Abstract

We report on a data model developed for the representation of lexical knowledge for the Duden ontology. The model is the result of a cooperation between the publishing house Duden and the software company *intelligent views*. Our general aim is to create an asset pool in which all the information present in the Duden dictionaries is integrated in order to support reusability for different print and electronic products, provide solutions for language technology applications as well as support the efficient maintenance of the Duden dictionary data.

1. Introduction

In this paper we describe the data model developed for the representation of lexical knowledge for the Duden ontology. Duden is a well-known publisher of language reference products in both print and electronic form as well as products for language technology for the German language. It belongs to the publishing house Bibliographisches Institut und F.A. Brockhaus AG (BIFAB). The model described here is the result of a cooperation project between Duden and the software company *intelligent views*, which is a spin-off company of the Fraunhofer Integrated Publication and Information Systems Institute (IPSI).

Our general aim is to create a rich computational resource in which all the information present in the Duden dictionaries is integrated in order to support

- the reusability for both print and electronic products,
- the development of language technology applications as well as
- the efficient maintenance of the Duden dictionary data, for example the ten volume Duden dictionary (Duden, 1999) or the Duden spelling dictionary (Duden, 2000).

Two further considerations have been important in developing this model:

- it should be flexible enough to adjust to new emerging requirements with regards to both the dictionary structure itself as well as the production of different titles and different types of dictionaries, and
- it should at a later stage allow the representation of encyclopedic information.

Note that a significant requirement has been that the Duden print dictionaries can be produced from the constructed computational resource at least as efficiently as is currently the case.

Furthermore, an important prerequisite has influenced the modeling of the data a great deal: the computational resource to be created should not only be useful for the production of print and electronic (both on- and off-line) dictionaries. It should also be useful for solving problems such as lexical and semantic ambiguity and reference resolution for knowledge intensive and real natural language applications such as, for example, a question answering system for German, for which broad-coverage of the morphological, grammatical and semantic information of the language is necessary.

1.1. Motivation

Although the majority of the Duden dictionary data are in SGML format, the markup of each dictionary is strongly print oriented rather than content oriented. For each of the SGML-based dictionaries there is a Document Type Definition (DTD) according to which the lexicographers maintain their data. Corrections or other modifications of existing lemmas and their properties as well as addition of new lemmas take place separately for each Duden title. This means that if, for example, a lexicographer modifies a lemma for the Duden dictionary *Duden – Fremdwörterbuch* (Duden, 2001a), the reference volume for the correct spelling of foreign words in German, each entry for the modified lemma in other Duden dictionaries, e.g. the Duden spelling dicitionary (2000) or Duden (2001b), has to be modified or updated manually. This is not only inefficient with regard to time but it is also prone to errors and inconsistencies. In contrast, the formal explicit representation of the Duden dictionary entries in a single knowledge base supports the administration and maintenance of dictionary data in an efficient, consistent and systematic manner.

[*] Since April 2002 at SFS, Universität Tübingen, Germany.

A further aspect concerns the additional possibilities offered by an explicit representation of all information relevant to each dictionary entry of the Duden data: depending on the quality of the data model it will be possible to generate different 'sub-lexicons' from a single data pool. These are, in principle, nothing more than different 'views' of the knowledge stored in the data pool. Examples of such sub-lexicons may be a list of all compounds in the Duden dictionaries, or a differentiated system of lexemes with their morphological (e.g. part of speech, gender), grammatical (e.g. subcategorization) and semantic (e.g. synonyms) information.

1.2. Related work

The work described in this paper relates to research on knowledge representation for lexical and semantic as well as for ontological information for the purposes of dictionary production and for natural language applications. It has to be emphasized, though, that it is our particular needs as publisher, our abilities and the tools supporting our work which guide the reported work in the first instance and not theoretical considerations. For this reason our main focus is not to construct *the* most expressive model for the representation of lexical and semantic representation but rather the construction of a large scale resource to be used for the efficient production of our dictionaries and for NLP applications.

Unlike Wordnet (Fellbaum, 1998), EuroWordNet (Vossen, 1998) and GermaNet (Hamp & Heldweg, 1997; Kunze, 2000) the Duden Ontology integrates extensive morphosyntactic properties of denotations with ontological information about their senses (see section 2). With regard to morphosyntactic information, this is represented in an extensive manner in the Duden Ontology, whereas WordNet and WordNet-like systems use elementary part-of-speech information and sub-categorization frames.

In contrast to the project WiW - Wissen über Wörter (Müller-Landmann, 2000; 2001), instead of a relational model we have opted for an object-oriented approach, which is advantageous for factorizing common information and supports inheritance of relations and attributes. A further point which distinguishes our work from the WiW-project is that we make use of the existing dictionary assets of Duden and therefore do not start from scratch. This allows us to build a comprehensive resource within a relatively short time and even more importantly to evaluate the expressiveness and suitability of the implemented model for our needs.

There are similarities between our approach and that of the Mikrokosmos project (Mahesh & Nirenburg, 1995): We too make a clear distinction between the representation of language-specific and language-neutral information. In our terminology language specific information is represented by *term* objects, whereas *concept* objects are used for representing language-neutral information (see section 2.1). One of the differences between the two projects is that the Duden Ontology integrates both kinds of information within a single resource, whereas the Mikrokosmos project uses two apparently separate databases, one for the lexicon and one for the ontology, for storing denotations and denotation-neutral concepts.

There are parallels of our work with the TransLexis conceptual schema (Bläser, 1995) with the distinction between lemma, homograph and sense. TransLexis is based on a relational model and has been driven by requirements for multilingual terminology management.

Currently, the Duden Ontology does not include an automatic classifier for classifying defined concepts on the basis of formal concept definitions, as for example the GALEN ontology and its related technology does (Rogers et al., 2001, Rector et al. 1998). With the exception of simple inference mechanisms, such as inheritance or relation path definition, the Duden Ontology does not feature a full-fledged inference engine.

2. Data model for the Duden Ontology

The Duden data model is based on a concept-oriented representation which offers the possibility of defining semantic relations between the concepts. In addition, it provides the hook for an integration of encyclopaedic data as well as for the representation of factual knowledge at a later phase.

To this end, the vocabulary of the Duden volumes is classified in a rigid manner according to a generic hierarchy relation. This is similar to WordNet where the synsets play the role of the concepts. In order to provide the hook for representing facts an explicit distinction between individuals and concepts (word senses) is necessary, which results in the creation of an ontology. According to our definition there are two essential features of an ontology:

- a classification of concepts according to a rigid generic hierarchy relation (SUBCONCEPT_OF relation) and
- the distinction between individuals and concepts, whereby an individual is related to a concept by means of an INSTANCE_OF relation.

Individuals in our data model are representations of concrete persons, geographical places, organizations, institutions, events etc. For example, 'Immanuel Kant', 'EU', 'Gran Canaria', 'Olympic Games 2004 in Athens' are all denotations of individuals.

2.1. Lemma-Term-Concept: roles of words in the language game

An ontology offers a formal method to structure sets of individuals with a set of individuals being an extension of a concept. Concepts are related to other concepts by means of a rigid hierarchy relation. This supports the factorizing of common information (see section 2.2.1) to more abstract levels.

Our idea is to represent the words of a language formally as *individuals*, called *lemmas* within our model. We consider morphosyntactic and word usage classes, e.g. information about the part-of-speech class of a word, its subcategorization frame, pragmatic usage, etc., formally as *concepts* and use them to group and classify the lemmas. This results in a further ontology, a kind of 'morphosyntactic ontology' about the 'world of words', which may be considered as a kind of further dimension of the first ontology described above, representing word senses and real world objects.

We bridge the two ontologies by using a denotation relation for connecting lemmas to one or more senses.

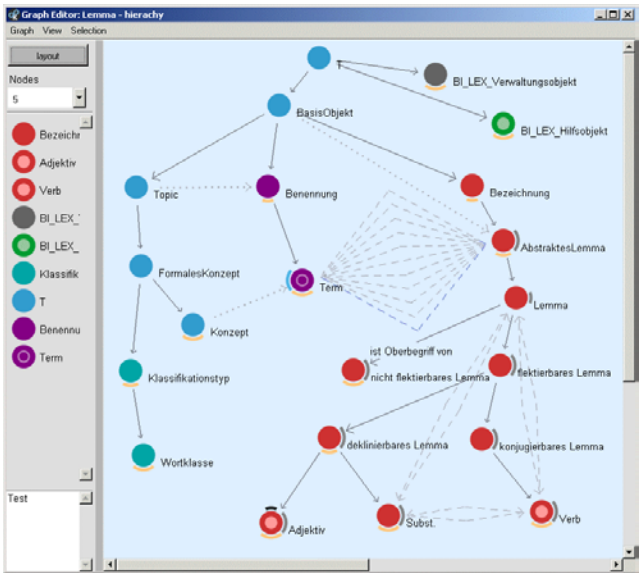

Figure 1: Top level of the Duden Ontology

Each sense of a lemma can be considered a role that this lemma plays in the language game, whereby each role played is represented by a single object, which we call *term*. In general, a lemma has more than one sense and thus a single lemma has more than one term assigned to it. Each sense of a lemma is represented by a single concept object.

On the other hand, a concept can be related to more than one term and thus to more than one lemma. This establishes the synonymy relation: Two lemmas are synonyms, if one of their corresponding terms points to the same concept.

We illustrate this in Figure 1: the top level concepts of the Duden Ontology are shown with the concept "Topic" being the root of the first ontology and "Bezeichnung" (denotation) being the root for the morphosyntactic ontology. The gap between the lemmas and concepts is bridged by means of a specific object class, i.e. "Term". All common information to all three object types is factorized at the "BasisObjekt".

2.2. Granularity gains

2.2.1. Factorizing of common information

One of our goals is to support the lexicographer in avoiding redundancy as this is one of the most important means for efficient maintenance, data consistency and multiple usage of the data. The means to avoid redundancy is the factorizing of common information: all information common to all objects should be stored in some more general object; when more general information is needed by the more specific object, this can be inherited (during runtime) from the more abstract one. Note that redundancy free storage does not hinder a redundant presentation of the data. The latter is not only useful for the lexicographer, but it is also advantageous for electronic products for which space restriction is not as rigid as in print products.

Obviously, it is not always possible to achieve a completely redundancy free data representation. Redundancy may, however, increase error-proneness in lexicography work. It has to be noted though that if redundant storage is required as a means for improving system performance, redundancy should be maintained by the system itself and be completely hidden from the user. The question of redundant storage is therefore "simply" a matter of the concrete implementation and not relevant to the model.

In our data model, the lemma is where the word-related information common to all its terms is factorized. A concept factorizes the meaning-related information common to all its synonymous lemmas. A term, though, may overwrite factorized information inherited by its corresponding lemma. In this way, we represent grammar and usage exceptions of particular lemmas, e.g. that a lemma in a particular sense may have no plural form.

2.2.2. Fine-grained relations

By representing terms as separate objects we gain granularity for the relations. In particular, we can link usage examples and citations for the dictionary entries to terms and not just to lemmas. By doing this, we disambiguate the meaning of the lemma in the usage example. Since we import data from the Duden dictionaries, the usage examples are already assigned to the particular meanings of a dictionary entry (for details see section 4.2.). With such information formally represented, one may get all usage examples of a concept simply by the union of all usage examples of all its terms.

In a similar manner, the representation of the decomposition of compound nouns on a term level and not only on a lemma level brings gains in granularity. This is advantageous when using such a resource for parsing or information retrieval tasks as the components of compounds are already disambiguated.

2.3. Concrete example

We explain the above model by means of an example from the Duden dictionary. The word "Bar" has three separate entries in the ten volume Duden dictionary (Duden, 1999):

[1]Bar, die; -, -s [engl. bar, urspr. = Schranke, die Gastraum u. Schankraum trennt < afrz. barre, Barre]: **1. a)** *intimes [Nacht]lokal, für das der erhöhte Schanktisch mit den dazugehörigen hohen Hockern charakteristisch ist:* eine B. besuchen, aufsuchen; in einer B. sitzen; **b)** *barähnliche Räumlichkeit in einem Hotel o. Ä.* **2.** *hoher Schanktisch mit Barhockern:* an der B. sitzen; Monsieur de Carrière lud mich ein, mich zu ihnen an die B. zu setzen (Ziegler, Labyrinth 258).

[2]Bar, das; -s, -s <aber: 3 Bar> [zu griech. báros = Schwere, Gewicht]: *Maßeinheit des [Luft]drucks;* Zeichen: bar (in der Met. nur: b).

