. We can do this with a simple additional pass over the least cost path through the composition with our basic labeled bracketing edit transducer.

This basic transducer cannot simply be changed to give less cost to deletion and insertion of multiple consecutive close brackets, because those brackets may be paired with open brackets or non-consecutive close brackets. We only want to give reduced cost to those consecutive brackets that are matched with other consecutive brackets. We could, in advance of composition with the basic labeled bracketing

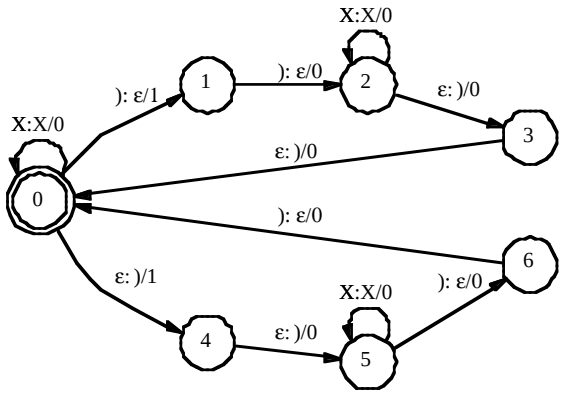

Figure 3: Example transducer giving cost 1 to multiple consecutive bracket insertion and deletion. 'X' is intended to range over all symbols.

edit transducer, pass the input through an arbitrary number of transducers that, for any given k, map the input to an output by deleting k consecutive close brackets and inserting k consecutive close brackets, at a cost of 1. Figure 3 shows one such transducer, for two consecutive brackets. Because an arbitrary number of these would need to apply in order to cover all possible movements, this is not a particularly useful approach.

Luckily, we can find the exact cost that corresponds to this approach, without having to actually perform these transductions, very quickly in the following manner:

1. Find the least cost path p through the composition with our basic labeled bracketing edit transducer
2. Calculate the total cost c of the edits in p
3. Find the length of the longest consecutive string of deleted close brackets m and the length of the longest consecutive string of inserted close brackets n in p
4. $r = \min(m,n)$
5. If $r \geq 2$
   a) remove r consecutive deleted and r consecutive inserted close brackets from p
   b) $c = c - (r - 1)$
   c) return to 3.
5. return c

This will yield the same edit cost that would have resulted from applying the arbitrary transductions described in the previous paragraph. To see this, one must recall that all consecutive close bracket symbols come immediately after terminal items. Because the terminal items cannot be inserted or deleted, this means that the only way to reposition close brackets into the correct location is to delete them and re-insert. The deletion or insertion of any other symbols will not change this. Hence the deletion and insertion of consecutive close brackets will be part of the least cost path through the basic transducer. If there exist consecutive deleted brackets and consecutive inserted brackets of the same length, then there would have been a better path between the input and gold standard parses that involved pairing these consecutive brackets, and hence ac-

Parser	F-measure	Label edit	Span edit	Rule edit
Charniak (2000)	89.74	87.95	86.5	85.6

Table 3: Comparison of four parsers with four measures of accuracy

cruing a single edit. The above algorithm will find all such instances, and adjust the cost accordingly.

We will call the score that results from this method of calculating the edit distance between two labeled bracketings, which counts movements of constituents as a single edit, "Label edit distance" to contrast it with the other edit distance scores that we have discussed, "Rule edit distance", which is based on the edit distance between ordered sequences of rules, and "Span edit distance", which is based on the edit distance between ordered constituents with span and label.

In the next section, we will present scores using different measures for four treebank-style parsers from the literature. This will be followed by a discussion of how these approaches generalize.

4. Evaluation

To evaluate these edit distance measures, we will measure performance of the output from four different parsers. Each of the four parsers was trained on sections 2-21 of the Penn Wall St. Journal Treebank, and tested on section 23. We can thus compare the parsers with each other using different measures, and compare the measures by looking at the distinctions that are made by the measures between the variously performing parsers.

The parsing outputs are those taken from the latest version of the parser presented in Charniak (2000), and the output from Collins (2000), Collins (1997), and Roark (2001a)[4]. For each of the edit distance measures – label, rule, and span – we can define the error rate, which is the number of edits per 100 events (i.e. rules or constituents) in the gold standard parse. The accuracy is then defined as 100 minus the error rate. The accuracy measures that we used were: (i) F-measure; (ii) Label accuracy (based on label edit distance); (iii) Span accuracy (based on span edit distance); and (iv) Rule accuracy (based on rule edit distance). To avoid penalizing the parsers for POS tagging errors, the POS tags in rule instances used for the rule edit distance were replaced with the terminals. Table 3 shows the four different scores of the four parsers.

All three of our edit distance metrics are harder on the parsers than the F-measure score, with rule edit distance giving the lowest scores overall. This is perhaps not surprising given the particular test domain, since the Penn Treebank annotation is known for having many flat constituents, most notably the base NP constituents. In this case, then, we can have structures with no rules correct, but some constituent span predictions correct.

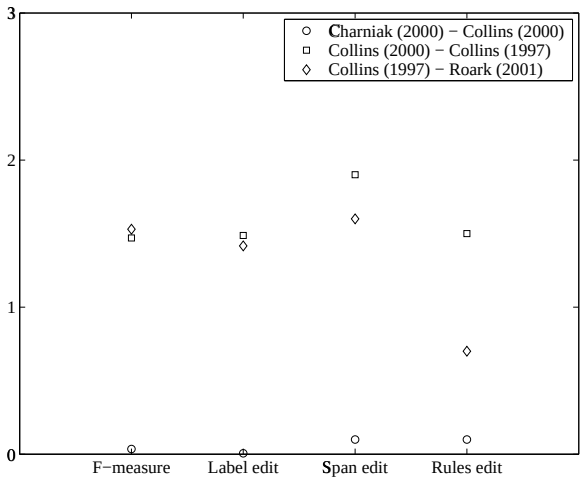

Figure 4: The difference between accuracy scores with F-measure and the three edit distances, for the four parsers: Charniak(2000) minus Collins (2000); Collins (2000) minus Collins (1997); and Collins (1997) minus Roark (2001)

It is interesting to note that, despite the differences in scores – with F-measure giving the highest scores, and rule accuracy generally the lowest scores – there is always the same ordering among parsers. To see how close the distinctions between the parsers are under the four different measures, in figure 4 we plotted the differences in score between parsers ranked n and (n+1), for each of the four measures. As one can see, the distinctions that are being made between parsers are remarkably consistent between the measures. The only exception to this is that the Roark (2001) parser does relatively better in rule accuracy – in fact half a point better than span accuracy, while all the other parsers had worse rule accuracy than span accuracy. This may be due to the fact that the Roark parser is a left-to-right incremental parser, making predictions about children of a left-hand side given the context, in contrast to the others, which also make predictions about heads of constituents given governing heads. Thus it may tend to do a better job choosing children of the left-hand side than it does choosing specific constituents. Alternately, it might be that this parser is making more grave attachment errors than the others, and hence benefitting from the rule-oriented evaluation, which has been shown to be more lenient on these errors. If this were true, however, we would expect the labeled bracketing accuracy to be similarly affected, which it is not.

This is all well-and-good for overall scores, but how do these measures differ on a sentence by sentence basis. Figure 5 plots each sentence from Charniak (2000), with its labeled bracketing error rate versus its E-measure, i.e. 100 minus F-measure. Along the line the scores are identical[5].

[4]The F-measure accuracy for the Charniak parser is 0.2 better than the published result. In addition to these four parsers, we also attempted to obtain the output from one other high accuracy parser, but were unable to do so.

[5]The labeled bracketing error rate goes above 100, because there can be more edits required than there are non-terminals in the parse, e.g. if there is nothing right.

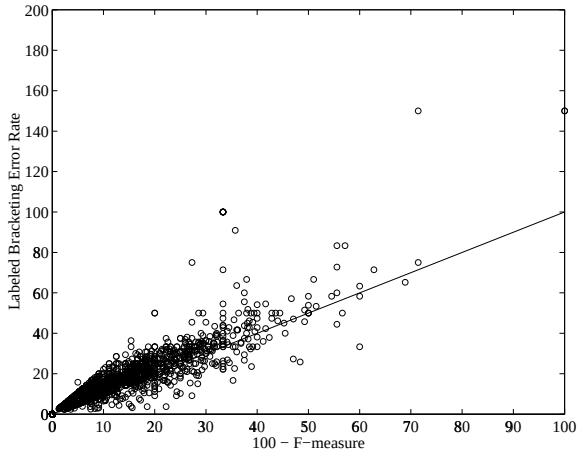

Figure 5: 100 - F-measure (E-measure) versus labeled bracketing edit rate for each sentence in section 23 from Charniak (2000)

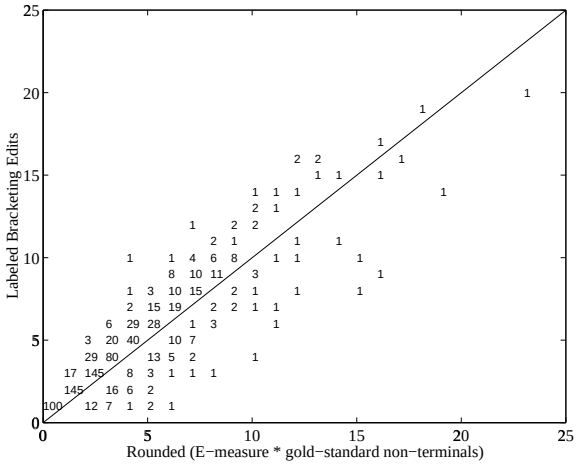

Figure 6: Number of sentences at (x,y), where x is E-measure * non-terminals rounded to the nearest integer, and y is labeled bracketing edits.

Most of the parses are close, but there are some outliers. A brief inspection of some of the outliers provides no surprises. Those out along the x-axis result from constituent attachment decisions that make many constituents incorrect with respect to their span. Those closer to the y-axis result from large differences in precision and recall – i.e. perfect precision and poor recall or vice versa – which tend to give higher F-measure scores than if we simply count the number of edits required to match the gold standard parse.

Most of the parses that have very divergent scores are quite small, so that a small number of required edits accounts for a large percentage of the non-terminals in the parse. These do not account for much when it comes to overall performance, because the raw numbers that they contribute are small. To try to get a better sense of where the bulk of the differences are, we plotted in figure 6 the raw numbers that fall into particular buckets. For the edit distance score, we have the number of edits. To approximate a number of errors in the precision and recall case, we took the E-measure times the number of non-terminals in the gold standard parse, and rounded it to the nearest integer. At each point (x,y), where x is the rounded approximation to errors from the E-measure, and y is the number of edits required for the labeled brackets, we plotted the number of sentences out of the test set of 2416 sentences that fall in that bucket. We omitted those sentences where x = y. As one can see, the bulk of the sentences that differ do so by one or two. Those that are greatly different are relatively rare.

To summarize this section, we have presented three evaluation measures based on edit distance. All three give lower scores than labeled precision and recall to the parsers evaluated, yet they maintain similar distinctions between the parsers. That is, these measures are just as useful as precision and recall in discriminating between parsers in the domain where precision and recall has been used most widely and most successfully. The labeled bracketing and rules edit rate scores give better scores than precision and recall for certain kinds of errors, although these parsers do not seem to be making these errors with much frequency.

In the next section, we will discuss how edit distance scoring allows for very natural generalizations for such things as heterogeneous labeling schemas.

5. Discussion

For the case of labeled bracketing, an edit distance approach provides a very natural way to extend evaluation to include such things as partial matches or equivalence classes. For example, suppose the gold standard parse includes things such as function tags, e.g. not simply NP, but NP-SBJ for subject NPs, or PP-TMP for temporal PPs. One may want to impose some cost for failure to label these tags onto the non-terminal node. This cost may be less than that imposed for a complete mismatch. In order to do this, all that one needs to do is include a transition in our transducer to map from one to the other with the desired cost. Similarly, one may want to include POS tags in the evaluation, but impose less of a cost for mis-tagging something that should be NN as, say, NNP, than one would for mistagging it as VBD. Errors in POS tagging as a whole could be assigned less cost than errors in non-POS labels.

Alternately, one might be more interested in whether or not the parser finds the categories of a shallow parse accurately. In this case, one might not impose any cost for deletion, just for insertion, i.e. more structure is okay. Some might consider this “dumbing down” the parser, but in fact getting very flat constituents high in the tree correct can be more difficult than making finer distinctions lower in the tree. For purposes such as information extraction, for example, a lot of hierarchical structure may be less important, which would lead one to an evaluation of this sort. Making deletion cost free is very straightforward.

Perhaps most importantly, edit distance generalizes to any sequence of parser decisions, including those of, say, a dependency parser. Given the left-to-right ordering of the words, we can stipulate an ordering among dependency relations to give an overall ordering of the dependencies. Edit distance can then straightforwardly apply in the same way

as it did to the sequence of rules. This approach was taken in evaluating a natural language generation system in Bangalore et al. (2000).

One benefit of using edit distance on a simple sequence of rules, constituents with span, or dependency relationships, is that existing error rate software, such as those used for speech recognition evaluation, can be used as is on the output. This is actually how the evaluation from the previous section was carried out for the rule edit distance and the constituent span edit distance[6]. This is beneficial, not only because one does not have to write new code to evaluate the output, but also because these evaluation routines often can output interesting diagnostic information, including frequent substitutions, merges, or splits.

One comment that is obvious, but deserves to be made nonetheless, is that the evaluation should fit the task. Why should the degree to which a parser can identify dependencies be a better evaluation than the degree to which it can identify constituents? Only insofar as some particular task requires lexical dependencies, not constituents. Parsing, unlike speech recognition, is not generally viewed as a task in and of itself. Rather, it is taken to be in service of something else, e.g. some kind of semantic processing or language modeling. This can also be true of the output of a speech recognizer – the recognized words might be used to attempt to classify the utterance, for example. In that case, it may be useful to measure WER, but ultimately the efficacy of the particular recognizer will be found in the classification accuracy. If an improvement can be had in recognizer accuracy that makes no difference in classification accuracy, then why bother. The same is true in parsing. The danger with embedding a parser in another system for evaluation is that it becomes more difficult to control for the other parts of the system. It thus is beneficial to be able to evaluate the output of the parser independently – but presumably with respect to its ability to recognize the hidden structures that are used by the system. In the absence of such a parser-independent criterion, objective evaluation is difficult. In its presence, error rate and accuracy based on edit distance is a good alternative for evaluation.

In this paper, we have presented three edit distance measures that can be used to evaluate parsers. The intent is not to exhaust the possibilities of the approach, but rather to show that, as a general framework, edit distance can provide the flexibility to meet the varied demands of parser evaluation. These measures can make similar distinctions between parsers as is made by precision and recall, yet repair some long-standing weaknesses of them. Edit distance can be applied to a variety of string representations of trees, including an ordered list of constituents with span, an ordered list of context-free rules, or even the labeled bracketing itself.

6. Acknowledgements

Thanks to Eugene Charniak and Michael Collins for sharing the outputs of their respective parsers. Thanks also to Mehryar Mohri and Srinivas Bangalore for useful discussion on this topic.

[6]Since the labeled bracketing edit distance required a special transducer, it was evaluated differently.

Evaluating Syllabification: One Category Shared by Many Grammars

Karin Müller

Department of Computational Linguistics
University of Saarland
Saarbrücken, Germany
kmueller@coli.uni-sb.de

Abstract

We apply a series of context-free grammars to syllabification by using a supervised training method. In our experiments, we investigate various phonological grammars, which strongly differ in structure. A simple evaluation metric "word accuracy" supports grammar development by denoting an increasing performance for grammars enriched with linguistic structure. This evaluation, judging one single category shared by all grammars, is in strong contrast to PARSEVAL, which is designed for a single grammar evaluating (almost) all categories. Using a toy-treebank, we show that the PARSEVAL measures are hard to interpret, since the results are inconsistent with one another. It turns out that evaluating only a limited number of categories (here only one single category) is a harder evaluation measure than measuring the precision of all occurring substructures of a grammar.

1. Introduction

In computational linguistics, the PARSEVAL measures suggested by Black et al. (1991) are now the standard measure for evaluation of context-free grammars (CFGs). The measures quantify precision and recall of common parenthesis based on a treebank. The metrics focus on the precision of all substructures that are specified by a CFG. However, the PARSEVAL metrics are not suitable for all problems that can be described with probabilistic context-free grammars (PCFGs) especially in cases when partial structures are more interesting. In comparison to the field of parsing, there are no phonological treebanks of transcribed words. However, large pronunciation dictionaries are available which can be exploited for evaluation and training. We develop a series of grammars in our supervised experiments and evaluate them on partial structures. There are two main reasons why we chose an evaluation procedure different from PARSEVAL. Firstly, if we had chosen the PARSEVAL evaluation metrics, a separate evaluation suite would have to be constructed for each grammar type. This would be very time-consuming. Secondly, we chose alternative evaluation metrics because syllabification tasks are usually evaluated either by syllable accuracy or even word accuracy, i.e. partial structures of a phonological tree are evaluated. Syllable accuracy means that each syllable is compared with an annotated syllabified corpus. If the system predicts the syllable boundary correctly, syllable accuracy increases. A stricter variant of measuring the capability of a system is to determine word accuracy, which means that each syllable boundary has to be predicted correctly within a word. We try to solve the evaluation problem by annotating and evaluating those structures which are usually referred to in the literature linked to syllabification, and which are shared by all grammars.

The paper is organized as follows: in Section 2, we introduce the syllabification task, as well as a series of phonological grammars describing German syllable structure. Section 3 discusses our evaluation measure in comparison to PARSEVAL. In Section 4, we conclude.

2. Syllabification

In text-to-speech (TTS) systems, like those described in Sproat (1998), the correct pronunciation of unknown and novel words is a crucial problem. Thus, TTS systems usually use large pronunciation dictionaries, however there are in all languages productive word formation processes which generate words that are new to the system. The correct pronunciation of a new word is not only dependent on the correct identification of phonemes but also on the correct assignment of syllables. Van Santen et al. (1997) showed that location in the syllable influences the duration of a phone. Furthermore, identifying syllables boundaries is essential for the application of phonological rules (Kahn (1976), Blevins (1995)), which is certainly the case e.g. for German syllable-final devoicing. Thus, we are interested in developing models that predict syllable boundaries of unknown words as well as possible. This means for context-free grammars, that we need a single category e.g. "SYL" (i) which spans a whole syllable, (ii) occurs in all grammars and (iii) which can be evaluated easily.

In our approach, we developed several context-free grammars and trained them on large automatically transcribed corpora extracted from newspaper corpora by looking up the words and their transcriptions in the pronunciation dictionary CELEX (Baayen et al. (1993)). The different grammars describe the internal structure of words and can be used to predict syllable boundaries after a training procedure. In our experiments, we use a supervised training method which is a combination of treebank and bracketed corpora training (Müller (2001)) exploiting the syllabification information of a pronunciation dictionary and the frequency information of a training corpus consisting of 182 000 words.

We investigate six different grammars to predict syllable boundaries by introducing new categories for each new grammar.

Treebank grammar. The first grammar describes a word as a sequence of syllables consisting of one or n phonemes. The analysis at the top of Figure 1 dis-

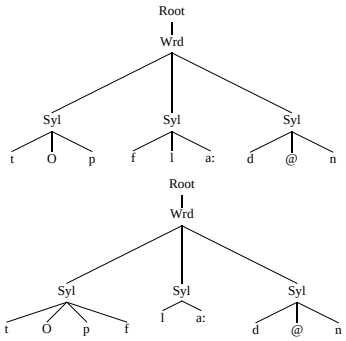

Figure 1: Treebank grammar

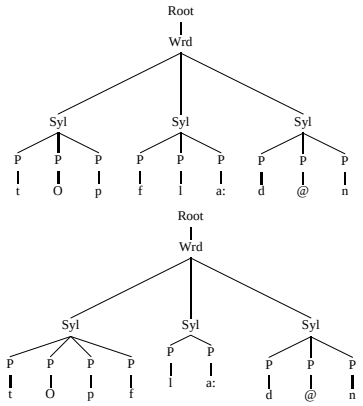

Figure 2: Phoneme grammar

plays a possible syllabification of the German word "Topfladen" ([tOpfla:d@n], which can be either translated by *top chapatti* (Top-fladen), or *pot shop* (Topfladen) (of course there are additional possible syllabifications)

Phoneme grammar. The second grammar introduces an abstract level between the phonemes and the syllables. Each phoneme is labeled by an abstract phoneme label. The grammar learns information about the complexity of a syllable. Figure 2 shows two possible analyses of the phoneme string [tOpfla:d@n] according to the phoneme grammar.