[3]Bar, der; -[e]s, -e [H. u.]: *regelmäßig gebautes, mehrstrophiges Lied des Meistergesangs.*

There are three lemmas for "Bar" in the sense of (1) pub or bar, (2) measurement unit for (air) pressure and (3) a special form of song. The first entry, **[1]Bar,** has three senses (pub, hotel bar and counter) whereas **[2]Bar** and **[3]Bar** each have only one sense. Although all three lemmas are nouns, each lemma belongs to a different gender and declination class shown in the entry with the article and the genitive and plural form suffixes, e.g. "**[1]Bar**, die; -, -s" is feminine and forms the plural with a final 's'.

For each of the five senses there exists a separate term and a corresponding (separate) concept. Each sense definition, e.g. "*intimes [Nacht]lokal, ...*" for 1(a), is stored at the concept level. The usage examples and citations, e.g. „an der B. sitzen" (*English translation*: sitting at the bar) and „Monsieur de Carrière lud mich ein, mich zu ihnen an die B. zu setzen (Ziegler, Labyrinth 258)." (*English translation*: Monsieur de Carrière invited me, to join them at the bar (Ziegler, Labyrinth 258)), are connected to the term **[1]Bar (2)**.

Only the lemma, **[2]Bar** is synonymous to the lemma "**[2]bar**" as well as to the meteorological use of the sign "b". If we wish to extract all usage examples for say the concept "night bar" only those examples of the lemma "Bar" belonging to the term **[1]Bar (1a)** will be extracted. All other usage examples belong to terms, whose concepts are either hyponyms of the concept "night bar" or the concept "night bar" itself.

3. Tools and implementation

3.1. Ontology as a knowledge network

The data model is implemented with the *intelligent views* software system K-Infinity, which offers broad support for object-oriented knowledge modeling as well as for the creation, maintenance and use of a knowledge network. The software distinguishes between concepts and individuals and allows for the definition of relations and attributes both of which are inherited via the concept hierarchies.

The way we define ontology in our model fits well with the definition of a knowledge network in K-Infinity. The cornerstone of a knowledge network is a collection of concepts that structure information and allow the user to view it. The concepts are organized into hierarchies where each concept is related to its super- and subconcepts. This forms the basis for inheriting defined attributes and relations from more general to more specific concepts.

Concepts, individuals, attributes and relations are central to the construction of the knowledge network. A means for handling multiple inheritance are the so-called extensions or roles, the terms, which we use to represent the different senses of a lemma.

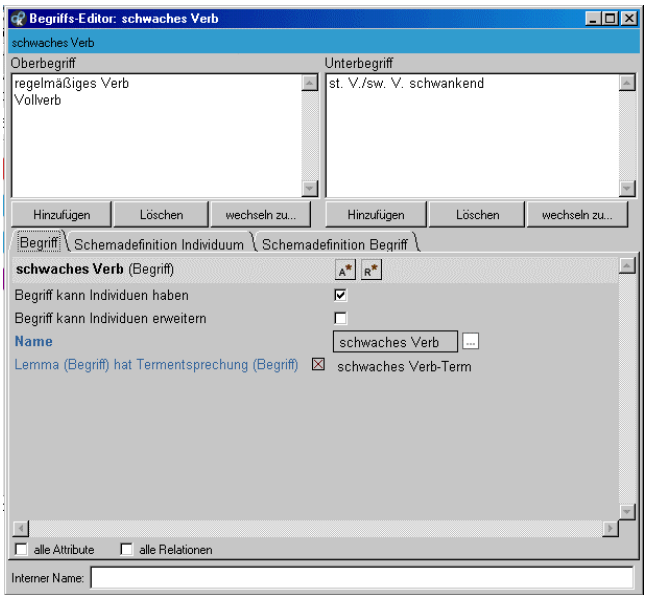

Figure 2: Concept Editor

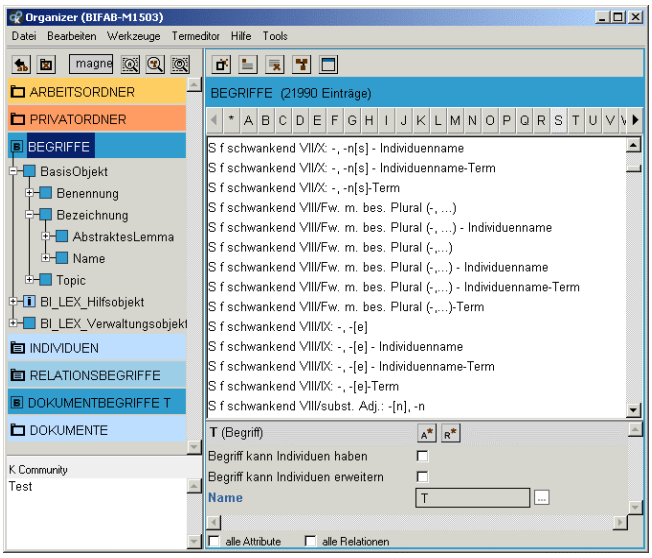

Figure 3: K-Organizer

3.2. K-Infinity Tools

The Knowledge Builder is K-Infinity's main component. It allows knowledge engineers and lexicographers to create, delete, rename and edit both objects and relations, as well as to relate objects to each other according to defined relations. This can be done in two different workspaces:

- The Graph Editor (shown in Figure 1) provides a graphical view of the network of objects and the relations between them. The network may be expanded according to the defined model. The Graph Editor supports the monitoring of the data by means of implemented consistency rules. One of the Editor's basic functions is an interactive network layout algorithm for the exploration of the knowledge network.
- The Concept Editor (see Figure 2) allows the user to focus on one object and its semantic links to neighboring objects. It is a supplement to the Graph Editor in that it allows the user to survey links and their attributes in detail, and to modify them if necessary.

Along with the tools for editing the knowledge network, there is the K-Organizer which supports administration, navigation, search and query formulation. The K-Organizer (Fig. 3) can be used to classify and group objects, either manually or by using existing object properties: for example, to organize all objects created before a certain date or all superconcepts with more than 10 subconcepts into a single folder.

Given the work context of the particular project, namely dictionary maintenance, an additional tool has been developed as a special extension for viewing and editing network objects from the perspective of a dictionary entry, called Term Editor. The Term Editor displays a lemma together with its associated terms and concepts in a single window in a comprehensive and compact way.

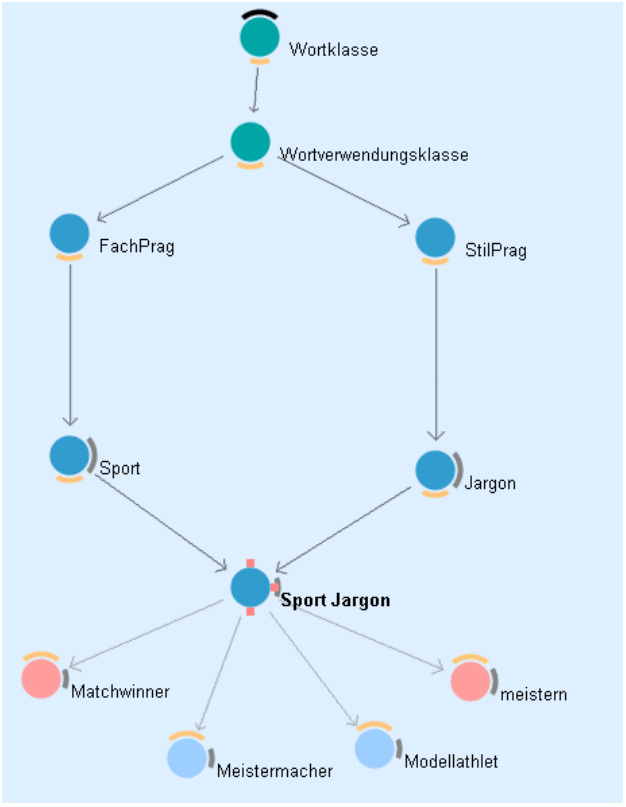

Figure 4: Example of pragmatic classes

3.3. Defined classes

There is a set of ca. 290 defined grammar classes, e.g. "noun which has a plural form", "masculine noun with declination type X", etc., ordered in a polyhierarchy. From these there are 160 classes which are assigned to lemmas; all the other classes are used to complement the poly-hierarchy as a means for flexible navigation and access.

Moreover, there are ca 1000 pragmatic classes, which are also ordered in a polyhierarchy, of which ca 250 are "basic pragmatic classes". The rest are combinations of pragmatic classes, such as for example, the class "Sport Jargon" shown in Fig. 4, which is a subclass of both "sport" and "jargon" classes. The class "jargon" is a subclass of "style" (StilPrag in Fig 4) whereas the super-class of "sport" is the pragmatic class "domain" (FachPrag). All in all there are at the moment over 200 relations defined in the model.

The defined grammar classes represent various aspects of the morphosyntactic nature of words. Starting from the general distinction of non-inflected and inflected word classes we divide the latter into conjugatable and declinable classes such as pronoun, article, adjective and noun and proceed to organize them extensively, which is necessary due to the rich morphology of German.

The noun hierarchy, shown in Figure 5, includes some abstract classes such as "noun by gender", "noun by type of declension", "noun with plural", "noun without plural", "noun derived from adjective", to classify the concrete noun classes such as the noun class the word "Aubergine" belongs to, namely, "feminine noun, declension type IX".

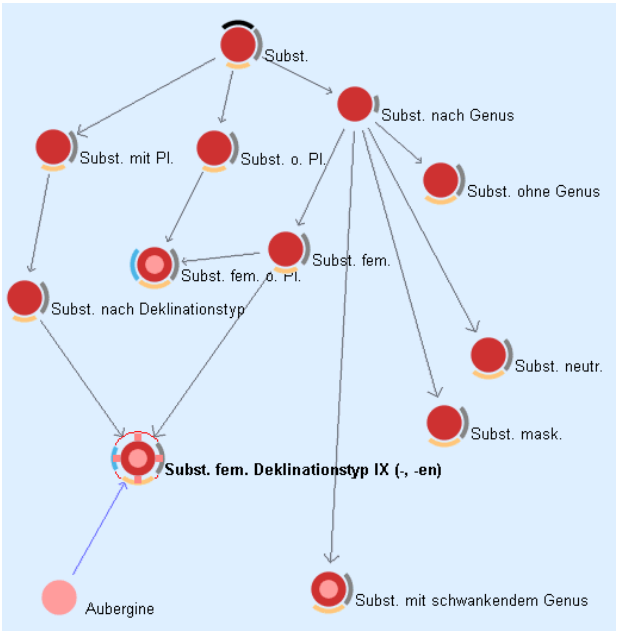

Figure 5: Example of noun classes

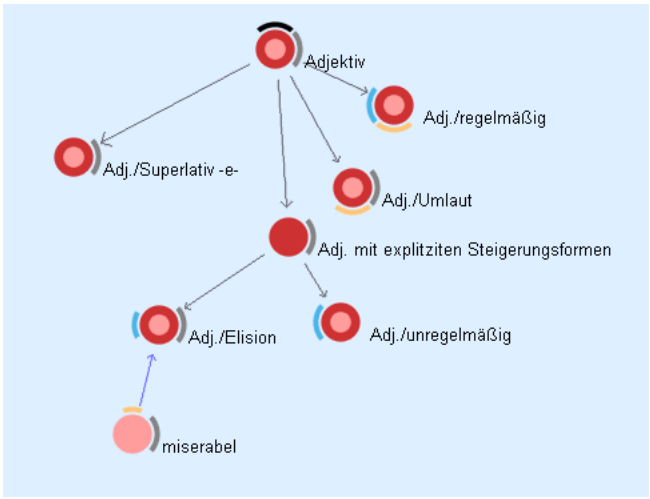

Figure 6: Example of adjective classes

As an additional example of the polyhierarchies consider the structure of the adjective classes (see Figure 6): In addition to the regular adjectives, we have defined subclasses for those with an explicit comparative form, with Umlaut and for those forming the superlative with "-e-". In the figure, the lemma "miserabel" is shown classified as an adjective belonging to the adjective subclass with an irregular comparative form, because of the elision of its -e-.

4. Import

To populate the Duden Ontology we first imported the data from the ten volume Duden dictionary (Duden, 1999), which contains ca. 200,000 lemmas, followed by the import of the entries of the Duden spelling dictionary (2000) with over 110,000 lemmas. Although there is a significant amount of overlap between the two dicitionaries, the former contains not only far more definitions than the latter, but also more grammatical,

etymological and pragmatic information. Importing and merging of further volumes are planned for the future.

The result of the complete import of the above data is a huge object network representing the information of over 200,000 entries from different dictionaries, whereby the entries themselves are decomposed into interlinked objects.