Consonant-vowel grammar. The third grammar distinguishes between consonants and vowels by labeling all phonemes either by a C or a V label. The grammar also demands a vowel inside of a syllable. The structure of the grammar is exemplified by Figure 3 displaying two possible syllabifications of the phoneme string [tOpfla:d@n].

Syllable structure grammar. The fourth grammar specifies syllable structure in more detail. Syllables are split into onset, nucleus and coda. The probability of a consonant depends on its occurrence in the onset or the coda. Two example trees of the phoneme string [tOpfla:d@n] are shown in Figure 4.

Positional syllable structure grammar. The fifth grammar further describes a phoneme depending on the position of the syllable within the word, and depending on the position of the phoneme within the syllable by enumerating the consonants. There are four possible positions of the syllable: word-initial, word-medial, word-final, and monosyllabic words. The consonants of the phonemes are enumerated according to their position inside of the syllable onset, or coda. The structure of the grammar is examplified in Figure 5

Advanced positional syllable structure grammar. An additional feature, cluster size is added to the last grammar. Thus, the consonants depend on their position within the cluster, and the size of the cluster. Figure 6 displays two examples.

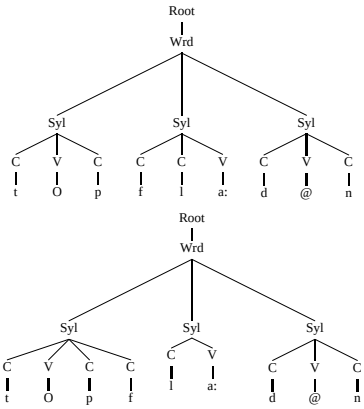

Figure 3: Consonant-vowel grammar

In a next step, the grammars are trained using a novel algorithm consisting of a combination of bracketed corpora and treebank training (see Müller (2001)). However, in contrast to older experiments (where we trained on a series of training corpora ranging from 4 500 to 2.1 million words), we use for our new experiments a fixed training corpus consisting of 182 000 words. Training on this corpus provides a probabilistic version for each of the six phonological grammars. Since all grammars have in common that they are written to predict syllable boundaries, they share the category "SYL" which spans a whole syllable. After training, we can use the most probable parse of a word, the so-called Viterbi parse, to read off the syllables of this word: all phonemes under a syllable node "SYL" belong to one syllable. In Section 3, we describe the performance for the trained grammars on a syllabification task using a huge evaluation corpus of about 240 000 words. Moreover, we try to relate these results to an evaluation using PARSEVAL measures for a toy-treebank.

3. Evaluation

As already presented in Section 2, our system is designed to predict syllable boundaries using probabilistic phonological grammars. For parsing, we used the implementation of Schmid (2000). Our evaluation corpus consists of about 242 000 correctly syllabified words. For syllabification of these words, we used the CELEX dictio-

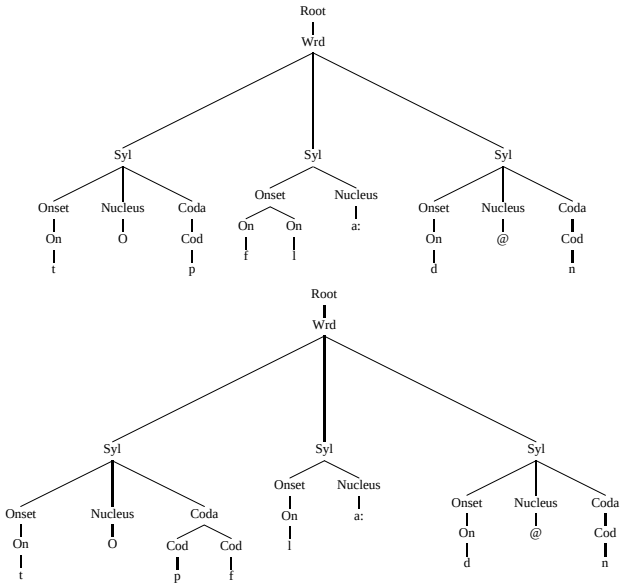

Figure 4: Syllable structure grammar

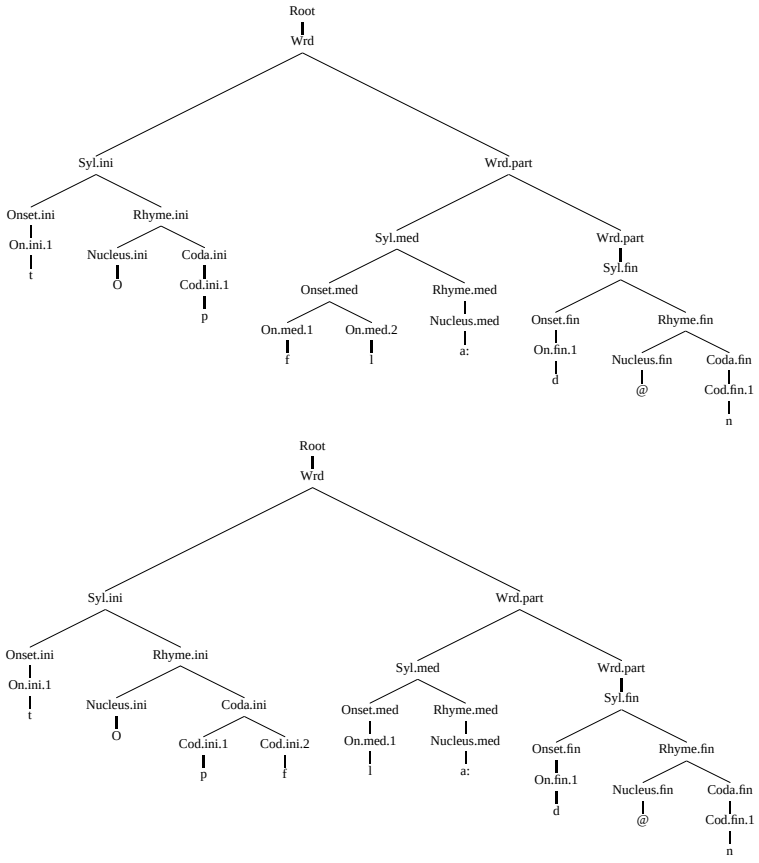

Figure 5: Positional syllable structure grammar

nary. For accuracy measurement, the raw phoneme strings of each word of the evaluation corpus are parsed with our various PCFGs, and the Viterbi parses are taken to extract the syllables of the phoneme strings. Then, the result is compared with the annotated variant in the evaluation corpus. Word accuracy is computed by counting the number of correctly syllabified words, and by dividing this number by the size of the evaluation corpus.

3.1. Evaluation Results

Figure 1 shows our evaluation results. Column 1 displays the series of grammars we investigated, and Column 2 displays the corresponding accuracy values.

The evaluation shows that the grammar with the richest

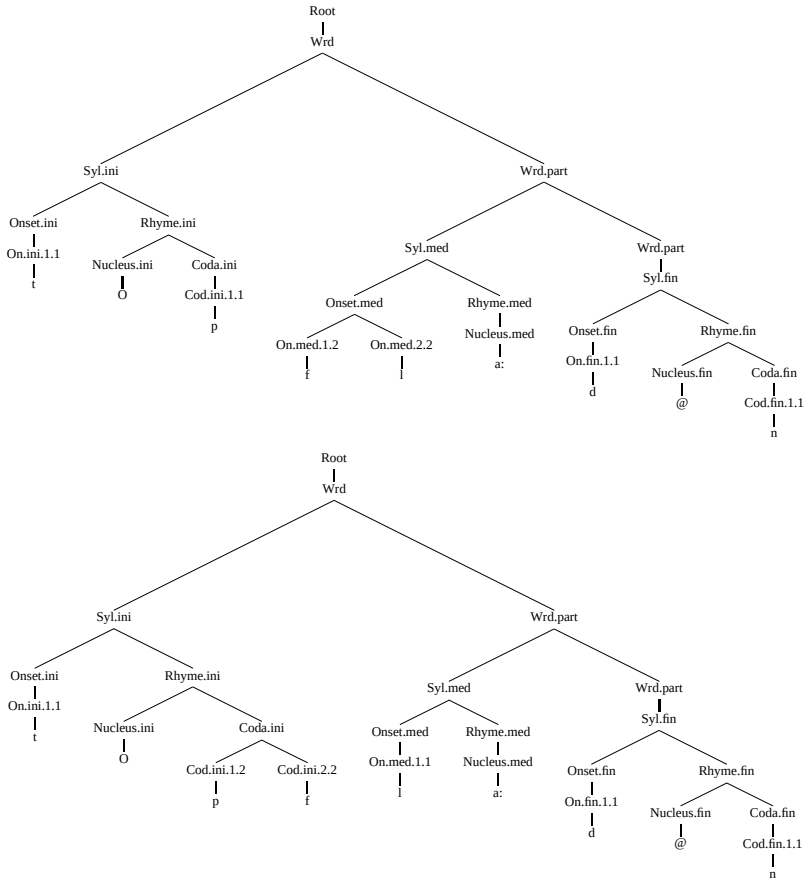

Figure 6: Advanced positional syllable structure grammar

grammar	word accuracy

syllable structure grammar	94.12
positional syllable structure grammar	96.42
advanced pos. syllable structure grammar	96.48

Table 1: Word accuracy of the probabilistic phonological grammars trained on a corpus of 182 000 words, and evaluated on a corpus of 242 000 words.

structure, the advanced positional syllable structure grammar, reaches the highest performance of 96.48% word accuracy for a training corpus size of 182 000 words. In general, the more linguistic knowledge is added to the grammar, the higher the accuracy of the grammar is. In contrast to the linguistic grammars, the results of the treebank grammar strongly depend on the size of the training corpus as reported in Müller (2001). They showed that even the simplest grammar, the phoneme grammar, was better than the treebank grammar until the treebank grammar was trained with a corpus size of 77 800. Of course, the low accuracy rates of the treebank grammar (trained on small corpora) were due to the high number of syllables that have not been seen in the training corpus.

3.2. Comparison to PARSEVAL

In this section, we want to exemplify that the problem of using PARSEVAL measures for this series of grammars is that an increase (or decrease) of the PARSEVAL measures can hardly be interpreted in terms of syllabification. In more detail, we show that it is simply unclear what it means for syllabification if two structurally varying grammars yield different values for "labeled precision".

The following example clarifies the problem why we choose an evaluation measure different from PARSEVAL. Let us suppose that

(i) the evaluation corpus consists of one single word, namely the above mentioned example word "Topfladen",

(ii) all six trained grammars predict the (wrong) syllable structure, Top-fladen ([tOp][fla:][d@n]) shown at the top of Figures 1-6,

(iii) the correct syllabification of Topfladen is annotated as Topf-laden ([tOpf][la:][d@n]) coded in six different treebanks shown at the bottom of Figures 1-6,

(iv) we evaluate our series of phonological grammars with the PARSEVAL measure "labeled precision".

Under these assumptions, all grammars fail in solving the syllabification task: all grammars yield a word accuracy of 0%, and a syllable accuracy of 33%. However, if the

grammars	analyses	PARSEVAL without preterminals	labeled precision
treebank grammar (Figure 1)	tree at the top tree at the bottom	**Wrd(0:9)** **Wrd(0:9)**	 1/1 = 100%
phoneme grammar (Figure 2)	tree at the top tree at the bottom	**Wrd(0:9)**, Syl(0:3), Syl(3:6), **Syl(6:9)** **Wrd(0:9)**, Syl(0:4), Syl(4:6), **Syl(6:9)**	 2/4 = 50%
consonant-vowel grammar (Figure 3)	tree at the top tree at the bottom	**Wrd(0:9)**, Syl(0:3), Syl(3:6), **Syl(6:9)** **Wrd(0:9)**, Syl(0:4), Syl(4:6), **Syl(6:9)**	 2/4 = 50%
syllable structure grammar (Figure 4)	tree at the top tree at the bottom	**Wrd(0:9)**, Syl(0:3), Syl(3:6), **Syl(6:9)**, **Onset(0:1)**, Coda(2:3), Onset(3:5), **Onset(6:7)**, **Coda(8:9)** **Wrd(0:9)**, Syl(0:4), Syl(4:6), **Syl(6:9)**, **Onset(0:1)**, Coda(2:4), Onset(4:5), **Onset(6:7)**, **Coda(8:9)**,	 5/9 = 55.5%

Table 3: PARSEVAL measure "labeled precision" (including preterminals) calculated on the basis of the examples shown in Figures 1-6

PARSEVAL measure "labeled precision" is expected to be useful for the syllabification task, then "labeled precision" should express that all grammars perform equally good (or bad) in our toy-setting.

Table 2 displays the results of "labeled precision". The matching brackets are shown in bold. Following the suggestion of Manning and Schütze (1999), the root node "Root" is not taken into account. Moreover, we omitted comparisons of pre-terminal nodes, since Manning and Schütze (1999) suggest to evaluate tagging and parsing separateley. In this evaluation, the simplest grammar, the treebank grammar, achieves the highest value for labeled precision (100%), since only the word-node is taken into account. The phoneme and the consonant-vowel grammar achieve the lowest values for labeled precision (50%). Table 3 also displays the results of "labeled precision", but here, we include the comparison of pre-terminals, due to the fact that we never applied our grammars using a

seperate tagger. Here, the treebank grammar achieves the lowest value for labeled precision (50%). The phoneme grammar, and the consonant-vowel grammar achieve the highest values for labeled precision (84.6%).

Thus, the results of both evaluations are hard to interpret, since they are inconsistent with one another. Furthermore, neither the first evaluation (omitting pre-terminals), nor the second evaluation (including pre-terminals) correspond to syllable accuracy, or word accuracy.

For these reasons, we doubt that the PARSEVAL measures are useful for evaluation of phonological grammars, at least for our grammars, which we developed for the syllabification task in mind. In contrast, we focus on evaluation of partial structures, namely on the category "SYL", and measure how good the grammars detect this single category on the word level. Interestingly, it seems that evaluating only a limited number of categories (here only a single category) is a harder evaluation measure than measuring the precision of all occurring substructures of a grammar.

3.3. Grammar Transformation: An Attempt to Map Word Accuracy to PARSEVAL

In this section, we discuss a grammar transformation enabling the measurement of word accuracy via PARSEVAL measures. In more detail, it could be suggested that the output of the phonological parser can be transformed to a tree, where all categories are removed except for the categories "Root", "SYL", and the terminals. However, if we follow this suggestion, there appear some problems. For the transformed grammar,

(i) the remaining category "SYL" is a pre-terminal node, which is usually NOT evaluated according to PARSEVAL; at least, if we follow Manning and Schütze (1999), who suggest to treat the tagging and parsing problem separateley.

(ii) all phonological information about syllable structure is lost, i.e., the syllabification problem is transformed to a tagging problem. However, we proved in recent work (Müller (2001), Müller (2002)) that it is advantageous to regard syllabification as a parsing problem.

(iii) although syllabification is a kind of segmentation, i.e., a one-dimensional process on a sequence of phonemes, we experienced, the more linguistic knowledge is added to the grammar, the higher the word accuracy of the grammar is. Thus, in our point of view, it is more adequate to model syllabification as a higher-dimensional process.

For these reasons, we prefer to use phonological enriched context-free grammars for stochastic inference and an evaluation focusing on partial structures most important for the particular task.

4. Conclusion

We presented an approach to supervised learning and automatic detection of syllable boundaries. In our experiments, we used a variety of grammars, which strongly differ in structure.

An evaluation using the standard measure for syllabification "word accuracy" shows that the grammar with the richest structures, the advanced positional syllable structure grammar, reaches the highest performance of 96.48% word accuracy for a training corpus size of 182 000 words. In general, the more linguistic knowledge is added to the grammar, the higher the word accuracy of the grammar is.

This evaluation, judging one single category of many grammars, is in strong contrast to PARSEVAL, which is designed for a single grammar evaluating (almost) all categories.

In a second evaluation using the original PARSEVAL measures on a toy-treebank, and a simple variant of the PARSEVAL measures, the results of both evaluations are hard to interpret, since they are inconsistent with one another. Furthermore, we found that neither the first evaluation (omitting pre-terminals), nor the second evaluation (including pre-terminals) correspond to syllable accuracy, or word accuracy.

Moreover, it turns out that evaluating only a limited number of categories (here only a single category) is a harder evaluation measure than measuring the precision of all occurring substructures of a grammar.

Lastly, we discussed a grammar transformation enabling the measurement of word accuracy via PARSEVAL measures. Here, it was necessary to reduce the syllabification problem to a tagging problem. However, we believe that it is advantageous to regard syllabification as a parsing problem.

For these reasons, future work will still use phonological enriched context-free grammars for stochastic inference and evaluations focusing on partial structures most important for the particular phonological task.

Abstract

Various efforts have been undertaken for developing methods for parser evaluation (Black et al., 1991; Lin, 1995; Carroll et al., 1996; Lin, 1998; Carroll et al., 1998; Carroll et al., 1999). These efforts concentrated on developing measures of parser performance, e.g. PARSEVAL (Black et al., 1991) labeled recall/precision for phrase-structure annotations. Different problems have been identified in the existing evaluation methods, but one of these problems strikes us as particularly challenging. The current benchmark for parser evaluation, Penn Wall Street Journal (WSJ) tree-bank (Marcus et al., 1993), cannot be used for the evaluation of parsers that are based on linguistic theories or annotation schemes that differ (*essentially*) from the annotation scheme found in this tree-bank. This problem can be restated as follows: how can parsers from different linguistic frameworks be *compared* in a quantitative and thorough manner? In this paper, we address this problem and suggest a new methodology for comparing parsers. The new methodology integrates Information Theoretic measures together with the PARSEVAL measures in a way that allows direct comparison of parsers that originate from different linguistic frameworks.

1. Introduction

In the last decade or so, a relatively large body of work in Computational Linguistics has been directed at the development and application of different parsing models for natural language processing e.g. (Brill, 1993; Magerman, 1993; Bod, 1995; Charniak, 1996; Eisner, 1996; Ratnaparkhi, 1997; Collins, 1997; Carroll et al., 1998; Lin, 1998; Chiang, 2000; Sima'an, 2000). Much work has been concentrating on how to extract stochastic models from existing tree-banks. One tree-bank in particular, the Penn Wall Street Journal tree-bank (Marcus et al., 1993) has received much attention in these efforts. Regardless of the reasons for this situation, this tree-bank has become a kind of bench mark for the evaluation and comparison of parsers. However, parsers that do not abide by the same linguistic framework as the WSJ tree-bank, or parsers for other languages than American English, are hard to compare to the mainstream which has been tested on the WSJ tree-bank. In this paper we address the issue of parser comparison across different linguistic frameworks. This problem is interesting as it touches on linguistic issues, but also on the question "how to view the role of language structure". In this preliminary report on our research into this question, we assume that the parsers that are being compared are built for the same language. We also assume the existence of a corpus of utterances, i.e. that parser comparison takes place on specific domains of language use. Furthermore, in our evaluation here we do not take into consideration the important aspect of parser efficiency.

The structure of this paper is as follows. Section 2 discusses the linguistic aspects of how to compare parsers that originate from different linguistic frameworks. Section 3 argues that parser comparison needs more thought than parser evaluation, exactly because the scores need to be compared somehow. Section 4 we extend PARSEVAL with an Information Theoretic methodology, which allows parser comparison across different linguistic frameworks. Finally, section 5 concludes this paper.

2. How to compare parsers?

Remarkably, current parser evaluation practice seems to have been limited to a single benchmark tree-bank (Penn WSJ tree-bank). The evaluation of newly developed parsers proceeds by testing on a held-out portion of this tree-bank. When the parsers are acquired from the tree-bank itself, evaluation (and comparison) of the parsers is based on the PARSEVAL measures (Black et al., 1991). However, when a new parser is devised and this parser employs a different linguistic framework than the annotation scheme of the Penn WSJ tree-bank (e.g. dependency grammar), a serious problem arises. The problem lies in how to relate the different syntactic schemes to one another. There seem to be two related ideas on how to address this problem: (1) devising a general, syntactic scheme, a kind of "common ground", which serves as an "interlingua", or (2) devising mappings between each pair of syntactic schemes. In this section we argue that both suggestions seem not be workable in practice. We review the more popular among the two, i.e. the methods of devising mappings from the WSJ annotation scheme to other schemes. Subsequently we suggest that it is more expedient to develop different tree-banks of the same corpus of utterances, each in a different syntactic annotation scheme.

2.1. Common syntactic scheme?

At first glance, the problem of specifying the syntactic "common ground" seems to rely on the choice of some general linguistic framework to which both parsers' outputs can be mapped in order to compare them. However, selecting a common linguistic framework seems a hopeless task:

the problem lies in anticipating the kinds of linguistic information that a new linguistic theory might be interested in. Take for example the *Minipar* parser (Lin, 1998) or the *Link parser* (Sleator D, 1991), the first outputs one type of dependencies, while the second outputs so called "links". Both parsers do not exactly coincide with the traditional grammatical relations used in other frameworks (or with the WSJ annotation). How this kind of syntactic information would be anticipated by a common framework is not completely clear. We believe that a common framework will always be contested as being more favorable to some parser than another. Moreover, it seems to us that the goal of devising such a framework coincides with the ultimate goal, which has evaded the syntactic linguistic work for so many years now. This might be inherent to deciding on the so called "borders" of syntax, which seems to overlap with morphology on the one side, and with semantics and pragmatics on the other. It is highly doubtful that such a framework can be developed.

2.2. Mappings between syntactic schemes

Various researchers (Lin, 1995; Carroll et al., 1998) have developed methods that attempt at transforming the the Penn WSJ format into the different output formats of their parsers. However, there is in these efforts a hidden assumption: a complete mapping can be constructed, which maps a WSJ parse-tree into a parse-tree in any of these schemes. Apart from the linguistic arguments that exist against the "relatively shallow" WSJ style of annotation, there is a serious problem in assuming the existence of a complete, possibly deterministic mapping.

The arguments against this practice emerge from linguistic frameworks (e.g. dependency grammar) that differ to a large extent from the framework employed in the WSJ tree-bank. The main arguments address the risks that accompany mapping parse-trees from one framework to another. When a parse-tree is mapped from one framework to another, one might

- risk losing linguistic information (e.g. some dependencies not found in the WSJ),
- face ambiguity, since the categories provided by the parser might map onto different WSJ categories (possibly dependent on context).

These problems suggest that the comparison of two parsers can not rely on mapping the output onto some pre-selected linguistic framework, since different linguistic frameworks address different syntactic aspects. Nevertheless, we find in the literature various empirical efforts aimed at devising such mappings, notably (Lin, 1995; Carroll et al., 1998). Next we first address what it takes to devise a mapping from Phrase-Structure to Dependency grammar and vice versa. Then we shortly discuss some of the problems that exist in the mappings devised by (Lin, 1995; Carroll et al., 1998).

2.3. What is necessary for a mapping?

We concentrate on two popular linguistic frameworks of syntax: dependency and phrase-structure. Although this could be an illusive task, we give here a simplified description of the two, each in a single line. Phrase-structure syntax allows describing the syntactic structure of utterances in terms of the phrases which constitute them, using a hierarchical and recursive set of concepts. In contrast, dependency syntax aims at making explicit the dependencies between the pairs of words in the utterance. Both approaches aim at facilitating the discovery of argument-structure, which is often assumed by subsequent semantic processing.

It has been suggested by (Hudson, 1984; Covington, 1992; Covington, 1994) that, according to a phrase-structure grammar, constituency is basic and dependency (or government) is derived, whereas according to dependency grammar, dependency is basic and constituency is derived. If this claim is correct, then a transformation procedure and its inverse that map phrase-structure parses to dependency parses could be defined; in that case, phrase-structure and dependency grammars are to a large extent isomorphic.

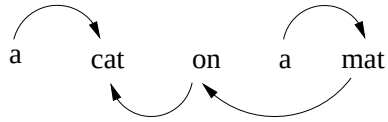

Figure 1: A dependency parse

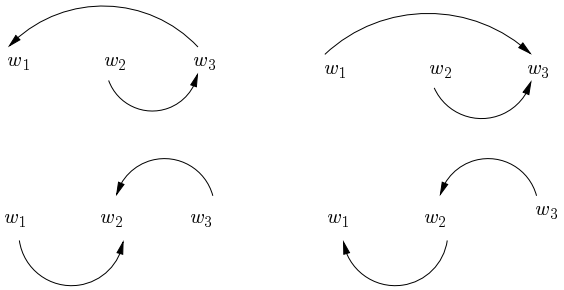

Figure 3: Different possible dependency trees

The problem lies, of course, in the kind of concepts that each framework presupposes: the types of dependencies and the constituent types must refer to the same abstract syntactic concepts, which is usually not the case. In order to shed some light on the problematic aspects of such a mapping, consider the expression *a cat on a mat* and the plausible dependency parse for it shown in figure 1; at least three distinct phrase-structure parses may be projected from it as shown in figure 2. Clearly, there is here a problem of how to decide on the single correct phrase-structure parse, given the dependency structure. The reverse mapping can also be problematic: consider the following unlabeled bracketing $(w1(w2w3))$ of an expression $w1w2w3$. At least four dependency parses can be generated from it as shown in figure 3. Again, a principled choice of the single correct dependency parse is not easy and demands a procedure for recognizing the head word of each phrasal category. The problem, however, in devising head word

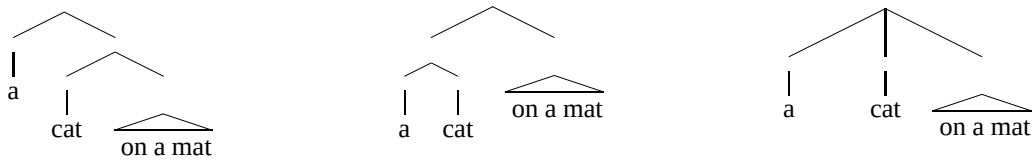

Figure 2: Three different phrase-structure trees for same dependency structure

recognition procedures for an existing tree-bank, has been exemplified by the various versions of the head recognition procedure developed by for the WSJ tree-bank (Magerman, 1993; Collins, 1997; Buchholz et al., 1999; Eisner, 2001). In any case, it seems that the problems that accompany these mappings can be summarized in two elements (1) a common set of concepts that underlie the types in each of the two frameworks, and (2) a clear and well founded definition of a head recognition procedure. Let us consider two attempts at developing such mappings.

2.4. Lin's proposal

In (Lin, 1995), a dependency parse of a sentence is defined as a set of tuples. Such dependency tuples consist of 5 components: a *dependent*, a *PoS*, a *position*, a *head* and a *type*. This last component is optional. Lin defines the values that can be assigned to these components as follows: a word in a sentence to be parsed is assigned to the *dependent* variable, *PoS* represents its lexical category, the head word on which the value of *dependent* depends is assigned to the *head* variable, the *position* takes a value in the set $\{<, >, <<, >>, <<<, ..., *, ?\}$. Remarkably, no well-defined set of values is defined for the optional component *type*. Furthermore, Lin gives no hints at how to label *head-dependent* relations.

Lin presents an algorithm to transform a constituency tree into a dependency tree. His transformation procedure exploits suggestions made in (Magerman, 1993) for determining *lexical representatives* of phrases. Whether the notion of *lexical representative* coincides with the notion of *head* as used in dependency grammar, is not clear. Suppose, for the sake of the argument, that *lexical representatives* are *heads* and consider the *wh*-interrogative, parsed according to the bracketing guidelines for the Penn Tree Bank as shown at the left side of figure 4. Let us apply Magerman's rules to it. According to these rules, the head-word of *SBARQ* is the head-word of *SQ*, that is *propose*. Therefore, the head-word of *which measures* is a dependent of *propose*. However, consider the *wh*-interrogative on the right hand side of figure 4. The head-word of *SBARQ* is *think*. Therefore, the *WHNP which measures* is not any more a dependent of *proposed*, it is a dependent of the head word *think*. This implies that transforming standard phrase structure analysis into some dependency representation in this way results in loss of information. Such information represented by the position of a trace is of course relevant to semantic interpretation. Our examples clearly show that such a transformation procedure fails to detect a dependency that relates a dependent to a "lower head" (one that does not percolate across the constituent boundaries).

2.5. Carroll et. al's proposal

Carroll et al. (Carroll et al., 1998) has proposed some relational evaluation measures that exhibit some resemblance to Lin's. They describe a corpus annotation scheme that encodes grammatical relations between heads and dependents. We believe that Carroll's proposal is somehow superior to Lin's in a few aspects. Firstly, the set of dependency types or grammatical relations is well-defined and constitutes a hierarchy. This allows robust and shallow evaluation. Secondly, grammatical relations are strictly speaking not dependency relations; the external argument of a "subject control verb" is grammatically related to the control verb and to the controlled verb (e.g. *I promise to come*, where *I* is related to both *promise* and *come*). Finally, grammatical relations are specified even for moved phrases that do not occur in a canonical position. This addresses a problem in Lin's proposal, mentioned above.

From the experience described in (Carroll et al., 1998), it might seem that dependency types (or grammatical relations) are easy to specify and extract from phrase-structure. Nevertheless, this is true only because (Carroll et al., 1998) assumes that the phrase-structure grammar is an explicit, determinate set of rules. As Carroll et al. recognize, extracting grammatical relations from an implicit grammar, induced automatically from a tree-bank, is much harder to do consistently. In addition, the grammatical relations in (Carroll et al., 1998) do not capture some relevant information. For instance, topicalized constituents of the Penn Tree Bank (bearing the TPC tag) are ignored, because they are allegedly difficult to specify under which conditions a constituent is topicalized.

Clearly, from these examples we observe that developing deterministic, complete mappings between phrase-structure and dependency grammars is a tedious and risky task. For a nice review of the problems that arise in relating Dependency to Phrase-Structure syntax see (Schneider, 1998). We believe that the development of different tree-banks, each in another linguistic annotation scheme, for the same corpus of utterances might provide a more fruitful path to proceed. When a pair of parallel tree-banks exits, it is possible to explore automatic means for learning complex, stochastic mappings between the two. More importantly, a pair of parallel tree-banks for the same corpus of utterances may serve as a suitable infrastructure for the comparison of parsers from different linguistic frameworks as we describe in the rest of this paper.

3. Comparison: more than evaluation

In line with current practice, we believe that empirical parser evaluation requires a manually constructed, gold-

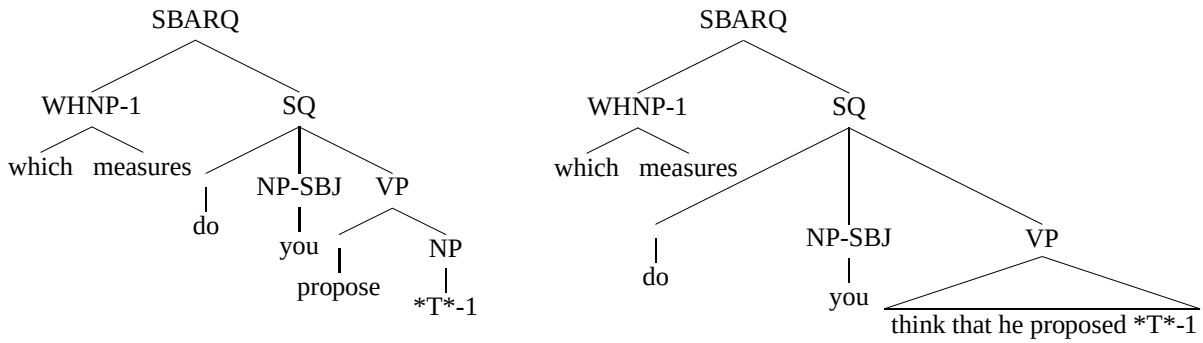

Figure 4: Two Penn WSJ style parse-trees

standard tree-bank and suitable measures of the "similarity" between the analyses output by the parser and the corresponding analyses that are found in the tree-bank. Usually, the measure of "analyses similarity" consists of different figures pertaining to coverage (or recall) and accuracy (or precision). In contrast, the task of *comparing* parsers can be more complex than the evaluation of a single parser (or the comparison of parsers that share the same output scheme). When two parsers are being compared, another major issue, beside evaluation, must be addressed: how to compare the similarity measures across different kinds of parser outputs (possibly originating from different linguistic frameworks)? We believe that the latter question is of theoretical importance and we address it in this section. First, however, we need to discuss the multiple possibilities for parser comparison and provide the argumentation that underlies the specific choices that we make.

3.1. Task-oriented comparisons

Initially, we distinguish between two goals of parser comparison: (1) the suitability of the parser to a given task, and (2) the suitability of the parser as a model of syntactic language processing. Although (ideally) the two goals are strongly related, in practice they might imply different comparison methodologies. The comparison of parser's suitability for a specific task is usually guided by some detailed specification of the requirements which the parser must meet. For example, the simplified Question-Answering task requires the parser to output (as fast as possible) the main predicate-argument structure of the input. In contrast, more complex tasks, such as the task of Machine Translation, will possibly require a much more detailed syntactic analysis of the input. Task-oriented comparison is interesting and useful, but is strongly specific to the task at hand, which means that it does not constitute a general comparison methodology.

3.2. Qualitative comparisons

When the parser comparison is not tied to a specific task[1], parser comparison is aimed at investigating the utility of the different models underlying the parsers. Clearly, a *qualitative* comparison, based on theoretical considerations of coverage of language phenomena (e.g. (Carroll and Weir, 1997)), could be illuminating. Issues such as "what phenomena the parser can be expected to cover" and "what quality of the output is provided by the parser" are important for advancing the state of the art. However, qualitative comparisons become more powerful when they are supplemented with quantitative comparisons that are based on actual empirical evidence (weighted according to expected frequency of occurrence). This is because the theoretical investigations might pay too much attention to relatively infrequent phenomena and less attention to frequent (yet seemingly irrelevant) phenomena. Empirical, quantitative parser comparison aims at providing an answer to the question: what quality of output is provided by the parser and how does it compare to other parsers? Before we address this question, however, we address a related idea which is currently being floated as an alternative for (full) parser comparison: partial evaluation.

[1]This is currently the case in parser evaluations on the Wall Street Journal corpus, for example.

3.3. Partial evaluation based comparisons

Because of the problematic mappings between the different linguistic frameworks, it seems suitable to consider only some of the issues upon which these frameworks agree. For example, one could conduct comparisons on the main predicate-argument structure of the input, or on recall/precision for the set of predicate-argument structures for the verbs in the input utterance. Similar suggestions have been made in order to contrast the so-called "shallow" parsers to existing "full" parsers, by e.g. listing the recall/precision on each phrasal category (or kind of dependency) separately (Tjong Kim Sang and Déjean, 2001). These suggestions for *partial evaluation* usually provide a detailed and informative listing of various aspects of the parser's behavior. We think that these should be taken more seriously in *practical parser evaluation*. It is important to have detailed lists of scores of a parser on different tasks. However, partial evaluation has its limitations, even for practical comparisons. It is very hard to predict what elements in the output of a given parser could be important. For example, predicate-argument structures, which take only verbal predicates into consideration, are useless for some applications where prepositional phrases are important (e.g. domains of travel information, or money transactions etc). Another weakness of partial evaluation is that, by definition, it does not answer the need for a "bottom line figure" which summarizes the behavior of the parser, and allows direct comparison to other parsers.

There is, moreover, a more urgent matter, which par-

tial evaluation does not address, and which is of theoretical importance. This concerns the question: how much information[2] does the parser return, and what is it's quality? Answering this theoretical question is important for advancing the state of the art in natural language processing. In the light of the current divergence in parser output formats (e.g. shallow vs. deep parsers) and given the differences between the linguistic frameworks, it becomes important to be able to measure differences in the informativeness of parsers, even when their outputs are not directly comparable.

3.4. Comparison on parallel tree-banks

As argued in Section 2., for comparing parsers that come from different linguistic frameworks (or different depths of analysis) it is necessary to maintain some kind of mapping between the outputs of the parsers. The mapping might be realized in one of two manners:

Explicit: a tree-bank exists in one annotation scheme (according to some linguistic framework) together with a sound, complete and correct mapping which translates every analysis in the tree-bank into the corresponding analysis in the other linguistic framework,

Implicit: two parallel tree-banks[3] of the same corpus of utterances, each annotated according to one of the linguistic frameworks.

We already showed in Section 2., that developing an explicit deterministic mapping seems a hard task. Therefore, we advocate the use of implicit mappings that are embodied in parallel tree-banks of the same corpus of utterances. It is evident that given such pairs of tree-banks, different automatic methods can be explored for learning complex, stochastic mappings between the two tree-banks. How to acquire these mappings is an interesting subject of research but is beyond the scope of this paper.

4. An Information Theoretic proposal for parser comparison

Suppose we are given two parsers P_1 and P_2 which have different output schemes, respectively, L_1 and L_2. Suppose also we are given a corpus of utterances C, and tree-banks TB_1 and TB_2 that are annotated versions of C according to schemes L_1 and L_2, respectively. In order to ground the discussion, the reader might want to imagine that L_1 is dependency grammar (Mel'čuk, 1988) and L_2 is phrase structure grammar (Manning and Schutze, 1999); or alternatively, L_1 could be the scheme output by a shallow parser and L_2 a "deeper" linguistic scheme. The question is, how do we compare P_1 and P_2 in a way that takes into consideration not only the coverage/accuracy but also the informativeness of their output? Below we discuss the two issues of coverage/accuracy and informativeness separately. Subsequently we propose combined measures which allow comparison.

[2]This is opposed to the practical question: how much information can the parser provide for this or that task?

[3]We will keep the term tree-bank when we refer to a bag of utterance-analysis pairs, where the analyses are syntactic structures according to some linguistic framework, e.g. dependency grammar or phrase-structure grammar.

4.1. Coverage/accuracy: generalizing PARSEVAL

The PARSEVAL measures of labeled constituent recall and precision (Black et al., 1991) have been central in current efforts at parser evaluation on the current American English language benchmark (Penn WSJ tree-bank). It has often been claimed that these measures are not suitable for evaluating e.g. dependency syntax. Indeed, when taken literally, constituency can be meaningless when evaluating dependency syntax. However, the PARSEVAL measures can easily be generalized to deal with whatever kind of parses as long as they can be represented as sets of relations. For example, a labeled constituent $\langle i, j, XP\rangle$ is a relation (where i and j are the positions of the left-most and right-most words respectively and XP is the label of the constituent); a labeled dependency $\langle h, d, L\rangle$ is a relation (where h and d are the positions of the head-word and the dependent, and L is the label of the dependency). A parse-tree, whether in dependency syntax or in phrase-structure, can be represented as a set of such relations (cf. (Goodman, 1998)). Recall and precision, as a direct generalization of the notation used in PARSEVAL, are defined as measures over sets of such relations. If a given parser outputs parse T for sentence U for which the gold standard parse is G, Goodman defines[4]:

$Recall(T,G) = \frac{|G \cap T|}{|G|}$ $Precision(T,G) = \frac{|G \cap T|}{|T|}$

We believe that the PARSEVAL measures can be generalized further to stricter recall/precision measures, where a parse-tree is viewed as a set of relations that range over different aspects of syntax, e.g. relations in which the labeled constituent is head-lexicalized, and possibly supplemented with the set of subcategorization frames of its head word. The notions of recall/precision over sets of relations are general enough to accommodate a wide range of aspects of parse-trees, including suggestions for partial evaluation, e.g. on the basis of predicate-argument structures of verbs.

Hence, the parsers P_1 and P_2, assumed earlier, can be evaluated on their own tree-banks TB_1 and TB_2 using the PARSEVAL recall/precision measures. However, the PARSEVEAL measures of recall/precision do not address the problem of comparison across different output/annotation schemes. To arrive at a suitable comparison methodology we first need to define measures of the informativeness of the output of a given parser.

4.2. Informativeness of a parser

What makes a parser informative? To answer this we turn to the Information Theoretic concept of compression. Suppose we are given two parsers. The one parser outputs only unlabeled bracketed parse-trees, while the other labels the same parse-trees with different syntactic categories. The output of the second parser can be described as more informative. As it turns out, the kind of concepts, e.g. phrasal categories or dependency types, which the parser includes in its output determine its informativeness. For example, a parser that marks the difference between singular/plural noun and verb phrases could be more informative than another that does not do so (all else being equal, of

[4]If $(|T| == 0)$ then $Precision(T,G) = 0$ by definition.

course).