4.1. SGML dictionary data

As already mentioned, for each Duden dictionary, e.g. Duden (1999) or Duden (2000), there exists an SGML DTD. The basic structure of the dictionary articles is similar, however: Each dictionary article has a start and an end tag and each article element is divided into two parts, the head and the body. The head contains mainly information relevant to the lemma object of our data model and the body contains more detailed information concerning the senses of a lemma. The elements for phonetic, grammatical, etymological and pragmatic information are included in the head element. The body contains the substructure of the article and within this part there are elements containing definitions, examples, explanations, proverbs, idioms and idiomatic phrases. This straightforward structure is often interrupted by so called "meta-tags" which may appear anywhere within the above elements and contain some kind of text fragments. Naturally, this adds to the complexity of the import task.

There is, of course, no explicit tagging for terms and concepts, which is why a mapping from the existing mark up to the object types of our model is necessary. Because of the differences between the DTD(s) and our model it is not possible to write a simple context-free look-up table for mapping the DTD tags into the modeled object types. The content model of some elements is an iteration of a sequence of elements with optional parts, as shown in the example below for the element `defphr` (definition phrases):

```
<!ELEMENT defphr  - -
((ph?,gr?,prag?,(def|erk),erg?)?,bsp?,uew?,
rw?,spw?,iw?,(kurzf+  |  kurzw  |  abk+  |
zeich+)?)+ >
```

We map each iteration to a term, but since there is no explicit tag around this sequence of elements, the parsing process needs to exploit the contexts of the sequence in order to assign the information to the appropriate term.

4.2. Mapping

4.2.1. Creation of lemmas

Each dictionary entry is mapped to a lemma object. Typically, the homograph entries are indicated in the printed dictionary by a superscripted digit, which is also explicitly marked up as an attribute value in the article element. In this case we create different lemma objects with the same name, but with a different homograph-ID. The orthographic variants, e.g. "Photo" and "Foto", are marked up explicitly in the data. Separate lemma objects, which are related to the main lemma, are created for such variants.

Idioms and proverbs form specific lemma types which are automatically created during import.

4.2.2. Creation of terms and concepts

The different senses of an entry are structured in the dictionary by numbers or letters. We map each sense to a term and for each definition element we create an additional concept object. The usage and citation examples are assigned to the term object.

Grammatical or pragmatic information, which typically holds for the lemma, is modified in the sense description. Such modifications are stored in the corresponding term and overwrite the grammatical or pragmatic information inherited by the lemma.

The examples and definition phrases of the dictionary entries are often condensed for space reasons, e.g. the lemma appears in an abbreviated form. For instance, the entry for "Bar" in section 2.3 contains the phrase "an der B. sitzen" the complete form of which is "an der Bar sitzen". We expand such abbreviated forms during import and store the full form. Moreover – if necessary – we can generate the condensed form for export purposes.

4.2.3. Cross-references

During import we take care that no information necessary for the export of the data for the production of the dictionaries, such as the cross-references, is lost. The dictionary data contain explicit SGML elements for cross-referencing. We use the attribute values for the target article number and the subsection (the sense) in order to link the source and the target at the term level. We further check whether the subsection for the target lemma exists and whether the content of the cross-reference element can match the target lemma. In this way, we introduce an additional control for checking the correctness of cross-references, which is obviously advantageous for the quality of the constructed pool.

Due to the fact that the SGML data were originally created by an automatic conversion several thousands of the 80,000 cross-references solely refer to a subsection and have no reference to the article-ID. To resolve the missing cross-references we lemmatise the content of the cross reference elements and generate a list of target candidates, which is proofread by the lexicographers.

4.3. Enriching

Our aim is to populate the network with semantic relations, such as synonymy, hyperonymy, PART_OF or INSTANCE_OF relations. The SGML data contain no explicit mark up for such relations and a fully automated acquisition of semantic relations is not possible. We thus depend on maximal exploitation of our dictionary data in order to acquire semi-automatically semantic knowledge of this kind. For instance, the structure of the definition texts – which are stored at the concept level – is sometimes indicative for a synonymy relation holding between a given dictionary entry and its definition. As an example consider the dictionary entry "Yellow Press" in Duden (1999):

Yel||low Press ['jɛloʊ 'prɛs], die; - - (auch:) **Yel||low|press,** die; - [engl. yellow press, eigtl. = gelbe Presse] (Jargon): *Regenbogenpresse:* Längst ist die Witwe, von deren Auftritten einst die Y. P. profitierte, ruhiger geworden (FR 2. 1. 99, 9).

The word "Regenbogenpresse" (literary translation: "rainbow press") is marked up as definition text of the

term “Yellow Press”. We establish a synonymy relation between the two terms “Regenbogenpresse” and “Yellow Press” and their corresponding lemmas by assigning the same concept object to both terms.

We further plan to exploit the definition texts in combination with the cross-references to acquire hyperonymy and INSTANCE_OF relations.

A further method for extraction of hyperonyms is to automatically analyse compound words with the aim of extracting the heads of the compounds as these are in most cases the hyperonyms of the compounds.[1] For example, by analysing the compound “Volkstanz” (folk dance) we can infer that it is a hyponym of the word “Tanz” (dance).

For the representation of the morphological decomposition we define two relations and an attribute: *hat_Bestimmungswort* (has_modifier), *hat_Grundwort* (has_head) and the attribute *hat_Fuge* (has_join_morpheme). These relations are defined for both terms and lemmas. This is necessary since we cannot acquire all information we need in a single step. Rather we proceed iteratively to achieve a decomposition at the term level. In a first step all compound words of the dictionary are automatically morphologically analysed with the morphological analysis tool MPRO (Maas, 1996) to generate their components. As the decomposition of compounds is not always unambiguous, we disambiguate the analysis output by rejecting those compound analyses which have at least one component which is not a dictionary lemma. To illustrate this, there are two possible decompositions of the word “Medizinaldirektorin” (medical director) when automatically analysed:

medizinal – direktorin (medical – director)
medizin – aldi – rektorin (medicine – Aldi – rector)

The second analysis is nonsensical: Aldi is the name of a well-known German supermarket chain. The second analysis is thus rejected on the basis that there is no lemma for the the name Aldi. This strategy, however, does not always work, for example, consider the automatic analysis of the word “Marineuniform”:

marine – uniform (navy – uniform)
marine – uni – form (navy – university – form)

Again, the second decomposition is nonsensical, but in this case all three components are proper dictionary lemmas. The rule for selecting the correct decomposition is here a different one: the candidates for the right decomposition are those with the minimal number of components.

This way we fill in the lemma relations for the components of compounds[2]. If the lemmas which are components of a compound have only one sense, we have also achieved a decomposition at the term level. This is only possible, however, for a small number of compounds. Further investigation is required to determine a method to support the decomposition of compounds at the term level.

5. Conclusions and future work

In constructing the Duden Ontology our aim is not to build a general ontology of the world, but rather to create a computational resource which both supports efficient dictionary production and aids real world NLP applications. The creation of the Duden Ontology has been driven by our products and needs as well as by the abilities within the context of our work and the tools chosen.

This approach is guided by practical needs and has practical advantages for the lexicography work: by means of such an approach it is possible to maintain the dictionary data in a homogenous manner within a single data pool, something which was not previously possible for the Duden data.

With regard to the data model presented here, we believe that this kind of integrated model of semantic and grammatical information helps to avoid redundancy in storage and to maintain data without losing the ability to filter different sets of data and to generate various views of them with different granularity. The implementation of the data model is such that it allows modifications and further extensions, such as for example the definition of further semantic relations.

The next steps of our work concern the enrichment of the ontology with subcategorization information as well as with further semantic information. In particular, we plan to exploit the definition texts in combination with the cross-references to acquire hyperonymy and INSTANCE_OF relations.

For the future we plan to model further semantic relations to embed factual knowledge and encyclopedic information.

[1] Note that ca 50% of the dictionary entries are compounds, which is attributable to the productivity of compounding in German.

[2] It is interesting to add that compound analysis at the lemma level is also important to determine the grammatical class for the compound word. Due to space reasons the single grammatical information coded for compound words in e.g. the ten volume Duden dictionary (1999) is gender. Whereas this is not problematic for a user of a dictionary, for automatic processing the missing information about the grammatical class of the compound is necessary. The grammatical class of the compound is determined by the class of the compound head.

Abstract

In this paper we discuss the possible types of relationships between participant roles in related situation types. We first discuss principles that might determine which roles are present in one type of situation, given the roles present in a related type of situation. While no simple general rules seem to exist, there are useful rules for particular cases. In addition, we discuss how relationships between roles themselves parallel relations between other elements in ontologies. Apart from the subrole relation, we consider relations analogous to meronymy and antonymy, which are rare in the domain of roles, and a complementarity relation between roles, which is fairly common.

1. Introduction

How are participant roles in one type of situation related to the roles in another? What implications do the relations between roles in different situation types have for the relations between other elements of ontologies? We will focus here on two topics that bear on these issues. First, we discuss which principles might determine, given the set of roles appropriate for one situation type, which subset of those roles are appropriate for a second, related situation type. Second, we examine the extent to which relationships between roles parallel those we find between other kinds of elements in ontologies.

2. Goals and assumptions

The way we have described the two topics above presupposes certain characteristics of an ontology (or related resource such as WordNet). We first briefly present these assumptions here, and pose the more detailed questions that we will address in this paper.

2.1. Participant roles, situation types, and hierarchies

We view participant roles for present purposes as relations between an entity and a situation.[1] Thus we will often refer to the entity as a participant in the situation.[2]. We also assume that for each role there can be type restrictions on the kinds of entities and situations that are appropriate arguments for that role. A *perceiver* role, for instance, is restricted to sentient entities in perception situations. This in turn rests on the assumption that situations and entities can be grouped into types, a strategy that has proven fruitful as a central organizing principle in many ontologies (e.g., the Cyc ontology, the SENSUS ontology, Mikrokosmos, the ontology developed in Sowa (2000), and numerous more specialized ontologies). Here we assume that types of entities and situations are hierarchically arranged, with multiple inheritance permitted (multiple inheritance is pervasive in the Cyc ontology but rare in WordNet).[3]

2.2. Subroles

In part because roles have type restrictions on the entities and situations that can serve as their arguments, it is reasonable to talk of subroles. One advantage of structuring roles in this way is that we can provide for arbitrarily specific roles for situation types anywhere in the situation-type hierarchy, while maintaining very general roles, which prove useful, for example, in stating the linguistic regularities in linking from semantic roles to syntactic arguments of predicators. The type restrictions on a subrole's arguments must be at least as restrictive as those on its super-roles. In addition, it is natural to assume that a participant playing a role in a situation also plays all of its super-roles:

(1) $R \subset R'$ implies $\forall x,e$: $R(x,e) \rightarrow R'(x,e)$

This entails a homomorphism under subsumption from the hierarchy of situation types to the hierarchy of roles, and from the hierarchy of entity types to the hierarchy of roles. The reverse implication—that all roles R and R' for which the condition on the right hand side of (1) holds are in the subrole-/super-role relation—is less obvious. This is an issue we briefly touch on below.

2.3. Role projectability between situation types

In section 3, we examine the problem of role projectability; that is, what principles and structures in an ontology determine, given the set of roles appropriate for one situation type, the set of roles of a related situation type. For example, are there any general statements we can make about the roles in subsituations, given the roles

[1] We use the term *situation* to speak of events and states. An event type is merely a situation type whose instances are events.

[2] We will not delve into the question of whether the entity actually must exist, or if it does, must temporally and spatially overlap the situation.

[3] Examples from the Cyc ontology are from the OpenCyc release of April, 2002, which can be examined or downloaded at www.opencyc.org. Version 1.7 of WordNet can be obtained from www.cogsci.princeton.edu/~wn/.

in a situation? This is particularly important in cases where it is debatable whether to analyze one situation type as a subtype of another or the second as a subsituation of the first (for instance, is *eating a meal* a subtype of *eating*, or is it better analyzed as containing a subevent of eating, along with other subevents such as serving oneself, and if the latter is the preferred analysis, how do the roles of the eating subevent project to the roles of eating a meal?). Another set of cases involves groups of similar situations, such as a group of *walking* events, for which we might wish to project some roles but not others. Finally, we also consider the interaction of role projectability and multiple inheritance.

We can classify projectability issues along three dimensions, as shown in the following table:

	situations	**entities**
type-level	sub/super-types of situations	sub/super-types of entities
individual level	sub-situations/ super-situations	sub-entities/ super-entities

Thus we can examine, for example, whether roles appropriate for a particular type of situation are appropriate for any subtypes of it, or we can examine whether a role played by a particular entity in a situation is also a role played by entities of which it is a part. Type-level projection is concerned with generalization and specialization relations between types (or hypernymy and hyponomy relations in lexical resources like WordNet), while individual-level projection is concerned with mereological (or meronymic) relations between individual situations and entities. One straightforward case is that of roles projecting from situation types to their subtypes, which is entailed by (1). We will not examine all of the possible options for projecting roles here (some of them are highly implausible in any case), but the table helps to situate the issues we examine in sections 3 and 4.