In general, a *linguistic concept* is viewed as a set of word sequences, e.g. the noun-phrase concept consists of a sequence of all noun constituents. Here, we take a slightly different perspective on this notion: a concept is a probability distribution over word sequences (Manning and Schutze, 1999). In a generative grammar, a finite set of concepts is specified hierarchically (and recursively). If the concepts are "stricter" or sharper they will tend to be more informative, provided that the strictness captures regularities in the language. This sense of an "informative annotation scheme" is strongly related to the notion of a "compression code" in the communication over a noisy channel view in Information Theory. The more the annotation scheme allows to compress a large corpus of utterances from the language, the more informative this annotation scheme is.

4.3. Cross entropy of an annotation scheme

Technically speaking, in language modeling techniques that originate from the speech community, the "goodness" of a model is captured through the notion of Perplexity of the model on a corpus of utterances. The strongly related notion of *Cross Entropy* is also known from the statistical parsing literature, e.g. (Manning and Schutze, 1999); it captures the average amount of surprise that the model encounters when parsing the utterances in the corpus. A model that captures the regularities in the corpus in a better way, through more adequate syntactic constructs and concepts, will encounter less surprises. How do we apply this idea to parser comparison where we want to measure the informativeness of an annotation scheme (the output of the parser)?

We stress that we would like to compare the outputs of the parsers, rather than their ambiguity resolution capacity[5]. To do so, we suggest a method for measuring a kind of "cross entropy" between each of the tree-banks TB_i and the corpus of utterances C. If the tree-bank parse-trees capture the regularities in the corpus utterances in a better way, the cross entropy will be smaller. But, how do we define this "cross entropy between a tree-bank (rather than a model) and a corpus"?

Although it is not a trivial task, we believe that every tree-bank annotation scheme, whether phrase-structure, head-lexicalized phrase-structure or dependency structure, allows the extraction of a probabilistic model which we will call the "basic generative model". The "basic generative model" must fulfill the following requirements:

1. the rewrite rules of this model must coincide with the atomic units assumed by the linguistic framework, and

2. only the information that exactly coincides with *the logical constraints on the composition] operators*[6] *that originate from the linguistic framework should be available as conditioning context for the model parameters*.

For example, for (context-free) phrase-structure grammars, the logical constraint on the substitution operator is *category substitutability*, which implies that the conditioning context in context-free rule probabilities consists of the label of the left-hand side of the rule, as in standard Probabilistic Context-Free Grammars. Accordingly, it is not suitable to condition the probabilities of the extracted basic model on e.g. the label of the parent node[7]. In effect, beyond the necessary conditions, the basic generative model assumes independence between the different basic rewrite units $r_1 \cdots, r_n$ that generate a parse-tree T, i.e. $P(T) = \prod_{i=1}^{n} P(r_i|\phi(r_i))$, where $P(r_i|\phi(r_i))$ is the relative frequency of r_i in the tree-bank, conditioned on the necessary information only.

Let us consider a few example frameworks from the literature. For phrase-structure annotations, as we just said, the basic model is a Probabilistic Context Free Grammar (PCFG) (Jelinek et al., 1990) (the so-called Tree-bank Grammar (Charniak, 1996)); for a dependency syntax tree-bank, this is a probabilistic generative model in which the dependency probabilities are conditioned on the head-words (see e.g. model 3 of (Eisner, 1996) without conditioning on the preceding child, i.e. 0^{th}-order Markov model for generation of dependents); for a head-lexicalized tree-bank, where head words augment the phrasal nonterminals, the basic model is similar to model 1 of (Collins, 1996) (simplified to exclude "distance measures").

Having extracted a basic generative model from the tree-bank, it becomes easy to specify how the measure of Cross Entropy between the model and the corpus can be estimated. Let model μ be a probabilistic generative model and let C be a corpus of utterances. The cross-entropy is defined by

$$H_\mu(C) = \lim_{|C|\to\infty} \frac{1}{|C|} \sum_{U \in C} \log P(U|\mu)$$

where $|C|$ is the number of utterances U in C. When C is a large corpus, it is possible to estimate this by dropping the limit:

$$\hat{H}_\mu(C) = \frac{1}{|C|} \sum_{U \in C} \log P(U|\mu)$$

Note that for our goal of comparison, it is enough to estimate only roughly the cross entropy on a reasonably large corpus (clearly, the larger the better).

4.4. Per bit recall/precision

For integrating the measures of disambiguation and informativeness of a parser, we will argue for the notion of "per bit disambiguation capacity". This new notion addresses the question: how good is the quality of the output of the parser given its informativeness? This notion is obtained by integrating the PARSEVAL Precision/Recall measures of disambiguation with the Cross Entropy of the annotation scheme (which is the scheme used in the output

[5]The latter issue has been addressed in the recall/precision aspect of the evaluation methodology suggested here.

[6]The composition operators that are used for the construction of parse-trees from the basic rewrite rules.

[7]Note that we say this is not suitable only for the goal of measuring the informativeness of the output of the parser, not for the ability of the parser to disambiguate.

of the parser):

$$Per\ bit\ Recall = \frac{Recall}{CrossEntropy}$$

$$Per\ bit\ Precision = \frac{Precision}{CrossEntropy}$$

The intuition underlying these notions is that frameworks that leave the parses more ambiguous, will demand less effort during parsing and so recall/precision must be discounted accordingly. We claim that the new measures of per bit recall and precision for different parsers can be compared directly, even when the parsers originate from different linguistic frameworks.

4.5. Discussion

We note that there exist various notions that are strongly related to Cross Entropy as a measure of model goodness. One of these notions is the *description length* (or the theoretical Kolmogorov complexity), another is the *message length* (Rissanen, 1983). However, the Cross Entropy measure is the most directly applicable among these closely related notions because of its direct interpretation in terms of smoothed relative frequency.

We expect two issues to constitute the critical points in the application of the methodology proposed in this paper: (1) the development of parallel tree-banks for the same corpus of utterances, (2) the benchmarking of methods for the extraction of basic probabilistic models from these tree-banks. The first issue is critical because it is labor intensive; the second because it demands further specification of what constitutes a basic model that can be extracted from a newly developed tree-bank, especially when this concerns simplified frameworks such as those used by shallow parsers. Despite of these possible difficulties, we believe that our proposal could provide a theoretical departure point towards workable approximations.

5. Conclusions

We presented a preliminary, informal discussion of what it takes to develop a methodology for parser comparison across different linguistic frameworks. We have presented a simple Information Theoretic approach to avoid the problems that arise in mapping between different linguistic frameworks. This approach takes into account the specific concepts of the framework, circumventing the problem of information loss.

As a positive side to this proposal, we envision that for a given domain of language use there will be different tree-banks, each according to a different linguistic framework. This will allow the development of automatic approximations for domain-specific mappings between the different frameworks (e.g. using Machine Learning techniques). Furthermore, this also enables the exploration of complementary aspects of the different existing linguistic frameworks, possibly leading to better stochastic parsers.

Future work in this direction might concentrate on evaluating existing parsers from dependency and phrase-structure grammar, and comparing them using the present approach. Another line of work might concentrate on the application of Machine Learning or stochastic methods to the induction of approximate mappings between these different frameworks. Finally, we are intrigued by the possibility of empirical studies that combine aspects from different frameworks based on parallel tree-banks.

Abstract

The paper describes an experiment in inside-outside estimation of a lexicalized probabilistic context free grammar for German. Grammar and formalism features which make the experiment feasible are described. Successive models are evaluated on precision and recall of phrase markup consisting of labels for noun chunks and subcategorization frames. Our approach to parsing is a blend of symbolic and stochastic methods where we use evaluation results in both incremental grammar development and validation of selected output to be used in lexical semantic clustering. Our results are that (i) scrambling-style free phrase order, case morphology, subcategorization, and NP-internal gender, number and case agreement can be dealt within a lexicalized probabilistic context-free grammar formalism, and (ii) inside-outside estimation appears to be beneficial, however relies on a carefully built grammar and an evaluation based on carefully selected linguistic criteria. Additionally, we report experiments on overtraining with inside-outside estimation, especially focusing on comparison of the results of mathematical and linguistic evaluations.

1. Introduction

From 1997 to 2000, the Gramotron group of the Institute for Natural Language Processing at Stuttgart University developed a stochastic parser for German (Beil et al. (1999), Schulte im Walde et al. (2001)). The symbolic component of the final parsing system is a manually written context-free grammar consisting of several thousand head-marked rules. Its stochastic component consists of probability weights assigned to the lexicalised grammar rules and to the lexical choice events by the so-called inside-outside algorithm (Lari and Young, 1990), the standard procedure for unsupervised training of a stochastic context-free grammar parsing free text. For training and parsing, the implementations of Carroll (1997b) and Schmid (1999a) were used.

The Gramotron parsing system was designed to be used for the induction of a semantically annotated lexicon of German nouns and verbs (Rooth et al., 1999). Accordingly, the grammar development focus was on the recognition of the grammatical relations between nouns and verbs.

Furthermore, since the parsing results were an intermediate step in an experiment to learn a semantic lexicon, reliable parsing results had to be acquired rapidly. We decided for an incremental grammar development, thus minimizing grammar development efforts in the early project phase.

The context-free grammar for German was developed in three stages: for (i) verb-final clauses, (ii) relative clauses, and (iii) verb-first and verb-second clauses. In this paper, we describe a concluded experiment and evaluation of the parsing system covering constructions (i) and (ii).

Grammar development and stochastic training was controlled by two types of evaluation: (i) an information-theoretic evaluation based on perplexity values measured on training and test corpora of free text, and (ii) a linguistic evaluation of noun chunks with case features and verb frame recognition on a manually annotated test corpus.

2. Data

The data for our experiments are two sub-corpora extracted from a 200 million token newspaper corpus, (a) a sub-corpus containing 450,000 verb-final clauses with a total of 4 million words, and (b) a sub-corpus containing 1,1 million relative clauses with a total of 10 million words. Apart from non-finite clauses as verbal arguments, there are no further clausal embeddings, and the clauses do not contain any punctuation except for a terminal period. The average clause length is 9.16 and 9.12 words per clause, respectively.

We used a finite-state morphological analyser (Schiller and Stöckert, 1995) to assign multiple morphological features such as part-of-speech tag, case, gender and number to the corpus words, partly collapsed to reduce the number of analyses. For example, the word *Bleibe* (either the case ambiguous feminine singular noun 'residence' or a person and mode ambiguous finite singular present tense verb form of 'stay') is analysed as follows:

```
analyse> Bleibe
1. Bleibe+NN.Fem.Akk.Sg
2. Bleibe+NN.Fem.Dat.Sg
3. Bleibe+NN.Fem.Gen.Sg
4. Bleibe+NN.Fem.Nom.Sg
5. *bleiben+V.1.Sg.Pres.Ind
6. *bleiben+V.1.Sg.Pres.Konj
7. *bleiben+V.3.Sg.Pres.Konj
```

Reducing the ambiguous categories leaves the two morphological analyses

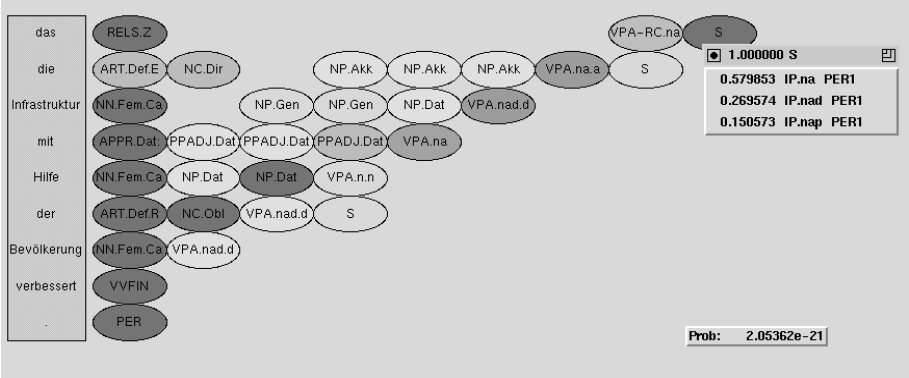

Figure 1: Chart Browser for Grammar Development

```
Bleibe { NN.Fem.Cas.Sg, VVFIN }
```

Apart from assigning morphological analyses the tool in addition serves as lemmatiser (cf. (Schulze, 1996)).

3. The German Context-Free Grammar

The context-free grammar consists of 5,033 rules with lexical head markings. With very few exceptions (rules for coordination, S-rule), the rules do not have more than two daughters. The 220 terminal categories in the grammar correspond to the collapsed corpus tags assigned by the morphology.

Grammar development is facilitated by (a) grammar development environment of the feature-based grammar formalism YAP (Schmid, 1999b), and (b) a chart browser that permits a quick and efficient discovery of grammar bugs (Carroll, 1997a). Figure 1 shows that the ambiguity in the chart is quite considerable even though grammar and corpus are restricted.

The grammar covers 92.43% of the verb-final and 91.70% of the relative clauses, i.e. the respective part of the corpora are assigned parses.

In the following, we describe two essential parts of the grammar, the noun chunks and the definition of subcategorisation frames. For details concerning prepositional phrases, adjectival chunks, adverbial chunks, complex determiners, and the treatment of coordination see (Schulte im Walde, 2000).

3.1. Noun Chunks (NCs)

On nominal categories, in addition to the four cases `Nom`, `Gen`, `Dat`, and `Akk`, case features with a disjunctive interpretation (such as `Dir` for `Nom` or `Akk`) are used. The grammar is written in such a way that non-disjunctive features are introduced high up in the tree. Figure 2 illustrates the use of disjunctive features in noun projections: the terminal `NN` contains the four-way ambiguous `Cas` case feature; the N-bar (`NN1`) and noun chunk `NC` projections disambiguate to two-way ambiguous case features `Dir` and `Obl`; the weak/strong (`Sw/St`) feature of `NN1` allows or prevents combination with a determiner, respectively; only at the noun phrase `NP` projection level, the case feature appears in disambiguated form. The use of disjunctive case features results in some reduction in the size of the parse forest. Essentially the full range of agreement inside the noun phrase is enforced. Agreement between the subject `NP` and the tensed verb is not enforced by the grammar, in order to control the number of parameters and rules.

The noun chunk definition refers to Abney's chunk grammar organisation (Abney, 1996): the noun chunk (`NC`) is a projection that excludes post-head complements and (adverbial) adjuncts introduced higher than pre-head modifiers and determiners, but includes participial pre-modifiers with their complements.

3.2. Subcategorisation Frames

The grammar distinguishes four subcategorisation frame classes: active (`VPA`), passive (`VPP`), non-finite (`VPI`) frames, and copula constructions (`VPK`). A frame may have maximally three arguments. Possible arguments in the frames are nominative (n), dative (d) and accusative (a) NPs, reflexive pronouns (r), PPs (p), and non-finite VPs (i). The grammar does not distinguish plain non-finite VPs from *zu*-non-finite VPs. The grammar is designed to distinguish between PPs representing a verbal complement or adjunct: only complements are referred to by the frame type. The number and the types of frames in the different frame classes are given in Table 1.

Frame Class	#	Frame Types

`VPA`	16	`n, na, nd, np, nad, nap, ndp`
		`ni, di, nai, ndi`
		`nr, nar, ndr, npr, nir`

`VPP`	18	`n, np-s, d, dp-s, p, pp-s`
		`nd, ndp-s, np, npp-s, dp, dpp-s`
		`i, ip-s, ni, nip-s, di, dip-s`

`VPI`	8	`-, a, d, p, r, ad, ap, dp, pr`
`VPK`	2	`n, i`

Table 1: Subcategorisation Frame Types

German, being a language with comparatively free phrase order, allows for scrambling of arguments. Scrambling is reflected in the particular sequence in which the arguments of the verb frame are saturated. Compare Figure 3 as example of a canonical subject-object order within an active transitive frame *der sie liebt* 'who loves her' and its scrambled object-subject order *den sie liebt* 'whom she loves'.

Abstracting from the active and passive realisation of

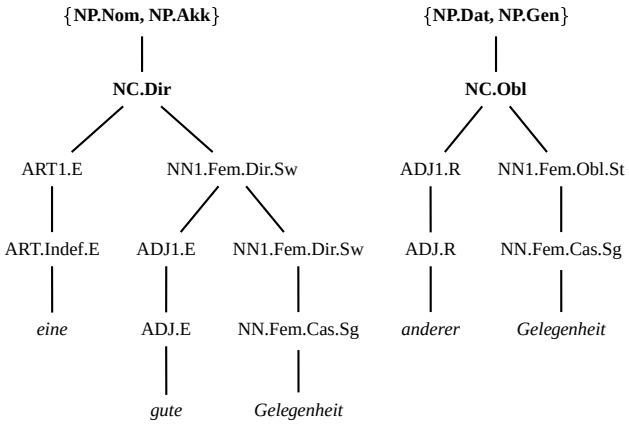

Figure 2: Noun Projections

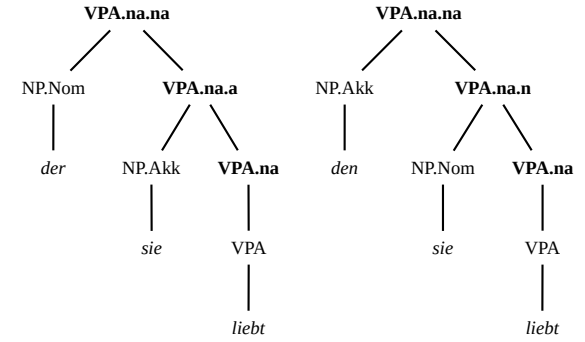

Figure 3: Realising Scrambling Effect in the Grammar Rules

an identical underlying deep-level syntax we generalise over the alternation by defining a top-level subcategorisation frame type, e.g. `IP.nad` for `VPA.nad`, `VPP.nd` and `VPP.ndp-s` (with `p-s` a prepositional phrase within passive frame types representing the deep-structure subject, realisable only by PPs headed by *von* or *durch* 'by'); see Figure 4 for an example, presenting the relative clauses *der die Frau verfolgt* 'who follows the woman', *die verfolgt wird* 'who is followed' and *die von dem Mann verfolgt wird* 'who is followed by the man'.

4. Probability Model

The probabilistic grammars are parsed with `LoPar`[1] (Schmid, 1999a), a head-lexicalised probabilistic context-free parser. The parser is an implementation of the Left-Corner algorithm for parsing and of the Inside-Outside algorithm for parameter estimation. Probabilistic context-free parsing (Lari and Young, 1990) maps a CFG to a probability model by assigning a probability to each grammar rule.

Innovative features of LoPar are head lexicalisation, lemmatisation, parameter pooling, and a sophisticated smoothing technique.

[1]LoPar is basically a re-implementation of the Galacsy tools which were developed by Glenn Carroll in the SFB, but LoPar provides additional functionality.

Syntactically, a head-lexicalised probabilistic context-free grammar (HPCFG) (Carroll, 1995; Carroll and Rooth, 1998) is a PCFG in which one of the right hand side categories of each grammar rule is marked as the head of the projection. The lexical head of a terminal category is the respective word form. Thus, lexical head properties, i.e. words, are propagated through head chains.

HPCFGs assign the following probability[2] to a parse tree `T`:

$$
\begin{aligned}
P(T) \;=\;& P_{start}(\text{cat}(\text{root}(T))) \cdot \\
& P_{start}(\text{head}(\text{root}(T))|\text{cat}(\text{root}(T))) \cdot \\
& \prod_{n \in T} P_{rule}(\text{rule}(n)|\text{cat}(n), \text{head}(n)) \cdot \\
& n \text{ : non-terminal} \\
& \prod_{\substack{n \in T \\ n \neq root(T)}} P_{choice}(\text{head}(n)|\text{cat}(n), \text{cat}(\text{p}(n)), \text{head}(\text{p}(n))) \cdot \\
& \prod_{n \in T} P_{rule}(\texttt{<terminal>}|\text{cat}(n), \text{head}(n)) \cdot \\
& n \text{ : terminal} \\
& \prod_{n \in T} P_{lex}(\text{word}(n)|\text{cat}(n), \text{head}(n)) \\
& n \text{ : terminal}
\end{aligned}
$$

Five families of probability distributions are relevant here. $P_{start}(C)$ is the probability that C is the category of the root node of a parse tree. $P_{start}(h|C)$ is the probability that a root node of category C bears the lexical head h. $P_{rule}(r|C,h)$ is the probability that a node of category C with lexical head h is expanded by rule r. $P_{choice}(h|C,C_p,h_p)$ is the probability that a (non-head) node of category C has the lexical head h given that the parent category is C_p and the parent head is h_p. $P_{rule}(\texttt{<terminal>}|C,h)$ is the probability that a node of category C with lexical head h is a terminal node. $P_{lex}(w|C,h)$, finally, is the probability that a terminal node with category C and lexical head h expands to the word form w.

In order to reduce the prohibitively large number of lexical parameters that have to be estimated, we employed linguistic generalisations for parameter reduction: lemmatisation and parameter pooling. Using uninflected lemma rather than inflected word form for lexicalisation eliminates splitting of estimated frequencies among inflectional forms. Parameter pooling is based on the assumption that lexical choice probabilities are unlikely to depend on inflectional features like gender, case, number etc. of categories or argument order in verb frames. For instance, there are (at least) nine different inflectional patterns for projecting the adjective *alt* (old) and *Buch* (book) to an `NN1` category. Instead of assigning a lexical choice probability

$$P_{choice}(alt|\texttt{ADJ.w}_\texttt{i}, \texttt{NN1.x}_\texttt{i}\texttt{.y}_\texttt{i}\texttt{.z}_\texttt{i}, Buch)$$

[2]The auxiliary functions `cat`, `head`, `p(arent)`, `word` and `rule` return the syntactic category, the lexical head, the parent node, the dominated word or the expanding grammar rule of a node. `root` returns the root node of a parse tree and `<terminal>` is a constant.

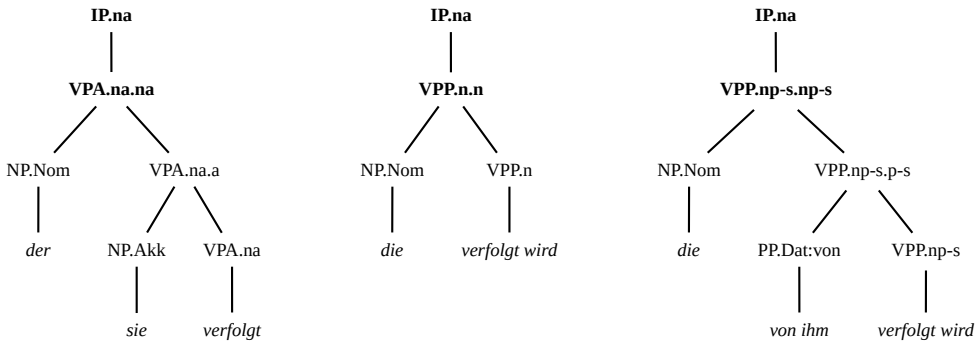

Figure 4: Generalising over the Active-Passive Alternation of Subcategorisation Frames

for each possible combination of w, x, y, z, the combinations are pooled to a single distribution

$$P_{choice}(alt|\texttt{ADJ}, \texttt{NN1}, \text{Buch})$$

for all inflectional variations of `NN1 -> ADJ NN1`. We obtain a single probability distribution for adjectival modifiers. In result, frequent observation of *altes Buch* in the trainng data also increases the probability of *alter Bücher*. For argument filling into verb frames, categories of the form `VP.x.y` are pooled to `VP.x` and active, passive and non-finite verb frames are pooled according to shared arguments, disregarding the saturation state of the frame. For instance, P_{choice} of a particular noun is the same as accusative NP head in the transitive active frame or nominative NP head in the passive frame of a particular verb (*[dass] sie den Hund füttert 'she feeds the dog'*, *der Hund gefüttert wird 'the dog is fed'*).

5. Grammar Training

5.1. Training Strategy

The training in our main experiment was performed in the following steps:

1. Initialisation of all CFG rules with identical frequencies. (Comparative initialisations with random frequencies had no effect on the model development.)

2. Unlexicalised training: The training corpus was parsed once, re-estimating the frequencies twice.

3. Lexicalisation: The unlexicalised model was turned into a lexicalised model by (i) setting the probabilities of the lexicalised rule probabilities to the values of the respective unlexicalised probabilities and (ii) initialising the lexical choice and lexicalised start probabilities uniformly.

4. Lexicalised training:
   Three training iterations were performed on the training corpus, re-estimating the frequencies after each iteration.

For training the model parameters we used 90% of the corpora, a total of 1.4 million clauses. The remaining 10% of serve as heldout data to measure overtraining.

Our experiments have shown that training an unlexicalised model first improves overall results. The optimal training strategy proceeds with few parameter re-estimations of an unlexicalised model. Without re-estimations or with a large number of re-estimations the model was effected to its disadvantage. With less unlexicalised training more changes during lexicalised training take place later on.

Comparative numbers of iterations (up to 40 iterations) in lexicalised training showed that more iterations did not have any further effect on the model.

6. Evaluation

Our evaluation methods were chosen to monitor the development of the grammar, to control the grammar training, and compare different training regimes. As part of our larger project of lexical semantic clustering, the parsing system had the specific task to collect corpus frequencies for pairs of a verbal head and its subcategorisation frame and frequencies for the nominal fillers of slots in a subcategorisation frame. The linguistic evaluation focuses on the reliability of these parsing results.

6.1. Mathematical evaluation

A		B		C	
1:	52.0199	1:	53.7654	1:	49.8165
2:	25.3652	2:	26.3184	2:	23.1008
3:	24.5905	3:	25.5035	3:	22.4479
⋮	⋮	⋮	⋮	⋮	⋮
15:	24.2861	57:	25.0549	90:	22.1443
16:	24.2861	58:	25.0549	95:	22.1443
17:	24.2867	59:	25.055	96:	22.1444

Table 2: Overtraining (iteration: cross-entropy on heldout data)

In order to control the amount of unlexicalised training, we measured overtraining by comparing the perplexity of the model on training and heldout data (or, respectively, cross-entropy[3] on heldout data in the experiments

[3]For a corpus consisting of sentences of a certain average length (`avg`), one can easily transform these cross-entropy values (`cross`) to the better known values of word perplexity (perp)

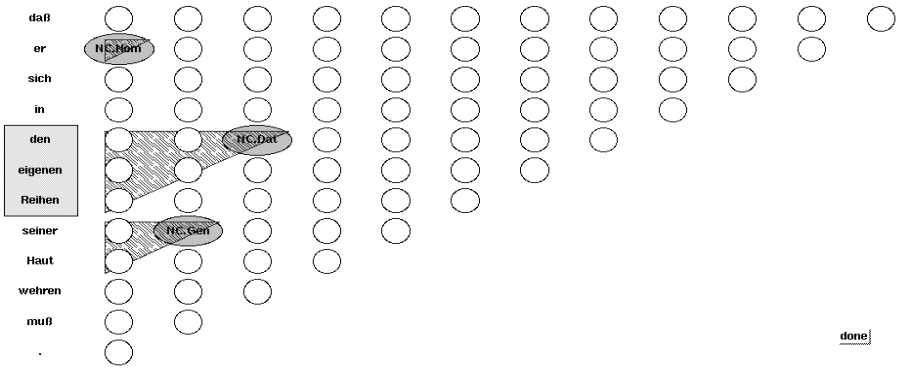

Figure 5: Chart Browser for manual constituent markup

in (Beil et al., 1999)). While perplexity on training data is theoretically guaranteed to converge through subsequent iterations, increasing perplexity on heldout data indicates overtraining. Table 2 shows comparisons of different sizes of training and heldout data (training/heldout) for unlexicalised training in an older experiment (Beil et al., 1999): (A) 50k/50k, (B) 500k/500k, (C) 4.1M/500k. The overtraining effect is indicated by the increase in cross-entropy from the penultimate to the ultimate iteration in the tables.

In previous experiments (Beil et al., 1999), we compared in more detail the mathematical evaluation with the linguistic evaluation of precision/recall measures on categories of different complexity through iterative unlexicalised training. The comparison shows that the mathematical criterion of overtraining may lead to bad results from a linguistic point of view. While precision/recall measures for low-level structures such as NCs converge, iterative unlexicalised training up to the overtraining threshold is disadvantageous for the evaluation of complex categories like subcategorisation frames. We observed precision/recall values for verb frames settling even below the results with a randomly initialised grammar. So the mathematical evaluation can only serve as a rough indicator whether the model reaches towards an optimum, but linguistic evaluation determines the optimum.

6.2. Linguistic evaluation

Although an appropriate treebank is available for German (the NEGRA treebank, cf. Skut et al. (1997) for an overview), we did not use it for our evaluation. One reason for this is the restriction of our initial grammar development to verb final and relative clauses while the treebank, of course, annotates full clauses. It turned out to be difficult to extract respective sub-treebanks. On the other hand, we did not intend to carry out the standard parser evaluation method of measuring precision/recall on phrase boundaries and crossing brackets (the PARSEVAL scheme) for which treebanks are widely used. Bracketing information is rather uninteresting for our objectives and we reckoned that rich structures as generated by our grammar would likely punished by the crossing bracket measure. (For a more general overview of problems using the crossing brackets measure for parser evaluation see (Carroll et al., 1998).)

Moreover, in transforming our bracketing to treebank annotation standards, we feared to loose too much information deemed important for our evaluation. In our efforts to find a transformation that maps treebank structures to a selection of ours (noun and verb chunks), we found two mapping problems: (i) mapping treebank phrase spans to our chunk spans and (ii) finding an information-preserving mapping from our labels to treebank labels. Concerning the first, it turned out to be difficult to define noun chunk ends within treebank NPs. An even harder problem is finding the rich information in our verbal category labels (i.e. type and frame annotation) in treebank VPs.

So we decided to build our own test data: Rather than pursuing the efforts of finding an appropriate treebank-to-gramotron transformation, we performed detailed evaluations of individual frames and of a set of selected verbs.

Test data The linguistic parameters of the models were evaluated concerning the identification of NCs and subcategorisation frames. We randomly extracted 200 relative clauses and 200 verb-final clauses from the test data and hand-annotated the relative clauses with noun chunk labels, and all of the clauses with frame labels. In addition, we extracted 100 randomly chosen relative clauses for each of the six verbs *beteiligen* ‘participate’, *erhalten* ‘receive’, *folgen* ‘follow’, *verbieten* ‘forbid’, *versprechen* ‘promise’, *versuchen* ‘try’, and hand-annotated them with their subcategorisation frames. The particular selection of verbs aims to be representative for the variety of verb frames defined in our grammar.

The manual annotation was facilitated by use of a chart browser. The labellers filled the appropriate chart cells with category names by selecting category labels from a given list that is displayed on clicking a cell. Figure 5 gives an example of NC-labelling which visualises the determination of NC-ranges via cell selection. Frames are annotated as IP

using the formula

$$\texttt{perp} = 10^{\texttt{avg}^{-1} \cdot \texttt{cross}}$$

(assuming that the cross-entropy is computed by a logarithm based on 10). For example, an average lenghth of avg=9.2 and a cross-entropy of cross=24.2 yields a word perplexity perp=427.0, which is a value comparable to the values presented in Schulte im Walde et al. (2001).

labels, i.e. they are always in the same chart cell and frame ranges are trivial.

Best-first consistency Our linguistic evaluation of the probability models is a version of measuring best-first consistency (Briscoe and Carroll, 1993). We made the models determine the Viterbi parses (i.e. maximum probability parses) of the test data and extracted the categories of interest (i.e. noun chunks and subcategorisation frame types). Only the relevant categories but not the entire Viterbi parses were compared with the annotated data. NCs were evaluated according to (i) range and (ii) range and label, i.e. category name. The subcategorisation frames were evaluated according to the frame label only. Precision and recall measures are defined as follows:

$$precision = \frac{correct}{guesses} \qquad recall = \frac{correct}{baseline}$$

with *baseline* referring to the set of annotated categories in the test corpus, *guesses* referring to the set of range/label annotated categories identified in Viterbi parses, and *correct* counting the cases where the chunk/label identified by the parser is a match to the annotator's choice ($correct = guesses \cap baseline$).

Overall results The precision values of the "best" model according to the training strategy were as in Table 3.

Noun Chunks		Subcategorisation Frames on Sub-Corpora	
range	range+label	relative clauses	verb final clauses
98%	92%	63%	73%

Subcategorisation Frames on Specific Verbs					
beteiligen 'participate'	*erhalten* 'receive'	*folgen* 'follow'	*verbieten* 'forbid'	*versprechen* 'promise'	*versuchen* 'try'
48%	61%	88%	59%	80%	49%

Table 3: Precision Values on Noun Chunks and Subcategorisation Frames

For comparison reasons, we evaluated the subcategorisation frames of 200 relative clauses extracted from the training data. Interestingly, there were no striking differences concerning the precision values.

Evaluation of training regimes Figure 6 present the strongly different development of noun chunk and subcategorisation frame representations within the models, ranging from the untrained model until the fifth iteration of lexicalised training. NCs were modelled sufficiently by an unlexicalised trained grammar. Unexpectedly, lexicalisation impaired the modelling slighlty. This observation is supported by related experiments of German noun chunking on an unrestricted text corpus (Schmid and Schulte im Walde, 2000). It remains to be explored whether the number of low-frequent nominal heads is—despite the use of lemmatisation for parameter reduction—still prohibitively large because of the pervasive morpho-syntactic process of noun compounding in German.

Verb phrases in general needed a combination of unlexicalised and lexicalised training, but the representation strongly depended on the specific item. Unlexicalised training advanced frequent phenomena (compare, for example, the representation of the transitive frame with direct object for *erfahren* and with indirect object for *folgen*), lexicalisation and lexicalised training improved the lexicalised properties of the verbs, as expected.

Parameter pooling Regarding the frame evaluation, we also did a test on the effects of parameter pooling in lexicalised traininng. Without pooling of frame categories the precision values for low-frequent phenomena such as non-finite frame recognition was significantly lower, e.g. the precision for the verb *versuchen* was 9% less than with pooling. This result suggests investigations into the importance of training data size and research into other pooling possibilities.

6.3. Error Analysis

A detailed investigation of frame recognition showed the following interesting feature developments:

- Highly common subcategorisation types such as the transitive frame are learned in unlexicalised training and then slightly unlearned in lexicalised training. Less common subcategorisation types such as the demand for an indirect object are unlearned in unlexicalised training, but improved during lexicalised training.
- It is difficult and was not effectively learned to distinguish between prepositional phrases as verbal complements and adjuncts.
- The active present perfect verb complexes and passive of condition were confused, because both are composed by a past participle and a form of *to be*, e.g. *geschwommen ist* 'has swum' vs. *gebunden ist* 'is bound'.
- Copula constructions and passive of condition were confused, again because both may be composed by a past participle and a form of *to be*, e.g. *verboten ist* 'is forbidden' vs. *erfahren ist* 'is experienced'.
- Noun chunks belonging to a subcategorised non-finite clause were partly analysed main verb arguments. For instance, *der ihn zu überreden versucht* 'who him$_{acc}$ tried to persuade' was parsed as demanding an accusative plus a non-finite clause instead of recognising that the accusative object is subcategorised by the embedded infinitival verb.
- Reflexive pronouns may trigger either a reflexive or, by virtue of projecting to an accusative or dative noun chunk, a transitive frame. The correct or wrong choice of frame type containing the reflexive pronoun was learned consequently right or wrong for different verbs. For instance, the verb *sich befinden* 'to be situated' was generally parsed as a transitive, not as inherently reflexive.

6.4. Shortcomings and evaluation alternatives

We are aware that there are some desirable aspects missing from our evaluation.

Firstly, we did not evaluate the relations between lexical heads directly, the main task our parsing system was designed for. Subcategorisation frame and noun chunk label

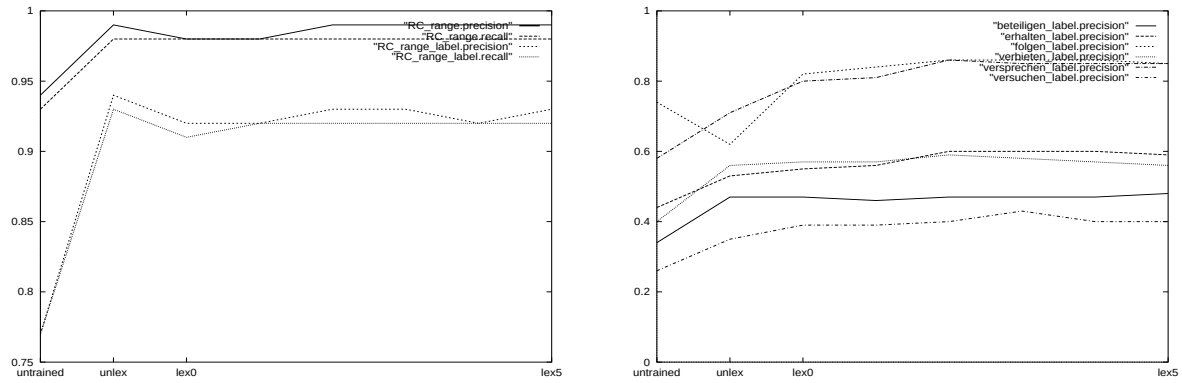

Figure 6: Development of Precision and Recall Values on Noun Chunk Range and Label (left-hand side), and Precision Values on Subcategorisation Frames for Specific Verbs (right-hand side)

recognition serve only as indirect evidence of how well our model does on recognising scrambling of verbal arguments. Because noun chunk annotation is not confined to verb argument slots—PP embedded noun chunks were annotated as well—and a detailed error analysis on noun chunk labels is missing, it remains unclear whether scrambled nominal arguments are subject to more errors than the remarkable 92% precision on NC labels suggests. Similarly, correctly recognised verb frames with a prepositional argument have not been evaluated as to whether the assigned PP argument is actually the correct one.

Secondly, we did not evaluate the correctness of lexical heads of phrases.

Relevant evaluation schemes that capture our shortcomings are the evaluation of dependency structure as described in (Lin, 1995) or the proposal of evaluating of grammatical relations of Carroll et al. (1998). Both evaluation proposals address the importance of selectively evaluating parsing systems with respect to specific types of syntactic phenomena rather than measuring overall performance as in "traditional" evaluation schemes. Selective evaluation is a definite desideratum for our own evaluation task. The proposals also point to a way to automatically extract evaluation relevant relations from an annotated corpus. Inquiring about the feasibility of mapping Negra, the treebank for German, to a respective test corpus will hopefully provide a more comprehensive basis for our future evaluations of head–head relations.

7. Conclusion

Our approach to parsing is a combination of symbolic and stochastic methods. The symbolic component usually involves a very high degree of overgeneration leaving disambiguation to the stochastic component. To facilitate disambiguation by statistical means, the symbolic component relies on certain categorial generalizations and uses non-standard categories to reduce the parameter space or allow for parameter pooling. We used evaluation results in both incremental grammar development and validation of selected output to be used in lexical semantic clustering.

Our principal result is that scrambling-style free-er phrase order, case morphology and subcategorization, and NP-internal gender, number and case agreement can be dealt with in a head-lexicalized PFCG formalism. A second result is that inside-outside estimation appears to be beneficial, however relies on a carefully built grammar where parses can be evaluated by carefully selected linguistic criteria.

Furthermore, we reported experiments on overtraining with inside-outside estimation. These experiments are made possible by the carefully built grammar and our evaluation tools, especially allowing to compare and to relate the results of our mathematical and linguistic evaluation. In combination, these provide a general framework for investigating training regimes for lexicalized PCFGs.

However, there are two relevant aspects missing from our evaluation. First, we did not evaluate grammatical relations directly. Frame and NC case recognition give only a crude idea of how well our model does on recognizing e.g. scrambled subject and direct object. Because NC evaluation is not confined to verb argument slots, the picture is distorted. Second, we did not evaluate the correctness of lexical heads of phrases. Clearly, if we can overcome our difficulties to map Negra, the treebank for German, to a respective test corpus, a more valuable basis for future evaluations of head–head relations supplied by the gramotron parsing system is provided.

Finally, although there is no guarantee that the maximization of the likelihood of the training data (which the inside-outside algorithm performs) also improves the linguistic correctness of the resulting syntactic analyses, our experiments show that in practice this is the case. Gaining more insight into the relationship between linguistic plausibility and likelihood of linguistic analyses will be an interesting future research topic.

Abstract

This paper compares three evaluation metrics for a CCG parser trained and tested on a CCG version of the Penn Treebank. The standard Parseval metrics can be applied to the output of this parser; however, these metrics are problematic for CCG, and a comparison with scores given for standard Penn Treebank parsers is uninformative. As an alternative, we consider two evaluations based on head-dependencies; one considers local dependencies defined in terms of the derivation tree, and one considers dependencies defined in terms of the CCG categories. The latter set of dependencies includes long-range dependencies such as those inherent in coordination and extraction phenomena.