2.4. Parallelism in relations between roles and relations in other elements of ontologies

Often independently of concerns about the relations between concepts, scholars in linguistics and philosophy have been concerned with determining and classifying the roles of participants in situations. When situations and entities are arranged in type hierarchies, it is natural to inquire whether participant roles can be similarly arranged (see, among others, Parker-Rhodes (1978), Ostler (1979), Somers (1987), Lehmann (1997), and Sowa (2000)). In addition to subtype-supertype relations, however, we also find other types of relationships frequently modeled in ontologies. This leads to our second objective, which is to compare the structures of the participant role hierarchy to the other two. To what extent does the role hierarchy parallel the others, and which relationships commonly posited among situation and object types are applicable to roles as well? This will be discussed in section 4.

3. Some cases of role projectability

In this section we consider three cases of role projectability between situations and subsituations. The first concerns the case of a situation that can be regarded as composed of a group of situations of some common type. We suggest that roles of the group situation can be systematically related to those in the subsituations; the latter are subroles of the former. We next examine a more general case motivated by Lehmann's (1998) discussion of situations and roles, in which multiple inheritance in the situation-type hierarchy is pervasive. We argue that freely allowing this kind of multiple inheritance creates complications for the role system and should probably be constrained more than Lehmann envisions, or recast as a form of embedding the parent situation types as subsituations in another type rather than as multiple inheritance. Finally, we note the case of related telic and atelic situation types, which seems to require projection of roles from situations to subsituations, rather than inheritance from situation types to subtypes.

3.1. Groups of events of a common type

One frequent case of situations and subsituations is that of a group of situations of a given types, treated as a group, which itself can be regarded as a situation. This kind of operation is frequently represented in ontologies; Cyc's *GroupFn* is one example.[4] What can we conclude about the roles in the group situation, given the roles in its elements? One possibility is that they are identical. But this seems problematic. Suppose that the role *R* is defined for the situation type of the group's elements, and that in the group event *g*, the participant playing *R* is the mereological sum of all the participants playing role *R* in each of the elements of *g*. We will write this as *R(y,g)*, where *y* is the sum of the individuals playing this role in each of the elements. This is simply a case of the *cumulativity* or *summativity* property of roles (Krifka, 1992, 1998). While for some roles this is a reasonable move, it vitiates the definition of others. It may not cause any difficulties, for example, to regard a group of children running around a playground as the collective *agent* in a group *running* event. However, the *path* role in such an event is a discontinuous set of trajectories, while for a single child running, and for motion of a single body in a continuous time interval generally, the trajectory is continuous. This property of paths is important to maintain; Krifka's (1998) analysis of telicity in motion event relies on it, for example. Another example concerns *source* and *goal* roles in groups of motion events. It is useful to have a rule that either the *source* and *goal* of a motion event are distinct locations, or that the *moving object* has not changed its position (if the motion is a complete revolution in a circle, for instance). But this rule will not apply to groups of motion events; two runners might exchange places, each ending up in the other's starting location. The *source* and *goal* would then be identical in the group event.

A more palatable alternative is to assume that for every role *R* such that *R(x,e)* for some *x* in each element *e* of *g*, there is a super-role of *R*, *R'*, such that *R'(g,y)*, where *g* and *y* are the mereological sums, as above. These super-roles can have some of the properties of the original roles but need not have all of them. For example, the super-role of the *path* role could have discontinuous trajectories as its

[2] This represents some kinds of group situations adequately, but not all. Situations involving joint action or intent, for example, are not always readily decomposed into subsituations of a closely related type.

value, and those of the *source* and *goal* roles would have weaker distinctness conditions. At the same time, nothing precludes using the original roles to describe a situation that can be regarded both as a group of subsituations and as a single situation of the same type as those subsituations; in this case the same participant (a group of entities) will play the role *R*, and hence *R'*. A potential drawback to this approach is that, if we adopt the definition of subrole in (1), we are then committed to treating the type of groups of situations of type *S* as a supertype of *S* (the two types could be identical in some cases, such as at the top of the situation-type hierarchy). However, we see no obvious problems with this move, although this condition is not typically found in ontologies.

3.2. Multiple inheritance and roles

When a situation type is a child of more than one parent type, there are two possible outcomes with regard to the roles in the parent types. One is that two roles from two parent types merge, so that a single participant in an instance of the child type plays both of these roles. From two parent situation types such as *eating in a restaurant* and *eating breakfast* we can construct a type inheriting from both, *eating breakfast in a restaurant*, in which the eater and eaten roles of both parent types are merged; that is, there is a single eater participant and a single eaten participant in a situation of *eating breakfast in a restaurant*. In this case, the roles in the child type must be subroles of the roles in the parent types. This is represented graphically in Figure 1.

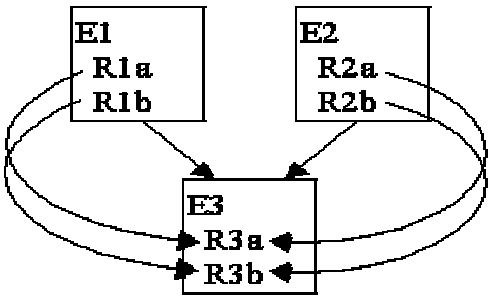

Figure 1. Merged roles in situation-type inheritance

A second possibility is that a role from one parent type does not merge with any other role, remaining distinct in the child type. In Cyc, for example, the type *CausingAnotherObjectsTranslationalMotion* is a subtype of *Movement-TranslationEvent*, which has the roles *objectMoving* and *trajectory*) and of *ActionOnObject*, with the roles *doneBy* and *objectActedOn*. The trajectory and *doneBy* roles remain distinct in the child type. As for the participant that is caused to move, it plays the roles of *objectActedOn* and *objectMoving* in an instance of *CausingAnotherObjectsTranslationalMotion*, but these two roles are not necessarily merged. There is no role reified within the Cyc system that inherits from these two roles. Instead, a rule states that the same participant plays both roles in situations of the type *CausingAnotherObjectsTranslationalMotion*. This second possibility is shown in Figure 2.

This has some implications for some of the ontological structures in Lehmann (1997). Lehmann exemplifies a situation-type hierarchy with increasingly complex types that inherit from multiple parents. For example, there are event types labeled "father gets harmed and angry child then gets revenge", a subtype of the situation types "father gets harmed" and "an angry child gets revenge".[5] Now if roles are inherited from types to their subtypes, this implies that the child type has all the roles of its two parent types. If this kind of type construction is fully productive in the situation-type hierarchy, however, it leads to the uncomfortable conclusion that roles always project from subevents to the events they are part of, since each conjunct can be considered a subevent. Consider the example of taking a trip in a car. We define event types of unlocking a car and driving a car in our hierarchy; the former type has a key as an instrument. Now we define the type of taking a trip in a car, inheriting from these two types of unlocking and then driving a car. By inheritance, this type also will have a key as an instrument, which is the undesirable situation we encountered above. This issue becomes particularly acute when there are two participants in the complex event type that are assigned the same role as a result of inheritance. Consider an event of taking dictation, where one person is reading aloud and another is copying down the words. The reader or writer in the parts of this event can both be considered agents, but we will certainly wish to distinguish these two roles in taking dictation. One solution here, of course, is to provide distinct, more specific roles, such as *reader* and *writer*. But this strategy is not always available; when two events of the same type are combined, the roles in the resulting type will be the same. As an example of this, picture a situation where two people compare versions of a text by having one read aloud and then the other, or a "call and response" situation where one person echoes another's words.

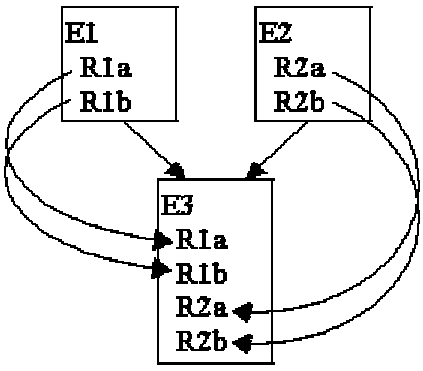

Figure 2. Distinct roles in situation-type inheritance

We could circumvent these problems in several ways. One is to postulate distinct roles for each situation type. Thus a key would play a role in the complex event type just mentioned, but it would not be the same role that it plays in the simpler subevent *unlocking a car*. This

[5] We disregard here the issue of how the temporal order of these two events in the subtype is specified. There must be some mechanism for doing so, however, since the reverse temporal order would describe a very different type of complex event.

allows us to be fully productive in creating complex situation types, at a cost of complicating our system of roles considerably. The number of roles is obviously indefinitely large, as the potential for creating successively more complex event types is unlimited, and there remains a problem of determining when two roles are necessarily filled by the same participant. For instance, a subtype of *unlocking a bicycle* is *unlocking a bicycle that is locked with a Kryptonite lock*. We can classify an instance of such an event in either fashion. This subtype has a distinct role for the key, but we want to equate the roles in the two event types, rather than worrying about whether there are two distinct keys. This representation, in which there are 4 roles, but only two participants, is shown in figure 3.

The large number of roles, and their uniqueness to individual situation types under this option, might become more palatable if we adopt a feature-based analysis of roles, along the lines of Somers (1987), Ostler (1979), Parker-Rhodes (1978), or Sowa (2000). From a linguistic standpoint, for instance, something like such features would be needed to account for regularities in the mapping from roles to syntactic arguments of verbs and nominalizations (see Dowty (1991) and Wechsler (1995) for similar accounts that can cast in a feature-based model). But in some sense we have merely shifted the problem from projectability of roles to projectability of features. If the features of a key as an instrument in unlocking a car are projected to its role in driving, why is it so odd to say that "we drove to the store with the key"?

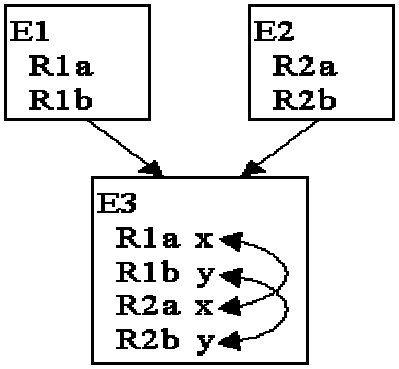

Figure 3. Distinct roles, shared by identical participants in subtype

Another option would be to structure the set of roles more richly, so that both sets of roles are inherited in a complex event, maintained as two separate structures (with additional roles potentially added as well). This option is in the spirit of feature structure representations, in which structures can be embedded recursively (Lehmann may allude to something similar when he refers to "structural specification"). A representation of this kind, in which the role-sets of the parent events are embedded within new role features in the child event, is shown in figure 4. The roles *R3a* and *R3b* within *E3* are filled by subevents; they might be relations such as *cause* and *effect*, for example. This allows roles to be inherited, albeit in a non-uniform way, which depends on how the parent situation types are combined in the child type. Furthermore, it is necessary to specify when a single participant fills roles in each part of the situation. In the type "father gets harmed and angry child then gets revenge on perpetrator", the same individual (the perpetrator) plays a role in both subevents.

Yet another approach would be to restrict the situation-type hierarchy to a set of types for which role inheritance makes sense. The trouble with this is that it seems too restrictive for many purposes. We sometimes do wish to refer to "composite" event types, like commuting to work on a bicycle, moving from one city to another, or holding a presidential election. But some kind of compromise position may be possible. We might maintain the kind of role inheritance that appears useful by designating one parent type as the "principal type", whose roles are inherited. For commuting by bicycle, the principal parent might be something like riding a bicycle, and the roles of the bicycle, the rider, the origin, and the destination would be inherited. Other, "minor" events involved in commuting, like locking and unlocking the bicycle, would not be involved in role inheritance. A subgraph of the hierarchy of situation types, filtered by "main event" or "principal type", links might be homomorphic to the role hierarchy. This approach seems reasonable for many of the situation types that we would be likely to reify in an ontology. It may apply less well to elaborate and complex events with many participants, such as political elections, which have many specialized roles, and would not necessarily inherit many of them from their parents representing their subevents. In some of these complex event types, the notion of a "main event" might not make much sense.

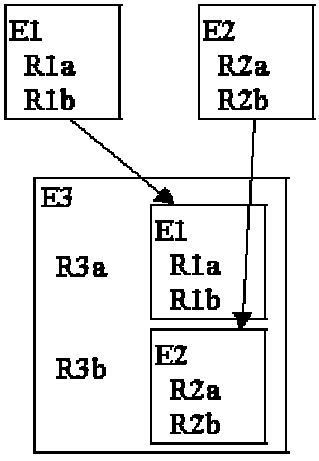

Figure 4. Embedded role-sets in subtype

From a linguistic standpoint, multiple inheritance in the situation-type hierarchy interacts with issues of linking; that is, the syntactic realization of predicates and their arguments. Subject selection is one good example; verbs denoting commercial transactions refer to situations in which there are two *agents*, as do causative verbs in the many languages that allow causativization of verbs denoting agentive situations. In each of these cases an accurate account of subject selection must appeal to more than the agentive status of a participant, since more than one participant plays an agentive role (see (Dowty 1991), (Wechsler 1995).and the Framenet system developed by

Filllmore and others for some approaches to this problem). Designating one of the subevents as the "main" or "salient" event for linguistic purposes, as in Framenet, accords well with the foregoing suggestion, although linguistic evidence is only a rough guide in these matters.

3.3. The inheritance of properties

One final issue regarding roles and subroles concerns how strictly we wish to enforce inheritance of properties. The OntoClean proposals of Guarino and Welty (2002), for example, place high importance on transmitting various properties dependably in inheritance. For instance, they argue against a pervasive characteristic of Cyc, that individual object types commonly inherit from the stuff types of which the objects are composed (thus *Ocean* is a subtype of *Water* in Cyc). When we examine the comparable situation in the realm of situations, we are led to the conclusion that telic situation types, such as eating an apple or painting a wall, should not be regarded as subtypes of atelic types such as eating or painting. The latter types are cumulative: two eating events may be combined and treated as a single eating event, but two events of eating an apple cannot be regarded as a single larger event of eating an apple.[6] This suggests that, parallel to the object and stuff types, telic and atelic event types should not be in a subtype-supertype relationship. If so, then telic event types will not inherit the roles of corresponding atelic event types. Instead, we could adopt a projectability rule that states: if *e* is an event of telic event type *T*, and *T* is "composed" of events of atelic type *A* (just as oceans are composed of water), then *e* also has those roles. In some cases, there may be no roles specified for events of type *T*, independently of type *A*. In others, such as many telic movement event types, additional roles are present, including *source* and *goal* roles.

In this case, then, we are led to a conclusion that is roughly the reverse of what we advocated in the case of groups of situations. For group situations, a consideration of roles for the group and for the subsituations comprising it led us to suggest that the group situation type is a supertype of the type of the elements. For the case of atelic and telic situation types, which might initially appear to be in a supertype-subtype relation, a re-examination of this assumption leads us to posit projection of roles from (atelic) subsituations to (telic) situations.

In sum, we see that there are unlikely to be simple general principles regulating the projection of roles between situations and their sub- or super-situations, although there do appear to be some useful, more specific principles covering some cases of interest.

4. Parallelism between roles and other elements in ontologies

In this section we explore what parallelisms may exist between the hierarchy of participant roles and other types of ontologies. Besides supertype-subtype relations, mereological relations are crucial in ontologies and in lexical resources like WordNet. Lexical resources also frequently employ an antonymy relation between words, though it is less clear that this is coherent ontological relation and ontologies emphasize this much less. In this section we will investigate to what extent these other relations can be applied to roles. In doing so, we will continue to mention issues of role projectability, this time with respect to entities and their parts.

4.1. Specialization/generalization (hyponymy/hypernymy)

Concept specialization is represented in WordNet with hyponymy links, and in Cyc with the predicate *genls* (and some extensions of it for relations). These apply both to entity types (or nouns in WordNet) and situation types (or verbs in WordNet, which then refers to this relation as "troponymy"). The comparable relationship for roles is simply the subrole relation; if one role is a subrole of another, then any participant that plays the first role in a situation necessarily also plays the second. This is the chief organizing relation for the hierarchy of roles, as it is for object and situation types.

However, we would like to remark here on one more linguistically relevant issue, since much of this same machinery is brought to bear on computational lexicons, including WordNet. Because the mapping from semantic roles to syntactic arguments is not completely semantically determined and displays some arbitrary variation, we cannot assume that hyponyms of a verb will exhibit the same mapping as that of the verb itself. In some cases, for example, an argument is incorporated in the verb (e.g., "spread butter on the bread" vs. "butter the bread", "put the money in the pocket" vs. the "pocket the money"). In others, the mapping is simply different (e.g., "eat oysters" vs. "dine/gorge on oysters"). This means that syntactic patterns are not necessarily reliable indicators of participant roles, and although hyponymy usually does imply inheritance of participant roles, corresponding roles may not occupy corresponding syntactic positions.

4.2. Partial roles (meronymy/holonymy)

Meronymy/holonymy, the lexical part/whole relation, and other mereological relations in ontologies, appear to be more complex, with several discernable subtypes. For example, Winston, Chaffin, and Hermann (1988) differentiate seven types of meronym: component-object (branch/tree), member-collection (tree/forest), portion-mass (slice/cake), stuff-object (aluminum/airplane), phase-process (adolescence/growing up), feature-activity (paying/shopping), and place-area (Baltimore/Maryland). Iris, Litowitz, and Evens (1988) acknowledge only four, however: functional part (wheel/bicycle), segment (slice/loaf), member (sheep/flock) and subset (meat/food), which is really specialization rather than meronymy. Likewise Cyc distinguishes numerous part/whole relations, including ingredients, physical and abstract parts, and subevents. The WordNet hierarchies employ just a single meronym link type, used only in the noun hierarchy. Meronymy applies just as usefully, however, to situation types (or verbs in WordNet), as we have been assuming throughout this paper. The type of meronymy called "phase-process" by Winston, Chaffin and Hermann

[6] Note that one and the same event can be regarded as both atelic or telic; eating an apple is certainly also eating. The telicity distinction is at the situation-type level, not at the individual level.

(1988) relates pairs of nouns and gerunds such as *adolescence/growing_up*. Feature-activity meronymy relates pairs of gerunds such as *paying/buying* or *steering/driving*. In short, events can be said to have component parts just as objects have them. The analogy to meronymy in the domain of participant roles is much less obvious than the specialization parallel, however.

We can begin by offering a definitions of "partial roles", as a mereololgical counterpart to the definition of subroles in (1):

(2) *R'* is a partial role of *R* iff:
R(x,e) → ∃*x,e*: *x'* is a part of *x* and *e'* is a subsituation of *e* and *R'(x',e')*

Unlike physical part and subsituation relationships, which are ubiquitous and obviously crucial to ontologies, there are relatively few instances of roles in this relationship that we are aware of, beyond the trivial case where *R* = *R'*, *x* = *x'*. and *e* = *e'*. Two cases are exemplified in the following sentences, where the participant denoted by the object of 'with' or 'by' is a part of another participant. Thus the "instrument" role is a partial role of *agent* in a. and the "body part" role is a partial role of the *grabbed* participant (or *theme*, or *affected object*) in b:

(3) a. I bumped the vase with my elbow.
b. I grabbed the iguana by the tail.

A third case of partial roles involves the *moving object* in movement events. In such events the parts of the object also move during at least some subintervals of the event, so the role *moving object* is partial to itself in a non-trivial way. In a parallel fashion, some roles in states are non-trivially self-partial. If someone owns a car for a year, that person owns the engine for the first six months, and if a beam supports a roof for a year, it is plausible to infer that a section of the beam supports a section of the roof for any period within that year.

Despite these cases, it appears that this type of part/whole relationship between roles is rare, and not particularly useful in inference. Possibly this is due to the relational character of roles, mediating between situations and their participants. We will now consider a more widespread phenomenon, the projection of role from participant entities to larger entities of which those participants are parts.

4.3. Projection of roles from entities to super-entities

We now examine the question of which roles can be projected from parts to wholes and vice versa; that is, if an object plays a role in a situation do larger objects of which it is a part and smaller objects that are parts of it also play that role in the situation? It should be clear that when this is the case, the role in question violates Krifka's uniqueness of objects property (Krifka 1992, 1998). Two kinds of roles for which this does seem to be true are roles of *source* and *goal* in motion events. For example, the following inferences seem valid:

(4) I flew from Baltimore to Boston. therefore,
I flew from Maryland to Boston. and
I flew from Baltimore to Massachusetts.

This inference has limits, in that the super-region cannot include both the origin and the destination of the trip, however, so the following are aberrant:

(5) #I flew (from the U.S.) (to the U.S.) and,
#I flew from the U.S. to Boston. and,
#I flew from Baltimore to the U.S.

The *path* role, in contrast, can be projected down to parts of the trajectory, but not to larger paths:

(6) Kim hiked (all of) the John Muir Trail. therefore,
Kim hiked the Tahoe-Yosemite Trail.

As Krifka (1992, 1998) has pointed out, we can make similar inferences from parts to wholes in the case of roles that involve contact or perception, as the following examples illustrate:

(7) John touched the door handle. therefore,
John touched the door.

(8) Kim rammed Sandy's bumper. therefore,
Kim rammed Sandy's car.

(9) The jar contacts the countertop. therefore,
The jar contacts the counter.

Note also that in situations involving both motion and contact, the contact inference is allowed even if the motion is not:

(10) I shook a link of the chain. therefore,
I touched the chain (even if I didn't shake it).

As for roles involving perception, the same pattern seems to apply, though the inference seems less solid:

(11) Fred saw the elephant's trunk. therefore,
Fred saw the elephant.

(12) Alice smelled the roasted chicken. therefore,
Alice smelled the meal.

As the story about the blind men and the elephant suggests, however, there is some uneasiness about such inferences. Perception differs from contact in this respect.

Finally, there are situation types in which one participant stands in a relationship of superiority to another, denoted by verbs such as 'exceed', 'surpass', 'dwarf', and verbs prefixed with 'out-'. In these cases, it arises virtually a matter of definition that the superior participant's role projects to objects of which it is a part, and the inferior one's role to its parts. This is exemplified in the following sentences:

(13) Nitrous oxide levels exceeded the Federal standards. therefore,
Smog levels exceeded the Federal standards.

(14) Bach outlived Vivaldi. therefore,
The Bach family outlived Vivaldi.

(15) Russia dwarfs Korea. therefore,
Russia dwarfs North Korea.

There are many roles for which projection to parts or wholes does not follow, except in some metaphorical or metonymic sense, including most roles involving agency, motion, and affectedness. In sum, "spatial" roles (including those that are appropriate for situation types whose linguistic realization is metaphorically based on spatial relationships) exhibit some projection properties that should prove useful in inference. But there is no direct parallel among roles to part/whole relationships of the type that apply ubiquitously to entities and situations.

4.4. Antonymy/opposition

Another relation in WordNet, more explicitly lexical, is antonymy, although as Miller (1998) points out, it is not a fundamental an organizing relation between nouns. True antonymy is present in the verb hierarchy, as well as among adjectives. Change-of-state verbs, for example, have antonymous counterparts quite similar to nouns, although the verb pairs don't normally share parents (e.g., 'lengthen'/'shorten' and 'strengthen'/'weaken'). Relations of opposition occur as well, where there is no common superordinate or entailed verb unique to the pair (e.g., 'give'/'take', 'buy'/'sell').

Antonymy is closely tied to lexical properties and not a coherent ontological relationship, but some aspects of it can be singled out and represented as conceptual relationships. For example, reversative actions (*zipping* and *unzipping*, *loading* and *unloading*, *arriving* and *leaving*, *creating* and *destroying*) exemplify a fairly coherent notion of opposition that bears on participant roles. We cannot say that the event types in each pair have the same roles; for example, *loading* and *arriving* both have a *goal* role, but may lack a *source*, while *unloading* and *leaving* are the opposite. But it is probably fair to say that each role of an event type has a counterpart in the corresponding reversative event type. The same may hold true for other sorts of opposites (e.g., *helping* and *hindering*, *benefiting* and *suffering*, *believing* and *doubting*), though in many of these cases we are more likely to say that the role's counterpart is itself. It seems less meaningful to posit a counterpart relationship between roles in some other types of situations sometimes thought of as "opposites" (being awake or asleep, liking and disliking, and many others), let alone antonyms in the domain of properties and objects.

4.5. Complementary roles

Another relation between two roles that seems worthwhile is what we term *complementarity*. For some situation types, we know that when one role is present, another role must be also. We then say that this second role is complementary to the first. Complementarity may unidirectional or bi-directional, but most of our examples will involve the latter case. Some examples of such roles are *buyer* and *seller*, *buyer* and *payment*, *moving object* and *path*, *driver* and *vehicle*, and *perceiver* and *perceived*. One application of a complementarity relation in inference should be fairly clear; it allows us to postulate the existence of a participant filling a role when the participant playing the complement role is known to be present. However, this sort of inference is probably equally simply performed with reference to situation types, as long as they specify which roles are necessary and appropriate. The complementarity relation bears some resemblance to meronymy and to the "partial role" relations; it could even be considered a type of partial role relation applied to situations, disregarding the requirement in (2) that participants playing each role be in a part-whole relationship. Complementarity certainly has counterparts in the entity and situation domains. The existence of a hole depends on the existence of a cavity wall, and the two transfer subevents of a commercial transaction seem complementary in much the same way that the roles are.