1. Introduction

In this paper, we compare the advantages and shortcomings of three evaluation metrics for a statistical parser based on Combinatory Categorial Grammar (CCG, Steedman (2000)). The parser (described in Hockenmaier and Steedman (2002b)) is trained and tested on a treebank of CCG normal-form derivations which has been derived (semi)-automatically from the Penn Treebank (Marcus et al., 1993).

We apply the standard Parseval metrics to compare the derivation trees produced by the parser with those in the gold standard. However, CCG derivation trees are binary-branching, and the set of CCG categories is much larger than the set of nonterminal labels in the Penn Treebank. Therefore, a comparison with Parseval figures given for standard Penn Treebank parsers is uninformative. Furthermore, in the presence of left and right modifiers to the same constituent, there are equivalent normal-form derivations, which Parseval does not take into account.

We also consider two dependency evaluations. Like the standard Penn Treebank parsers of Collins (1999) and Charniak (2000), the CCG parser models word-word dependencies defined in terms of local rule applications. Collins (1999) proposes an evaluation based on these dependencies, which we apply to our parser. This allows a direct comparison with Collins' parser and overcomes the problem of equivalent normal-form derivations.

Unlike the phrase-structure trees returned by standard Penn Treebank parsers, CCG derivations encode the long range dependencies involved in constructions such as raising, control, extraction and coordination. In order to evaluate another CCG parser, Clark et al. (2002) introduce an evaluation which incorporates the long range, as well as local, dependencies. This evaluation is applied to the output of the normal-form parser, using the Clark et al. parser to extract the relevant dependencies from the derivation trees. This evaluation is much closer to the dependency-based evaluations of Lin (1995) and Carroll et al. (1998).

2. Combinatory Categorial Grammar

A CCG grammar consists of a lexicon, which pairs words with lexical categories, and a set of combinatory rules, which specify how categories combine. Categories are either atomic or complex. Examples of atomic categories include $S[dcl]$ (declarative sentence), NP (noun phrase), N (noun) and PP (prepositional phrase).

Complex categories are functors which express the type and directionality of their arguments, and the type of the result. For example, the category for the transitive verb *bought* specifies that one NP is required to the right of the verb, and one NP to the left, resulting in a sentence:

(1) bought := $(S[dcl]\backslash NP)/NP$

Other examples of complex categories expressing subcategorisation are as follows ($[pt]$ denotes a past participle and $[pss]$ denotes a passive):

(2) has := $(S[dcl]\backslash NP)/(S[pt]\backslash NP)$
been := $(S[pt]\backslash NP)/(S[pss]\backslash NP)$
bought := $(S[pt]\backslash NP)/NP$
bought := $S[pss]\backslash NP$

Complex categories of the form X/X or $X\backslash X$ can express modification:

(3) big := N/N
quickly := $(S\backslash NP)\backslash(S\backslash NP)$

Constituents combine according to a set of combinatory rules, including function application, function composition and type-raising (see Steedman (2000) for the details). For example, the following derivation uses forward ($>$) and backward ($<$) application:

(4)
IBM	*quickly*	*bought*	*Lotus*
NP	$(S\backslash NP)/(S\backslash NP)$	$(S[dcl]\backslash NP)/NP$	NP
		$S[dcl]\backslash NP$ (>)	
	$S[dcl]\backslash NP$ (>)		
$S[dcl]$ (<)			

Composition and type-raising are necessary for certain types of extraction and coordination phenomena. In the following object-extraction example, type-raising ($>T$) first turns the NP for *IBM* into a functor looking for a verb-phrase, which then combines with the category for *bought* using forward composition ($>B$):

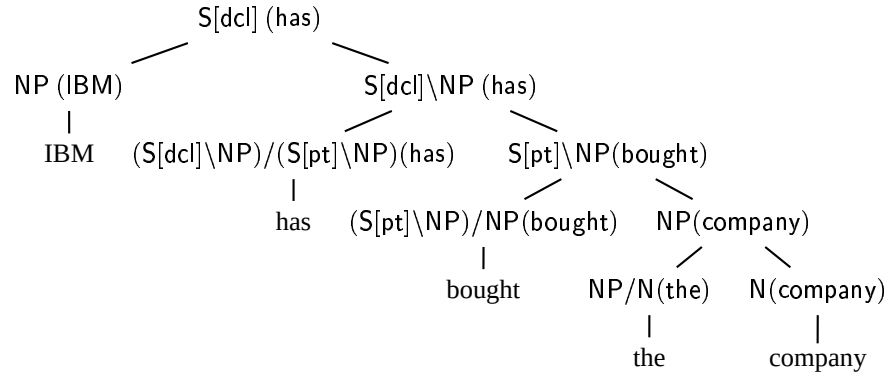

Figure 1: A derivation tree marked with heads

(5) *the company* *that* *IBM* *bought*

NP (NP\NP)/(S/NP) NP (S\NP)/NP

S/(S\NP) (>T)

S/NP (>B)

NP\NP (>)

NP (<)

Note that the use of composition introduces so-called "spurious ambiguity", in which distinct derivations for a sentence lead to the same semantic interpretation. Even a simple sentence such as *IBM bought Lotus* has several derivations, one using only function application, and the others using type-raising and composition. However, all derivations lead to the same interpretation: that *IBM* is the buyer and *Lotus* is the buyee.

One solution to the problem of spurious ambiguity is to only apply function composition when syntactically necessary; such a derivation is called *normal-form*. The corpus that we use to train and test the parser described here contains only normal-form derivations.

3. The parser

The parser that we evaluate is described in Hockenmaier and Steedman (2002b), and is based on a generative model of CCG derivation trees. Like most recent work in statistical parsing – including the generative models of Collins (1997) and Charniak (2000) – the parser models the word-word dependencies defined by local subtrees. Each constituent is assumed to have one lexical head (a word and its lexical category). The example derivation in Figure 1 shows how heads are percolated through the derivation tree.

The statistical model assumes a top-down tree-generating process in which heads are generated at the maximal projection of a constituent. Unless this maximal projection is the root of the entire tree, the constituent is a complement or adjunct of another constituent, and there is a dependency between the the heads of both constituents. This dependency is expressed in the statistical model by conditioning the head of complements or adjuncts on the head of the parent node and the local tree which defines the dependency relation. For example, in Figure 1, *bought* is not only conditioned on its lexical category $(S[pt]\backslash NP)/NP$, but also on the fact that it appears within a local tree with head word *has*, parent $S[dcl]\backslash NP$, left (head) daughter $(S[dcl]\backslash NP)/(S[pt]\backslash NP)$ and right (non-head) daughter $S[pt]\backslash NP$.

The parser is trained and tested on a treebank of CCG normal-form derivations. This corpus, which we call CCGbank, has been derived (semi)-automatically from the Penn Treebank (Marcus et al., 1993), using sections 02-21 for training and section 23 for testing. For further details of CCGbank we refer readers to Hockenmaier and Steedman (2002a).

4. Evaluation metrics

This section describes the different evaluation metrics, which we illustrate by evaluating the (fictitious) output tree in the bottom of figure 2 against the correct derivation given in the top of figure 2.

4.1. Parseval

The first measures are the standard Parseval metrics bracketed precision/recall and labelled precision/recall used to compare the normal-form derivation trees produced by the parser with those in the gold standard (section 23 of the CCGbank).

Following common practice, we disregard punctuation marks. Since CCG derivation trees are at most binary branching, punctuation marks introduce a separate level into the tree, which we also disregard in the evaluation.

Consider the trees given in figure 2. Discarding the lexical categories (but not their unary projections), the gold standard has six nodes, three of which are correctly identified in the output tree. The output tree has seven nonterminal nodes. Hence, labelled and bracketed precision are both 3/7; labelled and bracketed recall are both 3/6. Note that Parseval does not take the correctness of lexical categories into account, which is important for CCG since categories encode subcategorisation information. Therefore, we also give the accuracy of lexical categories (again disregarding punctuation marks), which in this case is 4/6.

4.2. Dependency evaluation 1

Collins (1999) gives an alternative evaluation to Parseval, measuring the recovery of word-word dependencies. According to his definition, there is a dependency between two words w and w' if the parse contains a local tree such that w' is the head of this tree and w is the head of a non-

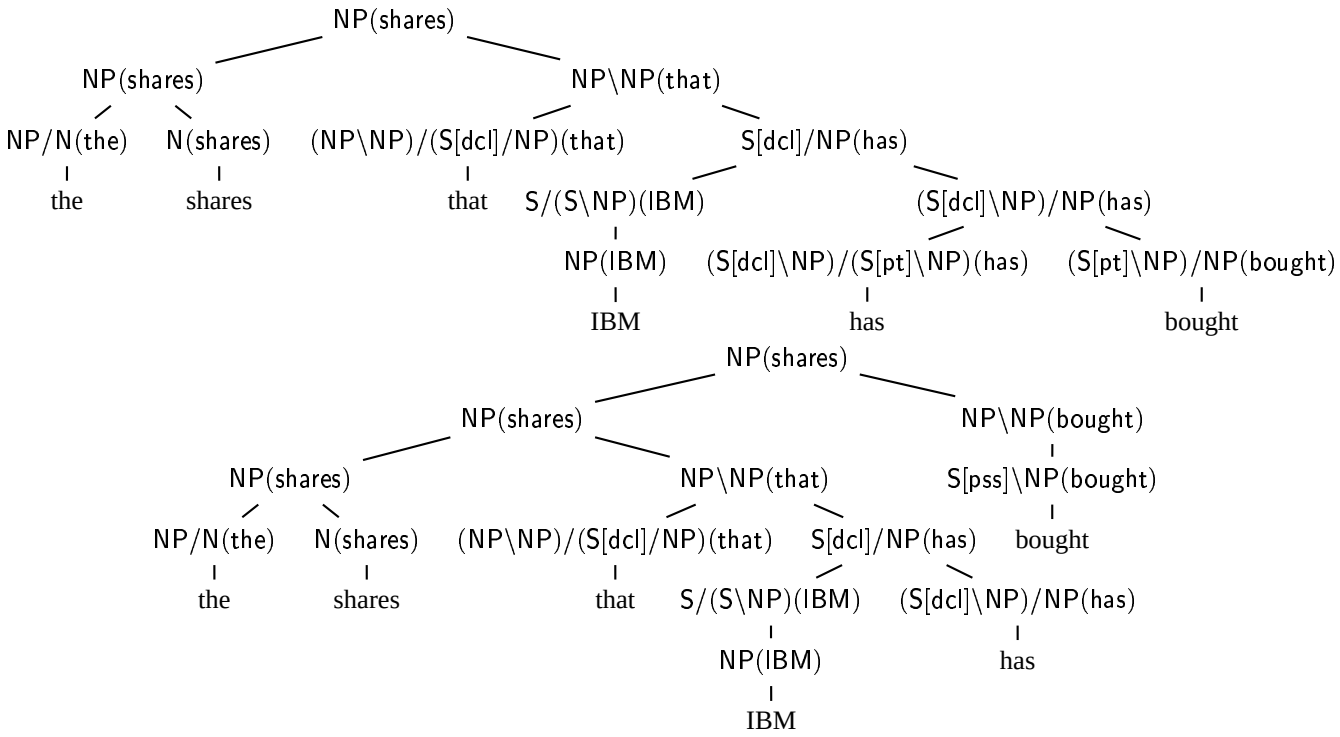

Figure 2: Example trees for evaluation: the top tree is the gold standard.

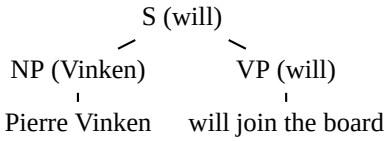
head daughter. The following tree defines a dependency between *Vinken* and *will*:



The dependency relation is determined by the label of the parent node (S), the label of the head daughter (VP), the label of the non-head daughter (NP), and the direction of the non-head daughter (left): $\langle \mathrm{S}, \mathrm{VP}, \mathrm{NP}, \mathrm{left} \rangle$. Furthermore, if the non-head daughter is a complement, its category carries a complement feature $-\mathrm{C}$. In Collins' original evaluation, coordinate constructions are distinguished by a further element CC. We adapt this evaluation to CCG; however, since the directionality of the head is directly encoded in the categories, there is no need for this feature. A similar comment applies to the complement feature. Also, in CCGbank, binary nodes within a coordinate construction carry a special coordination feature, and so the CC-feature is redundant as well.

The way in which these dependencies are defined means there is exactly one relation to be determined for each word. There is a special relation for the head of the sentence (which is not dependent on any other word). Collins gives scores for labelled and unlabelled dependencies. Unlabelled dependency scores only take into account whether there is a relation between w and w' such that w' is the head and w its modifier or complement, but not whether the local tree which defines this dependency is correctly labelled.

Returning to our example, the gold standard in figure 2 defines the following dependencies:

Relation $\langle Parent, Head, Sister \rangle$	**Head**	**Dep**
$\langle \mathrm{NP}, \mathrm{N}, \mathrm{NP/N} \rangle$	*shares*	*the*
$\langle$Head$\rangle$		*shares*
$\langle \mathrm{NP}, \mathrm{NP}, \mathrm{NP\backslash NP} \rangle$	*shares*	*that*
$\langle \mathrm{NP\backslash NP}, (\mathrm{NP\backslash NP})/(\mathrm{S[dcl]/NP}), \mathrm{S[dcl]/NP} \rangle$	*that*	*has*
$\langle \mathrm{S[dcl]/NP}, (\mathrm{S[dcl]\backslash NP})/\mathrm{NP}, \mathrm{S}/(\mathrm{S\backslash NP}) \rangle$	*has*	*IBM*
$\langle ((\mathrm{S[dcl]\backslash NP})/\mathrm{NP}, (\mathrm{S[dcl]\backslash NP})/(\mathrm{S[pt]\backslash NP}),$ $(\mathrm{S[pt]\backslash NP})/\mathrm{NP} \rangle$	*has*	*bought*

These are the dependencies in the incorrect analysis:

Relation $\langle Parent, Head, Sister \rangle$	**Head**	**Dep**
$\langle \mathrm{NP}, \mathrm{N}, \mathrm{NP/N} \rangle$	*shares*	*the*
$\langle$Head$\rangle$		*shares*
$\langle \mathrm{NP}, \mathrm{NP}, \mathrm{NP\backslash NP} \rangle$	*shares*	*that*
$\langle \mathrm{NP\backslash NP}, (\mathrm{NP\backslash NP})/(\mathrm{S[dcl]/NP}), \mathrm{S[dcl]/NP} \rangle$	*that*	*has*
$\langle \mathrm{S[dcl]/NP}, (\mathrm{S[dcl]\backslash NP})/\mathrm{NP}, \mathrm{S}/(\mathrm{S\backslash NP}) \rangle$	*has*	*IBM*
$\langle \mathrm{NP}, \mathrm{NP}, \mathrm{NP\backslash NP} \rangle$	*shares*	*bought*

Thus, according to this measure, five out of six dependencies are correct. Note that this measure is not always affected by errors in the lexical categories. For example, the dependency between *has* and *that* is considered correct, even though the gold standard analyses *has* as an auxiliary and the incorrect derivation analyses *has* as a transitive verb.

4.3. Dependency evaluation 2

The parser in Clark et al. (2002) can be used to yield a third measure. This parser uses CCG categories extended with head and dependency information and captures the "deep" dependencies inherent in cases such as raising, control, and extraction and coordination phenomena, as well

as the standard local dependencies. Figure 3 is an example from Clark et al. (2002), with the links expressing dependencies. (The labels are omitted for clarity.) Note that *investors* and *managers* are both subjects of *want*, and subjects of *lock*.

An example of an extended category for the transitive verb *bought* is as follows:

(6) bought := $(S_{bought}\backslash NP_1)/NP_2$

There are two dependency relations encoded: the subject of the transitive verb – here marked 1 – and the direct object – here marked 2. The subscript on the S category indicates that the head of the resulting sentence is *bought*. Since the argument slots in CCG categories correspond closely to the grammatical relations used by Carroll et al. (1998), this dependency evaluation is very much in the spirit of the Carroll et al. evaluation (and that of Lin (1995)).

A dependency is formally defined as a 4-tuple: $\langle h_f, f, s, h_a \rangle$, where h_f is the head word of the functor, f is the functor category (extended with dependency information), s is the argument slot, and h_a is the head word of the argument. For example, in the sentence *IBM bought Lotus*, the subject-verb dependency is as follows:

(7) $\langle bought, (S\backslash NP_1)/NP_2, 1, IBM \rangle$

The category set used by the parser consists of 398 category types (chosen according to frequency), derived automatically from the CCGbank. Each category has been manually marked-up with head and dependency information, and at this stage we encode every argument slot as a dependency relation. In future work we may use only a subset of the argument slots.

In order to recover such dependencies from the trees produced by the normal-form parser, the Clark et al. (2002) parser is run over the trees output by the normal-form parser, tracing out the derivations and outputting the dependencies. This method can also be applied to the trees in the test set, in order to provide a set of gold standard dependency structures. Note that the marked-up categories used by the Clark et al. parser are necessary to obtain these dependencies; without this information, they cannot be derived from the local dependencies used in the first dependency evaluation.

The evaluation metrics we use are precision and recall over the dependencies (labelled and unlabelled). To obtain a point for a labelled dependency, the head, dependent, functor category, and slot must all be correct. To obtain a point for an unlabelled dependency, the head and dependent must have appeared together in some relation (in any order) in the gold standard. The dependencies obtained from the trees in Figure 2 are given in table 1. The scores for the incorrect tree are $3/6$ labelled precision, $3/7$ labelled recall, $5/6$ unlabelled precision, and $5/7$ unlabelled recall.

5. Results and discussion

The results for the three evaluation metrics on Section 23 of CCGbank are given in Table 2. BP is bracketed precision; LP is labelled precision; UP is unlabelled precision. BR, LR, UR are defined similarly for recall. The scores for each evaluation are accumulated over all sentences in the test set, rather than averaged per sentence. We also give the score for accuracy of the lexical categories.

Gold standard
$\langle the, NP/N_1, 1, shares \rangle$
$\langle that, (NP\backslash NP_1)/(S[dcl]_2\backslash NP), 1, shares \rangle$
$\langle that, (NP\backslash NP_1)/(S[dcl]_2\backslash NP), 2, has \rangle$
$\langle has, (S[dcl]\backslash NP_1)/(S[pt]_2\backslash NP), 1, IBM \rangle$
$\langle has, (S[dcl]\backslash NP_1)/(S[pt]_2\backslash NP), 2, bought \rangle$
$\langle bought, (S[pt]\backslash NP_1)/NP_2, 1, IBM \rangle$
$\langle bought, (S[pt]\backslash NP_1)/NP_2, 2, shares \rangle$
Example tree

83.7%	84.2%	90.5%	91.1%

Table 2: Results for the three evaluation metrics

5.1. The Parseval scores

It is hard to draw conclusions from the Parseval scores because of the difficulty in comparing results across different tree representations. Our figures are below the 88.3%/88.0% labelled precision/recall of Collins (1999). However, a direct comparison of the Parseval result with Penn Treebank parsers is not informative, even for the same set of sentences. Because Penn Treebank trees are very flat, they contain far fewer brackets than CCG derivation trees; hence the rate of crossing brackets (and bracketed precision and recall) will automatically be much lower than for a grammar which produces at most binary-branching trees. The flat trees also mean that Parseval is too lenient towards mis-attachments produced by Penn Treebank parsers (Manning and Schütze, 1999). Furthermore, the set of node labels for Penn Treebank trees and the set of CCG categories are not comparable.