Roles that are complementary and that, in a given situation type, are entailed to be filled by the same participant, may violate the reverse of the implication in (1). That is, if *R'* is a complementary role of *R*, and a situation type is constrained so that *R(x,e)* and *R'(x,e)* for any situation *e* of that type, then a bi-directional interpretation of (1) would treat *R* as a subrole of *R'*.[7] There may be legitimate grounds, however, to distinguish two participant roles in such situations. For example, someone who is talked into performing an action is both a *addressee* and a *performer* (of the action). It is possible in such cases to create a role specific to that type inheriting from the two roles *R* and *R'*, but it does not always seem desirable to do so. We leave this question open.

5. Conclusions

We have seen that an examination of the relations among roles can be fruitful in illuminating other aspects of ontologies and lexical resources. Considering the question of role projectability has shown that permitting multiple inheritance to operate without constraint in the situation-type hierarchy is problematic, and that other mechanisms do not cause the same difficulties for inheritance of roles from situation types to their subtypes. We have also seen how role inheritance interacts with two particular cases of situations and subsituations: a group of like situations and telic situations composed of atelic subsituations. In these two cases, role projectability reveals interesting relationships among situation types in ontologies.

Roles parallel situation and entity types in constituting a hierarchy, but, perhaps because of their inherently relational nature, the parallelism beyond that is limited. While we can formulate coherent definitions of relationships between roles that parallel the mereological relations that are so pervasive among situations and entities, their usefulness is less apparent. In contrast, the complementarity relation between roles is widespread and its utility in inference clear.[8]

Abstract

In this paper we propose an analysis and a rearrangement of *WordNet's* top-level taxonomy of nouns. We briefly review WordNet and identify its main semantic limitations, in the light of the ontology evaluation principles lying at the core of the *OntoClean* methodology. Then we briefly present a first version of the *OntoClean Top* (OCT) ontology, and show how WordNet can be aligned with it. The result is a "cleaned-up" WordNet, which is meant to be conceptually more rigorous, cognitively transparent, and efficiently exploitable in several applications.

1 Introduction

The number of applications where WordNet is being used more as an ontology than just as a lexical resource seems to be growing more and more. To be used as an ontology, however, some of WordNet's lexical links need to be interpreted according to some formal semantics, which tells us something about "the world" and not (just) about the language. One of such links is the hyponym/hypernym relation, which corresponds in many cases to the usual subsumption (or IS-A) relation between concepts. An early attempt at exploring the semantic and ontological problems lying behind this correspondence is described in (Guarino, N., 1998).

In the recent years, we developed a methodology for testing the ontological adequacy of taxonomic links called OntoClean (Guarino, N. & Welty, C., 2002; Guarino, N. & Welty, C., 2002), which was used as a tool for a first systematic analysis of WordNet's upper level taxonomy of nouns (Gangemi, A. *et al.*, 2001). The first version of OntoClean was based on an ontology of properties (unary *universals*), characterized by means of meta-properties. We are now extending OntoClean with an ontology of *particulars* called OCT (OntoClean Top ontology), which is presented here in some detail, although still in an informal way. The OCT will be the first module of a minimal library of *foundational ontology* that we shall develop within the *WonderWeb*[1] project.

This paper is structured as follows. In the next section we present an extension of our FOIS paper (Gangemi, A. *et al.*, 2001), concerning some ontological inadequacies of WordNet's taxonomy of nouns. Then we introduce the most recent version of our OntoClean Top ontology, and discuss the preliminary results of an alignment work aimed at improving WordNet's overall ontological (and cognitive) adequacy, and facilitate its effective deployment in practical applications.

2 WordNet's Preliminary Analysis

2.1 Experiment Setting

We applied our methodological principles and techniques to the noun synsets taxonomy of WordNet 1.6.To perform our investigation, we had to adopt some preliminary assumptions in order to convert WordNet's databases[2] into a workable knowledge base. At the beginning, we assumed that the hyponymy relation could be simply mapped onto the subsumption relation, and that the synset notion could be mapped into the notion of concept. Both subsumption and concept have the usual description logics semantics (Woods, W. A. & Schmolze, J. G., 1992). In order to work with named concepts, we normalized the way synsets are referred to lexemes in WordNet, thus obtaining one distinct name for each synset: if a synset had a unique noun phrase, this was used as concept name; if that noun phrase was polysemous, the concept name was numbered (e.g. window_1). If a synset had more than one synonymous noun phrase, the concept name linked them together with a dummy character (e.g. Equine$Equid).

Firstly, we created a Loom[3] knowledge base, containing, for each named concept, its direct super-concept(s), some annotations describing the quasi-synonyms, the gloss and the synset topic partition, and its original numeric identifier in WordNet; for example

```
(defconcept Horse$Equus_Caballus
    :is-primitive Equine$Equid
    :annotations ((topic animals)
    (WORD |horse|)
    (WORD |Equus caballus|)
    (DOCUMENTATION "solid-hoofed herbivorous quadruped domesticated since prehistoric times"))
    :identifier |101875414|)
```

noun entries	116364
equivalence classes: synonyms, spelling variants, quasi-synonyms	50337
noun synsets (with a gloss and an identifier for each one)	66027
nouns	95135
monosemous nouns	82568
polysemous nouns	12567
one-word nouns	70108
noun phrases	25027

Table1: Elements processed in the Loom WordNet kb

The elements processed in the Loom WordNet knowledge

*In the process of moving to ISTC-CNR, Rome, Italy.

[2] We used the Prolog WordNet database, the Grind database, and some others from the official distribution.

[3] Loom is a knowledge representation system that implements a quite expressive description logic (MacGregor, R. M., 1991).

base are reported in Table 1. We report in Figure 2 an overview of WordNet's noun top-level as translated in our Loom knowledge base. The nine Unique Beginners are shown in boldface.[4]

2.2 Main problems found

Once the Loom WordNet was created, we systematically applied the OntoClean methodology to the upper taxonomy of noun senses. Let us discuss now the main ontological drawbacks we found after applying this cleaning process.

2.2.1 Confusion between concepts and individuals

The first critical point was the confusion between concepts and individuals. For instance, if we look at the hyponyms of the Unique Beginner Event, we'll find the synset Fall - an individual - whose gloss is “the lapse of mankind into sinfulness because of the sin of Adam and Eve”, together with conceptual hyponyms such as Social_Event, and Miracle.[5] Under Territorial_Dominion we find Macao and Palestine together with Trust_Territory. The latter synset, defined as "a dependent country, administered by a country under the supervision of United Nations", denotes a general kind of country, rather than a specific country as those preceding it. If we go deeper in the taxonomy, we find many other examples of this sort. For instance, the hyponyms of Composer are a mixture of concepts and instances: there are classes corresponding to different special fields, such as Contrapuntist, or Songwriter, and examples of famous musicians of the past, such as Bach, and Beethoven.

Under Martial_Art, whose top hypernym is Act, we find Karate, and Kung Fu, but these synsets do not stand for concepts, they represent individuals, namely particular examples of martial arts.

If we look through Organization, under the branch whose root is Group, we find conceptual hyponyms such as Company, Alliance, Federation, Committee, together with instances like Irish_Republican_Army, Red Cross, Tammany Society[6], and so on.

We face here a general problem: the concept/individual confusion is nothing but the product of an “expressivity lack”. In fact, if there was an INSTANCE-OF relation, we could distinguish between a concept-to-concept relation (subsumption) and an individual-to-concept one (instantiation).

2.2.2 Confusion between object-level and meta-level: the case of Abstraction

The synset Abstraction_1 seems to include both object-level concepts, such as Set, Time, and Space, and meta-level concepts such as Attribute and Relation. From the corresponding gloss, an abstraction “is a general concept formed by extracting common features from specific examples”. An abstraction seems therefore intended as a psychological process of generalization, in accordance to Locke's position ((Lowe, E. J., 1998), p.211). This meaning seems to fit the latter group of terms (Attribute, Relation, and possibly some hyponyms of Quantity), but not to the former. Moreover, it is quite natural to consider attributes and relations as meta-level concepts, while set, time, and space, seem to belong to the object domain.

2.2.3 OntoClean constraints violations

A core aspect of OntoClean is the analysis of subsumption constraints induced by the identity, rigidity, and unity meta-properties. In our analysis, we only found rigidity violations. We suspect that there are two reasons why we didn’t observe other kinds of violation: on one hand, we limited our analysis to the upper levels, where the criteria of identity and unity are very general; on the other hand, WordNet tends, notoriously, to multiply senses, so the chances of conflict are relatively limited.

The most common violation we have registered is bound to the distinction between roles and types. A role cannot subsume a type. Let's see an important clarifying example.

In its first sense, Person (which we consider as a type) is subsumed by two different concepts, Organism and Causal_Agent. Organism can be conceived as a type, while Causal_Agent as a formal role. The first subsumption relationship is correct, while the second one shows a rigidity violation. We propose therefore to drop it.

Someone could argue that every person is necessarily a causal agent, since ‘agentivity’ (capability of performing actions) is an essential property of human beings. Causal_Agent should therefore be intended as a synonym of ‘intentional agent’, and considered as rigid. But, in this case, it would have only hyponyms denoting things that are (essentially) causal agents, including animals, spiritual beings, the personified Fate, and so on. Unfortunately, this is not what happens in WordNet: Agent, one of Causal_Agent hyponyms, is defined as: "an active and efficient cause; capable of producing a certain effect; (the research uncovered new disease agents)". Causal_Agent subsumes roles such as Germicide, Vasoconstrictor, Antifungal. Instances of these concepts are not causal agents essentially. This means that considering Causal_Agent as rigid would introduce further inconsistencies.

These considerations allow us to add a pragmatic guideline to our methodology: when deciding about the formal meta-property to attach to a certain concept, it is useful to look at all its children.

2.2.4 Heterogeneous levels of generality

Going down the lower layers of WordNet's top level, we register a certain ‘heterogeneity’ in their intuitive level of generality. For example, among the hyponyms of Entity there are types such as Physical_Object, and roles such as Subject. The latter is defined as “something (a person or object or scene) selected by an artist or photographer for graphic representation”, and has no hyponyms (indeed, almost any entity can be an instance of Subject, but none is necessarily a subject)[7].

For Animal (subsumed by Life_Form) this heterogeneity becomes clearer. Together with classes such as Chordate, Larva, Fictional_Animal, etc., we find out more specific concepts, such as Work_Animal, Domestic_Animal,

[4] Note that the sense numeration reported in our Loom kb is different from the WordNet's original one. Nevertheless, the reader will easily recognize the synsets we are referring to.

[5] In the text body, we usually do not report all the synonyms of a synset (or their numeration), but only the most meaningful ones.

[6] “A political organization in New York city (late 1800’s early 1900’s) seeking political control by corruption and bossism”.

[7] We can draw similar observations for relation_1 and set_5 with respect to abstraction_1, etc.

Mate_3, Captive, Prey, etc. We are induced to consider the formers as types, while the latters as roles.
Although problematic on the side of ontological distinctions among event-classes, the hyponyms of Phenomenon_1 represent another meaningful example of heterogeneity. At the same taxonomic level there are "reasonably" general synsets like Natural_Phenomenon and Process together with a specific concept like Consequence, which could be modeled as anti-rigid (every event can be a consequence of the occurring of a previous event, but we could assume that this is not the essential characteristic of the event itself[8]).
In short, intuitively some synsets sound too specific when compared to their siblings. Look at them from the formal point of view we are developing, we can pinpoint their "different generality" by means of the distinction between types and roles.

3 The OntoClean Top Ontology

Before presenting our (still preliminary!) OCT ontology, a couple of clarifications may be useful. First of all, we do *not* intend this as a candidate for a "universal" standard ontology. Rather, we support the vision of a *library* of *foundational ontologies*, reflecting different commitments and purposes. In our opinion, the most important challenge today is not so much the agreement on a monolithic set of ontological categories, but rather the careful isolation of the fundamental ontological options and their formal relationships. If general ontologies reflecting different commitments and purposes are described in terms of these formal notions, then we can hope they will form a library of "foundational" ontologies accessible in a modular way, keeping the necessity of largely shared ontological commitments to the very minimum, and making the rationales and alternatives underlying the different ontological choices as explicit as possible. This is one of the goals of the *WonderWeb* project, where the OCT ontology will be linked to other foundational ontologies.
A second clarification concerns the general attitude underlying our ontological choices. The OCT ontology has a clear *cognitive bias*, in the sense that we aim at capturing the ontological categories lying behind natural language and human commonsense. Hence, we do not claim that our categories have "deep" metaphysical implications related to the intimate nature of the world: rather, they are thought of as "conceptual containers" useful to describe ontologies as cognitive artifacts ultimately depending on human perception, cultural imprints and social conventions. So, especially with respect to natural language, our attitude is more "descriptive" than "revisionary" (Strawson, P. F., 1959; Loux, M. J., 1998).
Finally, we have to point out that the ontology presented here is an ontology of *particulars*. Properties and relations are therefore not part of its domain. Some proposals for a ontology of properties have been made in (Guarino, N. & Welty, C., 2000). We are not aware of any systematic work on the ontology of relations.

[8] For instance, the extinction of dinosaurs could have be the consequence of the impact of an asteroid on the Earth, or of a sudden glaciation, or of a mortal epidemic – scientists are not sure about this – but in terms of ontology of events, it is a conclusive event, at most an annihilation event, and there is no need (and here no possibility) to model it as a consequence.

3.1 General notions

Before introducing the OCT categories, let us first introduce the general notions we shall use to characterize them. Some of these notions (like rigidity and unity) have already been defined in previous papers (respectively, (Guarino, N. & Welty, C., 2002) and (Gangemi, A. *et al.*, 2001)), and will not be discussed here. So we shall limit ourselves to the basic distinction between *enduring and perduring* entities, and the varieties of dependence relationships involving particulars.[9] We shall keep the discussion to an informal, introductory level; a rich axiomatization will be presented in a forthcoming paper.

3.1.1 Enduring and perduring entities

A fundamental distinction we assume in the OCT ontology is that between *enduring* and *perduring* entities. This is almost identical, as we shall see, to the distinction between so-called *continuants* and *occurrents* (Simons, P., 1987), which is still being strongly debated both in the philosophical literature (Varzi, A., 2000) and within ontology standardization initiatives[10]. Again, we must stress that this distinction is motivated by our cognitive bias: we do not commit to the fact that both these kinds of entity "really exist", and we are indeed sympathetic with the recent proposal made by Peter Simons, that enduring entities can be seen as equivalence classes of perduring entities, as the result of some kind of abstraction mechanism (Simons, P., 2000).
But let us see what this distinction is about. The difference between enduring and perduring entities (which we shall also call *endurants* and *perdurants*) is related to their behavior in time. Endurants are always *wholly* present (i.e., all their proper parts are present) at any time they are present. Perdurants, on the other hand, just extend in time by accumulating different temporal parts, so that, at any time they are present, they are only *partially* present, in the sense that some of their proper parts (e.g., their previous phases) may be not present. For instance, the piece of paper you are reading now is wholly present, while some temporal parts of your reading are not present any more. Philosophers say that endurants are entities that *are in time*, while lacking however temporal parts (so to speak, all their parts travel with them in time). Perdurants, on the other hand, are entities that *happen in time*, and can have temporal parts (all their parts are fixed in time).
This different behavior affects the notion of change in time. Endurants can "genuinely" change in time, in the sense that the very same whole endurant can have incompatible properties at different times; perdurants cannot change in this sense, since none of their parts keeps its identity in time. To see this, suppose that an endurant has a property at a time *t*, and a different, incompatible property at time *t':* in both cases we refer to the whole object, without picking up any particular part. On the other hand, when we say that a perdurant has a property at *t*, and an incompatible property at *t'*, there are always two different parts exhibiting the two properties.
We have already mentioned that endurants and perdurants can be taken as synonyms of the more common terms

[9] In the OntoClean taxonomy evaluation methodology only dependence between properties is used.
[10] See for instance the extensive debate about the "3D" vs. the "4D" approach at www.suo.org.

continuants and *occurrents*. We prefer however the adopted terminology, because the continuants/occurrents distinction is sometimes considered only within so-called *concrete* entities, while, as we shall see, we take it as spanning the whole domain of particulars, including abstracts that we shall consider as endurants. Finally, we shall take *occurrence*, and not *occurrent*, as synonym of *perdurant*, since it seems natural to use *occurrent* to denote a type (a *universal*), whose instances are occurrences (*particulars*).

The endurants/perdurants distinction evidences the general necessity of temporally indexing the relationships within endurants. This means that, in general, it is necessary to know *when* a specific endurant bears a certain relation to other endurants. Consider for instance the classical example of Tibbles the cat (Simons, P., 1987): Tail is part of Tibbles before the cut but not after it, i.e. we have to "temporalize" the part relation: *P*(Tail, Tibbles, *before*(cut)) and ¬*P*(Tail, Tibbles, *after*(cut)).

With respect to a temporalized relation *R*, we can distinguish *R-constant* endurants from *R-variable* endurants. An endurant *e* is called *R-constant* iff, when $R(x_1, \dots, x_n, e, t)$ holds for a temporal interval *t*, then $R(x_1, \dots, x_n, e, t')$ also holds whenever *e* is present at *t'*.

We can also strengthen this definition introducing the modal notion of an *R-invariant* endurant. An endurant *e* is called *R-invariant* iff, if it is possible that $R(x_1, \dots, x_n, e, t)$ then necessarily $R(x_1, \dots, x_n, e, t)$ holds whenever *e* is present at *t'*.

For the purpose of characterizing the OCT categories, the property of being constant (or invariant) with respect to the parthood relation (*mereologically constant* (*invariant*)) has a special relevance. For example, we usually take ordinary material objects as mereologically variable, because during their life they can lose or gain parts. On the other hand, amounts of matter are taken as mereologically invariant (all their parts are *essential part*), and so on.

3.1.2 Dependence

Let us now introduce informally some useful definitions based on the notion of dependence, adapted from (Thomasson, A. L., 1999). We focus here on *ontological dependence* (holding primarily between particulars, and only by extension between properties), to be distinguished from *notional dependence*, which only holds between properties).

A particular *x* is *specifically constantly dependent* (SCD) on another particular *y* iff, at any time *t*, *x* can't be present at *t* unless *y* is also present at *t*. For example, a person might be specifically constantly dependent on its brain.

A particular *x* is *generically constantly dependent* (GCD) on a property ϕ iff, at any time *t*, *x* can't be present at *t*, unless a certain instance *y* of ϕ is also present at *t*. For example, a person might be generically constantly dependent on having a heart.

1.2 The OntoClean Top Categories

The most general kinds of particulars assumed in the OntoClean Top ontology are described in Figure 1. They are assumed to be mutually disjoint, and covering the whole domain of particulars. They are also considered as *rigid* properties, according to the OntoClean methodology that stresses the importance of focusing on these properties first.

Figure 1: Onto Clean Top Categories.

1.2.1 Qualities and quality regions

'Quality' is often used as a synonymous of 'property', but this is not the case in the OCT ontology: qualities are particulars, properties are universals. According to our view, every entity comes with certain qualities, which exist exactly as long as the entity exists. These qualities belong to different *quality types* (like color, size, smell, etc.), and are characteristic (*inhere to*) specific individuals: no two particulars can have the same quality. So we distinguish between a quality (e.g., the color of a specific rose), and its "value" (e.g., a particular shade of red). The latter is called *quale*, and describes the "extension" (or "classification") of an individual quality with respect to a certain *conceptual space* (called here *quality space*) (Gärdenfors, P., 2000), So when we say that two roses have the same color their two colors are classified in the same way wrt the color space (they have the same *color quale*), but still they have two numerically distinct qualities.

The reason of this distinction between qualities and qualia, which is inspired to the theory of tropes (with some differences that can't be discussed here[11]), is mainly due to the fact that natural language – in certain constructs – seems often to make a similar distinction. For instance, when we say "the color of the rose turned from red to brown in one week" or "the room's temperature is increasing" we are not speaking of a certain shade of red, or a specific thermodynamic status, but of something else that changes its properties in time while keeping its identity. This is why we assume that qualities are endurants.

On the other hand, when we say that "red is opposite to green" or "red is close to brown" we are not speaking of qualities, but rather of regions within quality spaces. The specific shade of red of our rose – its color quale – is therefore an atom in the color space.[12]

[11] An important difference is that standard tropes theories explain a qualitative change in terms of a substitution of tropes (an old trope disappears and a new one is created). We assume instead that qualities are a sort of "enduring tropes".

[12] The possibility of talking of qualia as particulars rather than reified properties is another advantage of our approach.

Each quality type has an associated quality space with a specific structure. For example, lengths are usually associated to a metric linear space, and colors to a topological 2D space. The structure of these spaces reflects our perceptual and cognitive bias.
Under this approach, we can explain the relation existing between 'red' intended as an adjective (as in "this rose is red") and 'red' intended as a noun (as in "red is a color"): the rose is red because its color is located in the red region within the color space (more exactly, its color quale is a part of that region).
As a final remark, we note that qualities are assumed to be as specifically constantly dependent on the entities they *inhere to*.

1.2.1.1 Location

In the OCT ontology, space and time are considered as quality types like color, weight, etc. The spatial (temporal) individual quality of an entity is called *spatial* (*temporal*) *location*, while its quale is called *spatial* (*temporal*) *region* and it belongs to the associated quality space (respectively geometric space and temporal space). For example, the spatial location of a physical object is just one of its individual qualities: it belongs to the quality type *space*, and its quale is a region in the geometric space. Similarly for the temporal location of an occurence. This allows an homogeneous approach that remains neutral about the properties of the geometric/temporal space adopted (for instance, one may assume a circular time).
Notice that quality regions can have qualities themselves (for instance, the spatial location of a certain object can have a shape), in particular we assume that all quality regions are temporally located, and that their temporal qualia coincide with the temporal universe, i.e. quality regions are always present.