Hockenmaier (2001) notes a further problem with applying Parseval metrics to CCG derivation trees. Consider verb phrases, $(S\backslash NP)$, which can have left and right modifiers ($(S\backslash NP)/(S\backslash NP)$ and $(S\backslash NP)\backslash(S\backslash NP)$) with the following two rule instantiations:

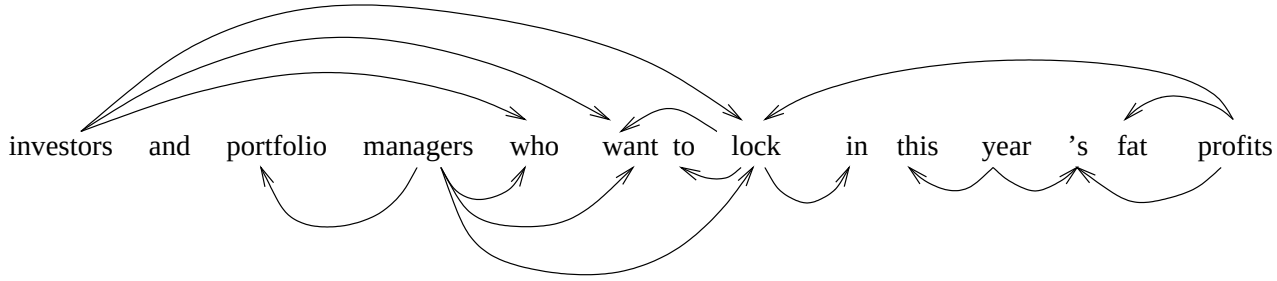

Figure 3: Example dependency structure

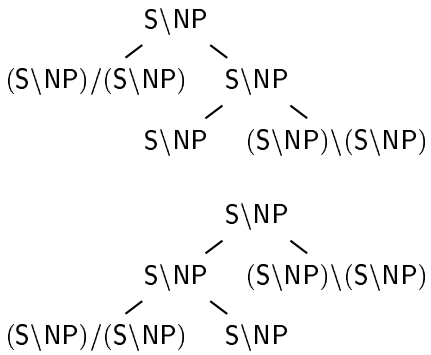
(8) $S\backslash NP \rightarrow (S\backslash NP)/(S\backslash NP)\ \ S\backslash NP$
$S\backslash NP \rightarrow S\backslash NP\ \ (S\backslash NP)\backslash(S\backslash NP)$

For any parsing model which is defined in terms of (possibly headed or lexicalized) local trees, the following two trees are equivalent:



This is also the case for the normal-form parser described above. A similar problem arises with coordinations/lists involving more than two conjuncts. The dependency evaluations described below do not suffer from this problem because the same dependencies are produced for each derivation.

5.2. Dependency evaluation 1

As expected, the results for the tree dependencies are higher than the Parseval scores. Unlike Parseval, the dependency measure is neutral with respect to the branching factor of the trees produced by the grammar. In particular, for a given sentence, the number of dependencies is identical to the number of words in the sentence. Since this is the same for any parser, unlabelled recovery of dependencies can be used to indicate how parsers based on different grammars compare. Note that our unlabelled figures (90.1% recall) are similar to those of Collins (90.9%).

However, a direct comparison with the labelled figures given by Collins (88.3% recall) is again problematic. First, the sets of labels are very different. In order for labelled dependencies as defined by a CCG derivation tree to be correct, complement-adjunct distinctions as well as extraction cases have to be correctly recovered. Extraction is not indicated in the trees returned by Collins' parser, and can therefore not be evaluated. Mistaking a complement daughter for an adjunct or vice versa has a much greater effect on the labelled scores for CCG than for Penn Treebank parse trees. In Collins' parser, the complement-adjunct distinction is only expressed in the label of the particular node in question. However, in CCG this can affect the entire tree below the parent – both the subtree underneath the head daughter and the subtree underneath the non-head daughter.

In addition, Collins performs the following preprocessing steps on the output of his parser and the Gold standard: all POS tags are replaced by a single token "TAG". All complement markings on the parent and head node are removed, so that one attachment decision made higher up in the tree does not affect the evaluation of its daughter. We cannot readily perform the same preprocessing steps: the choice of lexical categories can affect the tree at several levels, not just at the leaf nodes; furthermore, complement-adjunct distinctions are also encoded in all intermediate categories, not just a constituent's maximal projection.

5.3. Dependency evaluation 2

One of the advantages of a dependency-style evaluation is that the scores can be broken down by relation, as shown in Table 4, which gives scores for some of the most frequent types.[1] The table also gives some indication of the kinds of relations used in the evaluation.

The relations are defined in terms of CCG categories, which raises the question of how these compare with a more generic set such as that proposed by Carroll et al. (1998). First note that there are many more relations in our scheme: around 700 in total compared with 20 for Carroll et al. We have so many relations because each argument slot in each category (of which there are 398) encodes a separate relation.

Clearly there is room for generalisation in our scheme. For example, Carroll et al. have one relation for subjects, whereas we have a different relation for each category type encoding a subject. Examples of two categories encoding subject relations are $(S[dcl]\backslash NP_1)/NP_2$ and $(S[b]\backslash NP_1)/NP_2$. In future work we will investigate mapping our relations onto Carroll et al.'s.

One potential weakness of our evaluation (which follows from encoding all argument slots as relations) is that some relations are effectively counted more than once. For

[1] #ref is the number of dependencies with the given relation type in the gold standard; #test is the number of dependencies with the given relation type produced by the parser; LP/LR are labelled precision/recall; and the F-score is calculated as (2*LP*LR)/(LP+LR).

$\langle P, H, S \rangle$	#ref	#test	LP%	LR%
$\langle NP, NP, NP\backslash NP \rangle$	3,765	3,626	75.2	72.4
$\langle HEAD \rangle$	2371	2367	94.5	94.4
$\langle NP, NP, NP[conj] \rangle$	935	1,075	61.3	70.5
$\langle S[dcl]\backslash NP, S[dcl]\backslash NP, (S\backslash NP)\backslash(S\backslash NP) \rangle$	914	905	60.9	60.3
$\langle S[dcl]\backslash NP, (S[dcl]\backslash NP)/NP, NP \rangle$	880	858	86.7	84.6
$\langle S[pss]\backslash NP, S[pss]\backslash NP, (S\backslash NP)\backslash(S\backslash NP) \rangle$	442	470	70.6	75.1

Table 3: Some dependency relations in evaluation 1

Functor	Slot	Category description	LP %	# test	LR %	# ref	F-score

$(S[dcl]\backslash NP_{X,1})/(S[b]_2\backslash NP_X)$	2	*auxiliary*	97.6	631	98.6	625	98.1
$(S[dcl]\backslash NP_{X,1})/(S[b]_2\backslash NP_X)$	1	*auxiliary*	92.2	638	95.0	619	93.6
$(S[b]\backslash NP_1)/NP_2$	1	*infinitival transitive verb*	80.6	566	83.1	549	81.8
$(NP_X/N_{X,1})\backslash NP_2$	1	*s genitive*	96.6	472	95.2	479	95.9
$(NP_X/N_{X,1})\backslash NP_2$	2	*s genitive*	92.5	482	95.3	468	93.9
$(S[dcl]\backslash NP_1)/S[dcl]_2$	1	*sentential complement verb*	93.0	431	95.5	420	94.2
$(NP_X\backslash NP_{X,1})/(S[dcl]_2\backslash NP_X)$	1	*subject relative pronoun*	71.9	295	72.6	292	72.2
$(NP_X\backslash NP_{X,1})/(S[dcl]_2\backslash NP_X)$	2	*subject relative pronoun*	94.5	289	95.5	286	95.0

Table 4: Results for dependency evaluation 2 by relation; only a subset of the relations are shown

example, in the sentence *John has been eating beans*, *John* is evaluated as a subject three times: as the subject of *has*, *been* and *eating*. But if the subject of *eating* is correct in this example, then the subjects of the auxiliary verbs will be correct as well.

We would also like to make a distinction between arguments that have been extracted from a predicate, and those that are "in situ". Currently the direct object of a verb, for example, is the same relation whether it has been extracted or not. It would be useful to at least have the option to make this distinction.

5.4. Comparing the dependency evaluations

The dependencies expressed in dependency evaluation 1 are not simply a subset of the relations used in the second dependency evaluation. When the relations are broken down individually, this leads to an interesting comparison.

In dependency evaluation 2, it is possible to determine how well nominal prepositions have been recovered, whereas in dependency evaluation 1, we can only evaluate how well NP postmodifiers have been recovered.

In contrast to dependency evaluation 2, dependency evaluation 1 includes a separate relation for the head of a sentence $\langle HEAD \rangle$ (assuming a single head for each sentence, including coordinate structures).

In dependency evaluation 1, it can be seen for each type of constituent whether coordination is recovered properly, e.g. $\langle NP, NP, NP[conj] \rangle$. In dependency evaluation 2, coordination relations are not represented explicitly.

Some relations in dependency evaluation 1 (like the direct object of transitive declaratives, $\langle S[dcl]\backslash NP, (S[dcl]\backslash NP)/NP, NP \rangle$) seem to be the same as in evaluation 2. However, in dependency evaluation 1 only non-extracted cases are taken into account.

6. Conclusion

We have presented three evaluations for a wide-coverage CCG parser. Of these, Parseval seems the least appropriate, especially if a comparison is to be made with existing Penn Treebank parsers. In an attempt to compare with the Collins parser, we adopted a dependency evaluation in which dependencies are defined in terms of local trees; however, the different labelling used in the CCG derivation tree compared to the Penn Treebank made the comparison of labelled dependencies problematic. The comparison of unlabelled dependencies was more appropriate, however.

One of the features of CCG is its analysis of long-range dependencies. In an attempt to incorporate such dependencies into the evaluation, we proposed a second dependency evaluation, in which the dependency relations are defined in terms of the CCG categories. This is closer to evaluations based on grammatical relations, although if a comparison is to be made with parsers using such an evaluation, a map-

ping is required between the CCG dependencies and the set of grammatical relations.

Abstract

This paper reports on the use of two distinct evaluation metrics for assessing a stochastic parsing model consisting of a broad-coverage Lexical-Functional Grammar (LFG), an efficient constraint-based parser and a stochastic disambiguation model. The first evaluation metric measures matches of predicate-argument relations in LFG f-structures (henceforth the LFG annotation scheme) to a gold standard of manually annotated f-structures for a subset of the UPenn Wall Street Journal treebank. The other metric maps predicate-argument relations in LFG f-structures to dependency relations (henceforth DR annotations) as proposed by Carroll et al. (Carroll et al., 1999). For evaluation, these relations are matched against Carroll et al.'s gold standard which was manually annnotated on a subset of the Brown corpus. The parser plus stochastic disambiguator gives an F-measure of 79% (LFG) or 73% (DR) on the WSJ test set. This shows that the two evaluation schemes are similar in spirit, although accuracy is impaired systematically by mapping one annotation scheme to the other. A systematic loss of accuracy is incurred also by corpus variation: Training the stochastic disambiguation model on WSJ data and testing on Carroll et al.'s Brown corpus data yields an F-score of 74% (DR) for dependency-relation match. A variant of this measure comparable to the measure reported by Carroll et al. yields an F-measure of 76%. We examine divergences between annotation schemes aiming at a future improvement of methods for assessing parser quality.

1. Introduction

Recent years have seen increased interest in parsing systems that capture predicate-argument relations instead of mere phrase-structure representations. In aiming for this goal, considerable progress has been made by combining systems of hand-coded, linguistically fine-grained grammars with robustness techniques and stochastic disambiguation models. However, it can reasonably be argued that the standard evaluation procedure for stochastic parsing—precision and recall of matching labeled bracketing to section 23 of the UPenn Wall Street Journal (WSJ) treebank (Marcus et al., 1994)—is not appropriate for assessing the quality of parsers on matching predicate-argument relations. A new standard for evaluation on predicate-argument relations and for annotating a gold standard is needed.

In this paper we present a stochastic parsing model consisting of a broad-coverage Lexical-Functional Grammar (LFG), a constraint-based parser and a stochastic disambiguation model, and discuss the evaluation of this system on two distinct evaluation metrics for assessing the quality of the stochastic parsing model on matching predicate-argument relations. The first evaluation metric measures matches of predicate-argument relations in LFG f-structures (henceforth the LFG annotation scheme) to a gold standard of manually annotated f-structures for a representative subset of the WSJ treebank. The evaluation measure counts the number of predicate-argument relations in the f-structure of the parse selected by the stochastic model that match those in the gold standard annotation.

The other metric we employed maps predicate-argument relations in LFG f-structures to the dependency relations (henceforth the DR annotation scheme) proposed by Carroll et al. (Carroll et al., 1999). Evaluation with this metric measures the matches of these relations to Carroll et al.'s gold standard corpus.

Our parser plus stochastic disambiguator gives an F-measure of 79% (LFG) or 73% (DR) on the WSJ test set, showing that the two evaluation schemes are similar in spirit. However, accuracy is systematically impaired by mapping one annotation scheme to the other. A systematic loss of accuracy is incurred also by corpus variation: Training the stochastic disambiguation model on WSJ data and testing on Carroll et al.'s Brown corpus data gives a DR F-measure of 74% for matching dependency relations. For a direct comparison of our results with Carroll et al.'s system, we also computed an F-measure that does not distinguish different types of dependency relations. Under this measure we obtain 76% F-measure.

One goal of this paper is to highlight possible pitfalls and error sources in translating between different annotation schemes and gold standards. We believe that a thorough investigation of divergences in annotation schemes will facilitate a future standard for predicate-argument evaluation and annotation.

This paper is organized as follows. After introducing the grammar and parser used in this experiment, we describe in section 2. the robustness techniques employed to reach 100% grammar coverage on unseen WSJ text (in the sense of the proportion of sentences for which at least one analysis is found). Furthermore, we give in section 3. a short account of the stochastic model used for disambiguating LFG parses. Experiments on evaluating the combined system of parser and stochastic disambiguator on the two distinct evaluation measures and corpora are described in section 4.

2. Robust Parsing using LFG

2.1. A Broad-Coverage Lexical-Functional Grammar

The grammar used for this project has been developed in the ParGram project (Butt et al., 1999). It uses LFG as a formalism, producing c(onstituent)-structures (trees) and

f(unctional)-structures (attribute value matrices) as output. The c-structures encode constituency. Each c-structure has at least one corresponding f-structure. F-structures encode predicate-argument relations and other grammatical information, e.g., number, tense. The XLE parser (Maxwell and Kaplan, 1993) was used to produce packed representations, specifying all possible grammar analyses of the input.

The grammar has 314 rules with regular expression right-hand sides which compile into a collection of finite-state machines with a total of 8,759 states and 19,695 arcs. The grammar uses several lexicons and two guessers: one guesser for words recognized by the morphological analyzer but not in the other lexicons and one for those not recognized. As such, most common and proper nouns, adjectives, and adverbs have no explicit lexical entry. The main verb lexicon contains 9,652 verb stems and 23,525 subcategorization frame-verb stem entries; there are also lexicons for adjectives and nouns with subcategorization frames and for closed class items such as prepositions.

For estimation and testing purposes using the WSJ treebank, the grammar was modified to parse part of speech tags and labeled bracketing. A stripped down version of the WSJ treebank was created that used only those POS tags and labeled brackets relevant and reliable for determining grammatical relations. The WSJ labels are given entries in a special LFG lexicon, and these entries constrain both the c-structure and the f-structure of the parse. For example, the WSJ's ADJP-PRD label must correspond to an AP in the c-structure and an XCOMP in the f-structure. In this version of the corpus, all WSJ labels with -SBJ are retained and are restricted to phrases corresponding to SUBJ in the LFG grammar; in addition, it contains NP under VP (OBJ and OBJth in the LFG grammar), all -LGS tags (OBL-AG), all -PRD tags (XCOMP), VP under VP (XCOMP), SBAR- (COMP), and verb POS tags under VP (V in the c-structure). For example, our labeled bracketing version of wsj_1305.mrg is *[NP-SBJ His credibility] is/VBZ_ also [PP-PRD on the line] in the investment community.*

Some mismatches between the WSJ labeled bracketing and the LFG grammar remain. These often arise when a given constituent fills a grammatical role in more than one clause, usually when it is a SUBJ or OBJ in one clause and also the SUBJ of an XCOMP complement. For example, in wsj_1303.mrg *Japan's Daiwa Securities Co. named Masahiro Dozen president.*, the noun phrase *Masahiro Dozen* is labeled as an NP-SBJ, presumably because it is the subject of a small clause complement. However, the LFG grammar treats it also as the OBJ of the matrix clause. As a result, the labeled bracketed version of this sentence does not receive a full parse, even though the LFG output from parsing its unlabeled, string-only counterpart is well-formed. Some other bracketing mismatches remain between this stripped down WSJ corpus and the LFG grammar; these are usually the result of adjunct attachment. Such mismatches occur in part because, besides minor modifications to match the bracketing for special constructions, e.g., negated infinitives, the grammar was not altered to mirror the WSJ bracketing.

2.2. Robustness Techniques

To increase robustness, the standard grammar has been augmented with a FRAGMENT grammar. This grammar parses the sentence as well-formed chunks specified by the grammar, in particular as Ss, NPs, PPs, and VPs. These chunks have both c-structures and f-structures corresponding to them, just as in the standard grammar. Any substring that cannot be parsed as one of these chunks is parsed as a TOKEN chunk. The TOKENs are also recorded in the c- and f-structures. The grammar has a fewest-chunk method for determining the correct parse. For example, if a string can be parsed as two NPs and a VP or as one NP and an S, the NP-S option is chosen.

A final capability of XLE that increases coverage of the standard plus fragment grammar on the WSJ corpus is a SKIMMING technique. Skimming is used to avoid timeouts and memory problems when parsing unusually difficult sentences in the corpus. When the amount of time or memory spent on a sentence exceeds a threshhold, XLE goes into skimming mode for the constituents whose processing has not been completed. When XLE skims these remaining constituents, it does a bounded amount of work per subtree. This guarantees that XLE finishes processing a sentence in a polynomial amount of time, although it does not necessarily return the complete set of analyses. In parsing section 23, 7.2% of the sentences were skimmed; 26.1% of the skimmed sentences resulted in full parses, while 73.9% were fragment parses.

The final grammar coverage achieved 100% of section 23 as unseen unlabeled data: 74.7% of those were full parses, 25.3% FRAGMENT and/or SKIMMED parses.

3. Discriminative Statistical Estimation from Partially Labeled Data

3.1. Exponential Probability Models on LFG Parses

The probability model we employed for stochastic disambiguation is the well-known family of exponential models. These models have already been applied successfully for disambiguation of various constraint-based grammars (LFG (Johnson et al., 1999), HPSG (Bouma et al., 2000), DCG (Osborne, 2000)).

In this paper we are concerned with conditional exponential models of the form:

$$p_{\boldsymbol{\lambda}}(x|y) = Z_{\boldsymbol{\lambda}}(y)^{-1} e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)}$$

where $X(y)$ is the set of parses for sentence y, $Z_{\boldsymbol{\lambda}}(y) = \sum_{x \in X(y)} e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)}$ is a normalizing constant, $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_n) \in \mathbb{R}^n$ is a vector of log-parameters, $\boldsymbol{f} = (f_1, \ldots, f_n)$ is a vector of property-functions $f_i : \mathcal{X} \to \mathbb{R}$ for $i = 1, \ldots, n$ on the set of parses $\mathcal{X}$, and $\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)$ is the vector dot product $\sum_{i=1}^{n} \lambda_i f_i(x)$.

In our experiments, we employed around 1000 complex property-functions comprising information about c-structure, f-structure, and lexical elements in parses, similar to the properties used in Johnson et al. (1999). For example, there are property functions for c-structure nodes and c-structure subtrees, indicating attachment preferences. High versus low attachment is indicated by property functions counting the number of recursively embedded phrases.

Other property functions are designed to refer to f-structure attributes, corresponding to grammatical functions in LFG, or to atomic attribute-value pairs in f-structures. More complex property functions are designed to indicate, for example, the branching behaviour of c-structures and the (non)-parallelism of coordinations on both c-structure and f-structure levels. Furthermore, properties refering to lexical elements based on an auxiliary distribution approach as presented in Riezler et al. (2000) are included in the model. Here tuples of head words, argument words, and grammatical relations are extracted from the training sections of the WSJ, and fed into a finite mixture model for clustering grammatical relations. The clustering model itself is then used to yield smoothed probabilities as values for property functions on head-argument-relation tuples of LFG parses.

3.2. Discriminative Estimation

Discriminative estimation techniques have recently received great attention in the statistical machine learning community and have already been applied to statistical parsing (Johnson et al., 1999; Collins, 2000; Collins and Duffy, 2001). In discriminative estimation, only the conditional relation of an analysis given an example is considered relevant, whereas in maximum likelihood estimation the joint probability of the training data to best describe observations is maximized. Since the discriminative task is directly kept in mind during estimation, discriminative methods can yield improved performance. In our case, discriminative criteria cannot be defined directly with respect to "correct labels" or "gold standard" parses since the WSJ annotations are not sufficient to disambiguate the more complex LFG parses. However, instead of retreating to unsupervised estimation techniques or creating small LFG treebanks by hand, we use the labeled bracketing of the WSJ training sections to guide discriminative estimation. That is, discriminative criteria are defined with respect to the *set of parses consistent with the WSJ annotations*[1].

The objective function in our approach, denoted by $P(\boldsymbol{\lambda})$, is the joint of the negative log-likelihood $-L(\boldsymbol{\lambda})$ and a Gaussian regularization term $-G(\boldsymbol{\lambda})$ on the parameters $\boldsymbol{\lambda}$. Let $\{(y_j, z_j)\}_{j=1}^m$ be a set of training data, consisting of pairs of sentences y and partial annotations z, let $X(y, z)$ be the set of parses for sentence y consistent with annotation z, and $X(y)$ be the set of all parses produced by the grammar for sentence y. Furthermore, let $p[f]$ denote the expectation of function f under distribution p. Then $P(\boldsymbol{\lambda})$ can be defined for a conditional exponential model $p_{\boldsymbol{\lambda}}(z|y)$ as:

$$
\begin{aligned}
P(\boldsymbol{\lambda}) &= -L(\boldsymbol{\lambda}) - G(\boldsymbol{\lambda}) \\
&= -\log \prod_{j=1}^{m} p_{\boldsymbol{\lambda}}(z_j|y_j) + \sum_{i=1}^{n} \frac{\lambda_i^2}{2\sigma_i^2} \\
&= -\sum_{j=1}^{m} \log \frac{\sum_{X(y_j,z_j)} e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)}}{\sum_{X(y_j)} e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)}} + \sum_{i=1}^{n} \frac{\lambda_i^2}{2\sigma_i^2} \\
&= -\sum_{j=1}^{m} \log \sum_{X(y_j,z_j)} e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)} \\
&\quad + \sum_{j=1}^{m} \log \sum_{X(y_j)} e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)} + \sum_{i=1}^{n} \frac{\lambda_i^2}{2\sigma_i^2}.
\end{aligned}
$$

Intuitively, the goal of estimation is to find model parameters which make the two expectations in the last equation equal, i.e. which adjust the model parameters to put all the weight on the parses consistent with the partial annotation, modulo a penalty term from the Gaussian prior for too large or too small weights.

Since a closed form solution for such parameters is not available, numerical optimization methods have to be used. In our experiments, we adapted a conjugate gradient routine to our task (see Press (1992)), yielding a fast converging optimization algorithm where at each iteration the negative log-likelihood $P(\boldsymbol{\lambda})$ and the gradient vector have to be evaluated.[2]. For our task the gradient takes the form:

$$
\nabla P(\boldsymbol{\lambda}) = \left\langle \frac{\partial P(\boldsymbol{\lambda})}{\partial \lambda_1}, \frac{\partial P(\boldsymbol{\lambda})}{\partial \lambda_2}, \ldots, \frac{\partial P(\boldsymbol{\lambda})}{\partial \lambda_n} \right\rangle, \text{ and}
$$

$$
\begin{aligned}
\frac{\partial P(\boldsymbol{\lambda})}{\partial \lambda_i} &= -\sum_{j=1}^{m} \Big(\sum_{x \in X(y_j,z_j)} \frac{e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)} f_i(x)}{\sum_{x \in X(y_j,z_j)} e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)}} \\
&\quad - \sum_{x \in X(y_j)} \frac{e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)} f_i(x)}{\sum_{x \in X(y_j)} e^{\boldsymbol{\lambda}\cdot\boldsymbol{f}(x)}} \Big) + \frac{\lambda_i}{\sigma_i^2}.
\end{aligned}
$$

The derivatives in the gradient vector intuitively are again just a difference of two expectations

$$
-\sum_{j=1}^{m} p_{\boldsymbol{\lambda}}[f_i|y_j, z_j] + \sum_{j=1}^{m} p_{\boldsymbol{\lambda}}[f_i|y_j] + \frac{\lambda_i}{\sigma_i^2}.
$$

Note also that this expression shares many common terms with the likelihood function, suggesting an efficient implementation of the optimization routine.

4. Experimental Evaluation

Training: The basic training data for our experiments are sections 02-21 of the WSJ treebank. As a first step, all sections were parsed, and the packed parse forests unpacked and stored. For discriminative estimation, this data set was restricted to sentences which receive a full parse (in contrast to a FRAGMENT or SKIMMED parse) for both its partially labeled and its unlabeled variant. Furthermore, only sentences which received at most 1,000 parses were

[1] An earlier approach using partially labeled data for estimating stochastics parsers is Pereira and Schabes (1992) work on training PCFG from partially bracketed data. Their approach differs from the one we use here in that Pereira and Schabes take an EM-based approach maximizing the joint likelihood of the parses and strings of their training data, while we maximize the conditional likelihood of the sets of parses given the corresponding strings in a discriminative estimation setting.

[2] An alternative numerical method would be a combination of iterative scaling techniques with a conditional EM algorithm (Jebara and Pentland, 1998) However, it has been shown experimentally that conjugate gradient techniques can outperform iterative scaling techniques by far in running time (Minka, 2001).

taken under consideration. From this set, sentences from which a discriminative learner cannot possibly take advantage, i.e. sentences where the set of parses assigned to the partially labeled string was not a proper subset of the parses assigned the unlabeled string, were removed. These successive selection steps resulted in a final training set consisting of 10,000 sentence each with parses for partially labeled and unlabeled versions. Altogether there were 150,000 parses for partially labeled input and 500,000 for unlabeled input.

For estimation, a simple property selection procedure was applied to the full set of around 1000 properties. This procedure is based on a frequency cutoff on instantiations of properties for the parses in the labeled training set. The result of this procedure is a reduction of the property vector to about half of its size. Furthermore, a held-out data set was created from section 24 of the WSJ treebank for experimental selection of the variance parameter of the prior distribution. This set consists of 150 sentences which received only full parses, out of which the most plausible one was selected by manual inspection.

Testing: Two different sets of test data were used: (i) 700 sentences randomly extracted from section 23 of the WSJ treebank and given gold-standard f-structure annotations according to our LFG scheme, and (ii) 500 sentences from the Brown corpus given gold standard annotations by Carroll et al. (1999) according to their dependency relations (DR) scheme[3]. Both the LFG and DR annotation schemes are discussed in more detail below, as is a mapping from LFG f-structures to DR annotations.

Gold standard annotation of the WSJ test set was bootstrapped by parsing the test sentences using the LFG grammar and also checking for consistency with the Penn Treebank annotation. Starting from the (sometimes fragmentary) parser analyses and the Treebank annotations, gold standard parses were created by manual corrections and extensions of the LFG parses. Manual corrections were necessary in about half of the cases.

Performance on the LFG-annotated WSJ test set was measured using both the LFG and DR metrics, thanks to the LFG-to-DR annotation mapping. Performance on the DR-annotated Brown test set was only measured using the DR metric, owing to the absence of an inverse map from DR to LFG annotations.

Results: In our evaluation we report F-measures for the respective types of annotation, LFG or DR, and for three types of parse selection, (i) *lower bound*: random choice of a parse from the set of analyses, (ii) *upper bound*: selection of the parse with the best F-measure according to the annotation scheme used, and (iii) *stochastic*: the parse selected by the stochastic disambiguator. The *error reduction* row lists the reduction in error rate relative to the upper and lower bounds obtained by the stochastic disambiguation model. F-measures is defined as $2 \times precision \times recall/(precision + recall)$.

[3]Both corpora are available online. The WSJ f-structure bank at `www.parc.com/istl/groups/nltt/fsbank/`, and Carroll et al.'s corpus at `www.cogs.susx.ac.uk/lab/nlp/carroll/greval.html`.

Table 1 gives results for 700 examples randomly selected from section 23 of the WSJ treebank, using both LFG and DR measures. The effect of the quality of the parses on disambiguation performance can be illustrated by breaking down the F-measures according to whether the parser yields full parses or FRAGMENT or SKIMMED parses or both for the test sentences. The percentages of test examples which belong to the respective classes of quality are listed in the first row of Table 2. F-measures broken down according to classes of parse quality are recorded in the following rows. The first column shows F-measures for all parses in the test set, as in Table 1, the second column shows best F-measures when restricting attention to examples which receive only full parses. The third column reports F-measurs for examples which receive only non-full parses, i.e., FRAGMENT or SKIMMED parses or SKIMMED FRAGMENT parses. Columns 4–6 break down non-full parses according to examples which receive only FRAGMENT, only SKIMMED, or only SKIMMED FRAGMENT parses. Since most results on predicate-argument matching have been reported for length-restricted test sets (20–30 words), we also provide for comparison results for a subset of 500 sentences in our sample which had less than 25 words. These results are reported in Table 3.

Table 1: Disambiguation results for 700 examples randomly selected from section 23 of the WSJ treebank using LFG and DR measures.

	LFG	DR
upper bound	84.7	80.7
stochastic	78.7	72.9
lower bound	75.0	68.8
error reduction	38	35

	LFG	DR
upper bound	88.0	85.4
stochastic	82.8	77.5
lower bound	78.0	72.6
error reduction	42	38

Results of the evaluation on Carroll et al.'s Brown test set are given in Tables 4 and 5. Table 4 presents an analysis of evaluation results according to parse-quality for the DR measure applied to the Brown corpus test set. In Table 5 we show the DR measure along with an evaluation measure which facilitates a direct comparison of our results to those of Carroll et al. (1999). Following Carroll et al. (1999) we count a depedency relation as correct if the gold standard has a relation with the same governor and dependent but perhaps with a different relation-type. This dependency-only (DO) measure thus does not reflect mismatches be-

error reduction	33	34

5. Comparison of Evaluation Metrics

Tables 1 and 3 point to systematically lower F-scores under the DR measure than under the LFG measure, though both indicate similar reductions in error rate due to stochastic disambiguation.

5.1. LFG Evaluation Metric

The LFG evaluation metric is based on the comparison of 'preds-only' f-structures. A preds-only f-structure is a subset of a full f-structure that strips out grammatical attributes (e.g. tense, case, number) that are not directly relevant to predicate-argument structure. More precisely, a preds-only f-structure removes all paths through the f-structure that do not end in a PRED attribute. Figures 1 and 2 illustrate the difference between the full and preds-only f-structures for one parse of the sentence *Meridian will pay a premium of $30.5 million to assume a deposit of $2 billion.* As this example shows, the preds-only f-structure lacks some semantically important information present in the full f-structure, e.g. the marking of future tense, the marking of a purpose clause, and the attribute showing that *a deposit* is an indefinite.

Figure 2 also shows the set of individual feature specifications that define the preds-only f-structure. The first property indicates that the f-structure denoted by `n0` has the semantic form `sf(pay,i15,[n5,n3],[])` as the value of its PRED attribute. `pay` is the predicate, `i15` is a lexical id, `[n5,n3]` a list of f-structure nodes serving as thematic arguments, and `[]` an (empty) list of non-thematic arguments. The grammatical roles associated with thematic and non-thematic arguments are identified by the corresponding `subj`, `obj`, etc., predicates. In this experiment, we measured precision and recall by matching at the granularity of these individual features.

The matching algorithm attempts to find the maximum number of features that can be matched between two structures. It proceeds in a stratified manner, first maximizing the matches between attributes like `pred`, `adjunct` and `in_set`, and then maximizing the matches of any remaining attributes.

5.2. Comparison with DR Metric

As a brief review (see Carroll et al. (1999) for more detail), the DR annotation for our example sentence (obtained via the mapping described below) is

(aux _ pay will)	(subj pay Meridian _)
(detmod _ premium a)	(mod _ million 30.5)
(mod _ $ million)	(mod of premium $)
(dobj pay premium _)	(mod _ billion 2)
(mod _ $ billion)	(mod in $ deposit)
(dobj assume $ _)	(mod to pay assume)

Some obvious points of comparison with the f-structure features are: (i) The DR annotation encodes some information, e.g. the 'detmod' relation, that is not encoded in preds-only f-structures (though it is encoded in full f-structures). (ii) Different occurrences of the same word (e.g. "$") are distinguished via different lexical ids in the LFG representation but not in the DR annotations so that correctly matching DR relations can be problematic. (iii) The DR annotation has 12 relations instead of the 34 feature-specifications. This is because a given predicate-argument relation in the f-structure is broken down into several different feature-specifications. For example, the DR 'mod' relation involves an f-structure path through an ADJUNCT, IN_SET and two PRED attributes; the DR 'subj' relation is a combination of an f-structure PRED and SUBJ attribute. Thus the LFG metric is more sensitive to fine-grained aspects of predicate-

Figure 2: Preds-only f-structure: graphical & clausal representation as produced by XLE

argument relations. However, it imposes a greater penalty than DR on a modifier that is misattached to something that does not have any other modifiers. The LFG measure counts both an extra ADJUNCT feature and an extra IN_SET feature as mismatches, whereas DR only counts a single mismatched MOD. Conversely, LFG gives more credit for getting the singleton attachments correct. Similarly for argument structure. The LFG metric penalizes getting arguments wrong, counting both a PRED and a grammatical relation mismatch, but conversely gives more credit if the argument structure is exactly right.

5.3. Mapping F-structures to DR Annotations

The DR evaluation metric matches the dependency relations provided by the Carroll et al. gold standard with relations determined from information contained in the LFG representations. This enables us to measure the accuracy of our system with a separately defined predicate-argument-oriented standard and to compare our results to other systems that may use the same metric (at this point, perhaps only the Carroll et al. grammar/parser). The DR metric also enables a cross-validation assessment of the LFG-derived predicate-argument measure.

Carroll and Briscoe provide conveniently downloadable files containing the raw input sentences and the corresponding sets of gold standard dependency relations. We assumed it would be relatively straightforward to run the sentences through our system and extract dependency relations that could be compared to the gold standard. But for reasons that ranged from the ridiculous to the sublime, this turned out to be a surprisingly difficult task. One of the lessons learned from this experiment is that even at the level of abstract dependencies it is still very hard to create a standard that does not incorporate unintended framework-specific idiosyncracies.

One set of problems arose from the way the sentences are recorded in the input file. The 'raw' sentences are not formed as they would appear in natural text. They are pro-

vided instead as pre-tokenized strings, with punctuation split off by spaces from surrounding words. Thus commas and periods stand as separate tokens and *I'm* and *clients' guilt* show up as *I 'm* and *clients ' guilt*. This preprocessed format may be helpful for parsing systems that embody this particular set of tokenizing conventions or that learn (a la tree bank grammars) from the data at hand. But our system includes a hand-written finite-state tokenizer that is tightly integrated with our grammar and lexicon, and it is designed to operate on text that conforms to normal typographical conventions. It provides less accurate guesses when text is ill-formed in this way, for example, introducing an ambiguity as to whether the quote in *clients ' guilt* is attached as a genitive marker to the left or as an open quote to the right. Another peculiar and troublesome feature of the raw text is that some non-linguistic elements such as chemical formulas are replaced by the meta-symbol <*formul*>; our tokenizer splits this up at the angle brackets and tries to guess a meaning for the word *formul* surrounded by brackets. Faced with these low-level peculiarities, our first step in the evaluation was to edit the raw text as best we could back into normal English.

The gold standard file presented another set of relatively low-level incompatibilities that resulted in spurious mismatches that were somewhat harder to deal with. First, the input sentences conform to American spelling conventions but the head-words in the gold standard relations use British spelling (*neighbor* is coded as *neighbour*). Second, in the gold standard the head-words are converted to their citation forms (e.g. "*walking*" in the text appears as *walk* in the relations). Generally these match the head-words that are easily read from the LFG f-structures, but there are many discrepancies that had to be tracked down. For example, our f-structures do not convert *should* to *shall*, as the gold standard does, whereas we do convert *himself* to *he* (with a reflexive feature) while the gold standard leaves it as *himself*. We ended up creating by trial-and-error a coercion table for this test set so that we could properly match different manifestations of the same head.

The experiment revealed some higher-level conceptual issues. In LFG it is the f-structure rather than the c-structure that most closely encodes the properties on which a non-tree, dependency-oriented evaluation should be based. So we defined our task to be the construction of a routine for reading dependencies from the f-structure alone. It turns out, however, that the Carroll et al. dependencies encode a mixture of superficial phrase-structure properties in addition to underlying dependencies, and it proved a challenge to recreate all the information relevant to a match from the f-structure alone. For example, our f-structures do not represent the categories (NP, S) of the phrases that correspond to the functions, but the gold standard dependencies make tree-based distinctions between non-clausal (e.g. NP) subjects, clausal (e.g. sentential) subjects, and open-complement (VP) subjects. We avoided this kind of discrepancy by neutralizing these distinctions in the gold standard prior to making any comparisons. As another example, our English grammar decodes English auxiliary sequences into features such as PERFECT, PROGRESSIVE, and PASSIVE while the gold standard provides a set of AUX relations that represent the left-to-right order in which *have* and *be* appeared in the original sentence. To obtain the intuitively correct matches, our mapping routine in effect had to simulate a small part of an English generator that decodes our features into their typical left-to-right ordering. In at least one case we simply gave up—it was too hard to figure out under which conditions there might have been do-support in the original string; instead, we removed the few aux-do relations from the gold standard before comparing.

There were a number of situations where it was difficult to determine exactly the gold standard coding conventions either from the documentation or from the examples in the gold standard file. Some of the confusions were resolved by personal communication with Carroll and Briscoe, leading in some cases to the correction of errors in the standard or to the clarification of principles. We discovered for some phenomena that there were simple differences of opinion of how a relation should be annotated. The corpus contains many parentheticals, for example, whose proper attachment is generally determined by extrasyntactic, discourse-level considerations. The default in the LFG grammar is to associate parentheticals at the clause-level whereas the Carroll-Briscoe gold standard tends to associate them with the constituent immediately to the left—a constituent that we cannot identify from the f-structure alone. As other examples, there are still some mysteries about whether and how unexpressed subjects of open-complements are to be encoded and whether and how the head of a relative clause appears in a within-clause dependency.

With considerable effort we solved most but not all of these cross-representation mapping problems, as attested by the relatively high F-scores we have reported. Our current results probably understate to a certain extent our true degree of matching, but the relative differences between sentences using the DR measure are quite informative. A low F-score is an accurate indication that we did not obtain the correct parse. For F-scores above 90 but below 100 it is often the case that we found exactly the right parse but our mapping routine could not produce all the proper relations.

6. Discussion

The general conclusion to draw from our results is that the two metrics, LFG and DR, show broadly similar behavior, for the upper bounds, for the lower bounds, and for the reduction in error relative to the upper bound brought about by the stochastic model. The correlation between the upper bound F-scores for the LFG and DR measures on the WSJ test set is .89. The lower reduction in error rate relative to the upper bound for DR evaluation on the Brown corpus can be attributed to a corpus effect that has also been observed by Gildea (2001) for training and testing PCFGs on the WSJ and Brown corpora.[4] Breaking down evaluation results according to parse quality shows that irrespective of evaluation measure and corpus around 5% overall per-

[4]Gildea reports a decrease from 86.1%/86.6% recall/precision on labeled bracketing to 80.3%/81% when going from training and testing on the WSJ to training on the WSJ and testing on the Brown corpus.

formance is lost due to non-full parses, i.e. FRAGMENT or SKIMMED parses or both.

While disambiguation performance of around 79% F-score on WSJ data seems promising, from one perspective it only offers a 4% absolute improvement over a lower bound random baseline. We think that the high lower bound measure highlights an important aspect of symbolic constraint-based grammars (in contrast to treebank grammars): the symbolic grammar already significantly restricts/disambiguates the range of possible analyses, giving the disambiguator a much narrower window in which to operate. As such, it is more appropriate to assess the disambiguator in terms of reduction in error rate (38% relative to the upper bound) than in terms of absolute F-score. Both the DR and LFG annotations broadly agree in their measure of error reduction.

Due to the lack of standard evaluation measures and gold standards for predicate-argument matching, a comparison of our results to other stochastic parsing systems is difficult at the moment. To our knowledge so far the only direct point of comparison is the parser of Carroll et al. (1999) which is also evaluated on Carroll et al.'s test corpus. They report an F-measure of 75.1% for a DO evaluation that ignores predicate labels but counts dependencies only. Under this measure, our system of parser and stochastic disambiguator achieves 75.8% F-measure. A further point of comparison is the parsing system presented by Bouma et al. (2000). They report comparable relations on lower bounds and upper bounds for their constraint-based parsing systems. On test corpora of a few hundred sentences of up to 20 words an upper bound of 83.7% F-score and a lower bound of 59% is reported; the best disambiguation models achieves 75% F-score.