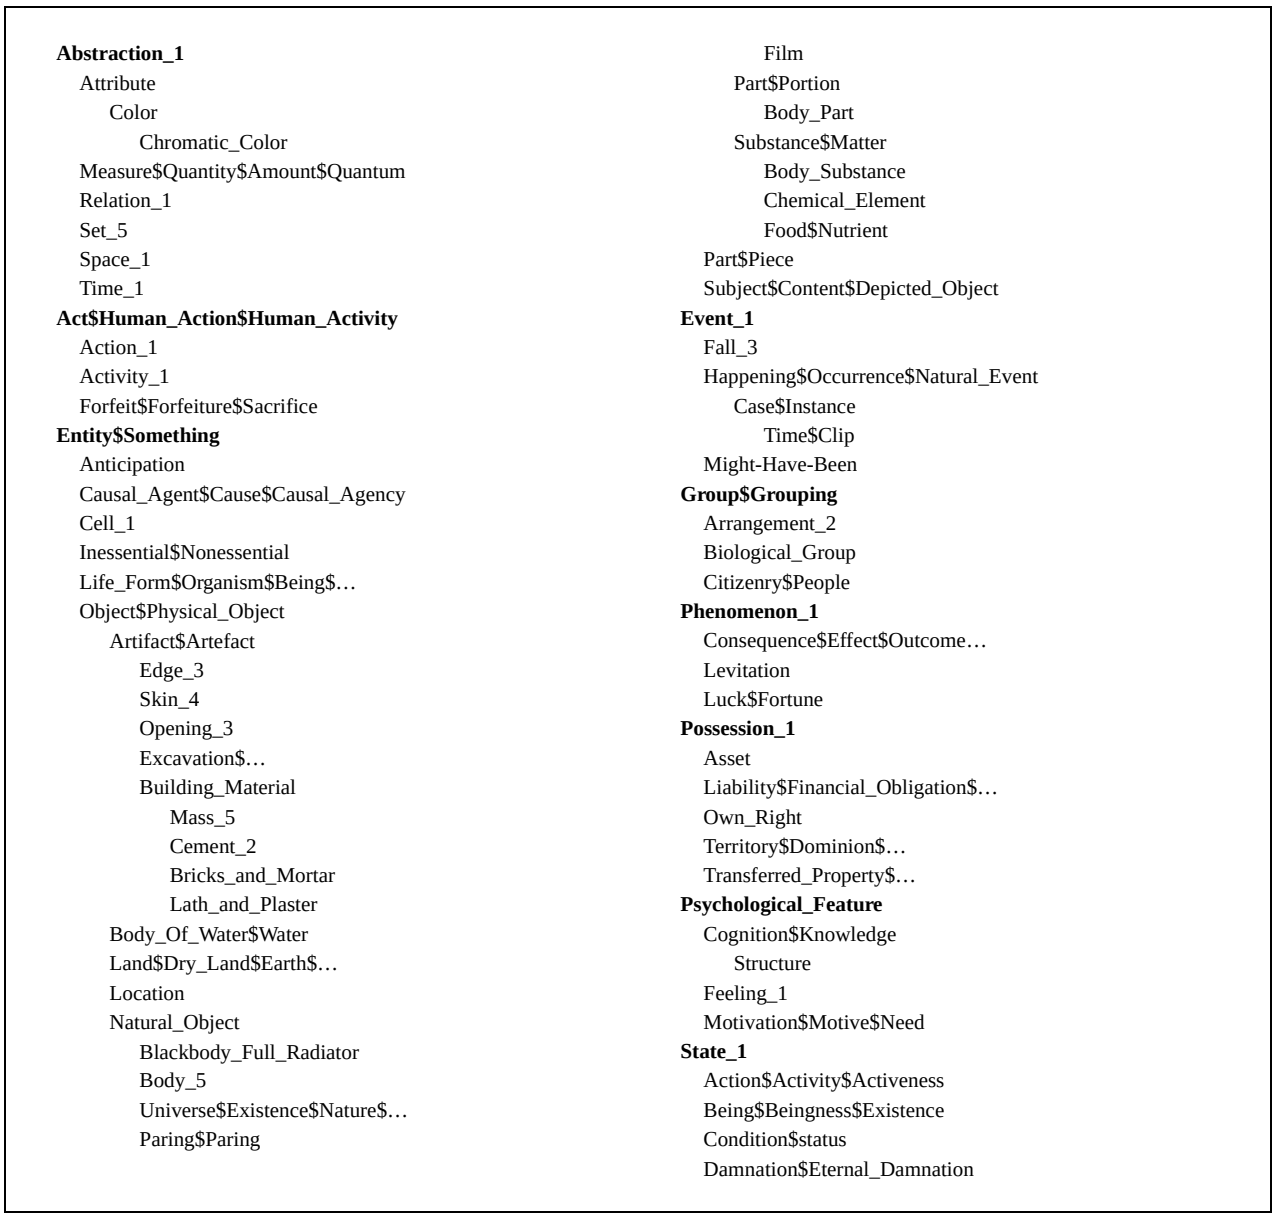

Figure 2: WordNet's top Level

1.2.2 Aggregates

The common trait of aggregates is that they are endurants and none of them is an essential whole. We consider two kinds of aggregates: *Amounts of matter* and *Arbitrary collections*. The former are mereologically invariant, in the sense that they change their identity when they change some parts. The latter are defined as "mere mereological sums" of essential wholes which are not themselves essential wholes (like the sum of a person's nose and a computer keyboard). They are essentially mereologically *pseudo-constant*, in the sense that they change their identity when a member (i.e. a special part of a collection, see (Gangemi, A. *et al.*, 2001)) is changed, while a change in the non essential parts of a member is allowed. We may have called arbitrary collections *groups*, or perhaps *sets*; but we prefer to use *set* for abstract entities, and *group* for something having an intrinsic unity.

1.2.3 Objects

The main characteristic of objects is that all of them are endurants and essential wholes. They have no *common* unity criterion, however, as different subtypes of objects may have different unity criteria. Often objects (indeed, all endurants) are considered ontologically independent from occurrences (discussed below). But, if we admit that every object has a life, it is hard to exclude a mutual ontological dependence between the two. Nevertheless, we can use the notion of dependence to distinguish between objects that are not specifically constantly dependent on other objects and have a spatial location (*physical objects*) and objects that are generically constantly dependent on *persons* (that are also objects) and do not have a spatial location (*mental objects*). Among physical objects, we further distinguish between *bodies* and *ordinary objects*. Bodies are mereologically invariant, and then they are material objects in the sense of physics.[13]. Ordinary objects (and mental objects even more) have a more cognitive nature, as they are admitted to change some of their parts while keeping their identity: they can have therefore *temporary parts*. Among mental objects, we could distinguish between purely *subjective mental objects*, i.e. objects depending on a singular person (like an intention, or a competence), and *intersubjective mental objects*, i.e. objects depending on a community of persons (like a project, a legal norm, a moral value, an aesthetic notion).

1.2.4 Features

Typical examples of features are "parasitic entities" such as holes, bumps, surfaces, or stains, which are generically constantly dependent on physical objects[14] (their *hosts*). All features are essential wholes, but no common unity criterion may exist for all of them. However, typical features have a topological unity, as they are *singular* entities. Features may be *relevant parts* of their host, like a bump or an edge, or *places* like a hole in a piece of cheese, the underneath of a table, the front of a house, which are not parts of their host.

[13] Notice that differently from the amounts of matter they are essential whole.

[14] We may think that features are specifically constantly dependent on their host, but an example like "a whirlpool" is very critical in this sense. Notice that we are not considering as features entities that are dependent on mental-objects.

1.2.5 Occurrences

Occurrences are synonymous of perdurants. They comprise what are variously called events, processes, happenings, and states. Occurrences can have temporal parts or spatial parts. For instance, the first movement of (the execution of) a symphony is a temporal part of it. On the other side, the play performed by the left side of the orchestra is a spatial part. In both cases, these parts are occurrences themselves. Clearly objects can't be parts of occurrences, rather they *participate* to them.

Within occurrences, we consider two main ontological dimensions of distinction: homeomery and relationality. The first dimension has been introduced by Parsons, Cresswell, and Mourelatos (see (Casati, R. & Varzi, A., 1996)): intuitively, we say that an occurrence is homeomeric iff all its temporal parts can be described *in the same way* used for the whole occurrence: for instance, every temporal part of "my sitting here" for an hour is still a "sitting here of mine". But if we consider "Messner's ascent to Everest" (intended in the complete sense), no parts of it are a "Messner's ascent to Everest". To formalize this notion, we need to refer to a certain property that holds for all the temporal parts of a certain occurrence *o*. We individuate this property by considering the most specific *occurrent* of *o*, i.e. the most specific occurrence type *o* is instance of. Then we can say that *o* is homeomeric iff all its temporal parts are instances of the same most specific occurrent.

The second dimension takes inspiration mainly from (Smith, B., 1982). An occurrence is said *non-relational* when only one object participates to it, while it is *relational* when it has two or more objects as participants. Occurrences involving qualities varying in time (i.e., which can change their qualia in time) are prototypical examples of non-relational occurences: the change of color of a rose has only one object as a participant (there may be other participants, such as the rose's color, but this is a quality and not an object).

In our proposal, homeomery seems to be enough to account for the distinctions proposed in the literature (especially (Mourelatos, A., 1996)) among *states*, *processes*, and *accomplishments*. It is easy to see that states are homeomeric occurrences (e.g., "the air smelling of jasmine"), while *accomplishments* are non-homeomeric (e.g. "the sunset"). Processes can be characterized as *weakly non-homeomeric*, in the sense that *some* temporal parts of them are instances of the same most specific *occurrent*, and some are not. For instance, in the case of "running", if you consider that instantaneous temporal part of your running through the park in which your right foot touches the ground while your left foot does not (think about photo-finish in a race), this sub-event is no more a "running". Together, processes and accomplishments are often described as *dynamic events*, just because of an (apparent) change of some of their properties across their different temporal parts.

In any case, we can further divide each of these categories into relational and non-relational occurrences.

1.2.6 Abstracts

Like mental-object and their qualities, abstracts are enduring entities that do not have a spatial location (indeed they do not have any "physical quality"). Differently from mental-object and their qualities, abstracts are independent from objects (and in particular from persons). Exam-

ples of abstracts are *sets, symbols, propositions, structures*, and *physical laws.*

4 Mapping WordNet into the OCT ontology

Let us consider now the results of integrating the WordNet top concepts into our top-level. According to the OntoClean methodology, we have concentrated first on the so-called *backbone taxonomy*, which only includes the rigid properties. Formal and material roles have been therefore excluded from this preliminary work.

Comparing WordNet's unique beginners with our ontological categories, it becomes evident that some notions are very heterogeneous: for example, Entity looks like a "catch-all" class containing concepts hardly classifiable elsewhere, like Anticipation, Imaginary_Place, Inessential, etc. Such synsets have only a few children and these have been already excluded in our analysis.

The results of our integration work are sketched in Table 2. Our categories are reported in the first column; the second column shows the WordNet synsets that are *covered* by such categories (i.e., they are either equivalent to or included by them); the third column shows some hyponyms of these synsets that were rejected according to our methodology. Finally, the last column shows further hyponyms that have been appended under our categories, coming from different places in WordNet. The problems encountered for each category are discussed below.

4.1 Aggregates, Objects, and Features

Entity is a very confused synset. As sketched in the table, a lot of its hyponyms have to be "rejected": in fact there are roles (Causal_Agent, Subject_4), unclear synsets (Location[15]) and so on. This Unique Beginner maps partly to our Aggregate and partly to our Object category. Some hyponyms of Physical_Object are mapped to our new top concept Feature.

By removing roles like Arrangement and Straggle, Group$grouping becomes a partition of the Ordinary Object category. In fact, hyponyms like Collection, Social_Group, Biological_Group, and so on, are nothing but plural objects, supporting a clear unity criterion.

Possession_1 is a role, and it includes both roles and types. In our opinion, the synsets marked as types (Asset, Liability, etc.) should be moved towards lower levels of the ontology, since their meanings seem to deal more with a specific domain - the economic one - than with a set of general concepts (except some concepts that can be mapped to Mental Object, such as Own_Right). This means that the remainder branch is also to be eliminated from the top level, because of its overall anti-rigidity (the peculiarity of roles).

4.2 Abstracts and Qualities

ABSTRACTION_1 is the most heterogeneous Unique Beginner: it contains abstracts such as Set_5, mental objects such as Chromatic_Color (an example of quality space[16]), qualities (mostly from the synset Attribute) and a hybrid concept (Relation_1) that contains mental objects, concrete entities (as Substance_4[17]), and even meta-level categories (see §2.2.2). Each child synset has been mapped appropriately.

Psychological_feature contains both mental objects (Cognition[18]) and events (Feeling_1). We consider Motivation as a material role, so to be added to lower levels of the taxonomy of mental objects.

The classification of qualities deals mainly with adjectives. This paper focuses on the WordNet database of nouns; nevertheless our treatment of qualities foreshadows a semantic organization of the database of adjectives too, which is a current desiderata in the WordNet community (see (Fellbaum, C., 1998), p. 66).

4.3 Occurences

Event_1, Phenomenon_1, State_1 and Act_1 are the Unique Beginners of those branches of WordNet denoting events. WordNet does not support the distinction between relational and non-relational occurrences, so first of all, in order to restructure this partition of the top level, we need to separate the hyponyms of the above-mentioned four synsets by means of our defined first dimension. We see, for example, that State_1 maps in part to non-relational state (condition$status, cognitive_state, existence, death_4, degree, skillfulness…), in part to relational state (medium_4, relationship_1 and relationship_2, disorder, order, hostility, conflict…). We register a similar behavior for the children of Process (a subclass of Phenomenon_1): decrement_2, increment and shaping could be seen as kinds of process involving a single main participant, while chelation, economic_process, execution and some hyponyms of Natural_Process (a direct hyponym of Process) seem to denote relational occurrences. Under Act_1 we find in general events of two kinds: processes (see activity_1 and its hyponyms) and accomplishments (see the homonymous synset under action_1). For sake of simplicity, we consider the hyponyms of Act_1 as being both relational and non-relational, depending on the context in which they are used. Event_1 has a too much generic composition in order to be partitioned clearly in terms of our approach (see, for instance, the beginning of §2.2.1): to a great extent, however, its hyponyms could be added to lower levels of the taxonomy of occurrences.

5 Conclusions

The final results of our integration effort are sketched in Figure 3. Our results show that a serious taxonomy rearrangement is needed. The blind application of OntoClean's taxonomy evaluation methodology provides a first guideline, but stronger ontological commitments seem to be unavoidable in order to get a "disciplined" taxonomy. In our opinion, strong (and explicit) ontological distinctions do also reduce the risk of classification mistakes in the ontology development process, and simplify the update and maintenance process.

Our research is still in progress: we hope we have paved

[15] Referring to Location, we find roles (There, Here, Home, Base, Whereabouts), instances (Earth), and geometric concepts like Line, Point, etc.).

[16] By looking to the corresponding hyponyms, it becomes clear that this synset could also be viewed as denoting a quality (by means of this we decide to append it both under Quality and Quality Region top concepts).

[17] "The stuff of which an object consists".

[18] "The psychological result of perception, and learning and reasoning".

the way for future work and possible cooperation.

Parallel Hierarchies in the Verb Lexicon

Christiane Fellbaum

Cognitive Science Laboratory, Department of Psychology
Princeton University, Princeton, NJ 08544, USA

Abstract

We discuss semantically heterogeneous manner-relations in the verb component of a lexical database. To make verb hierarchies more consistent while at the same time including instances of links among verbs that are based on expectancy instead of logical necessity, we propose to augment the lexical database with a parallel relation among hierarchically organized verbs. Possibilities for identifying instances of para-troponymy in corpora are outlined and the advantages of an enriched lexical database for NLP are briefly discussed.

1. Introduction and Background

It has been pointed out that the noun hierarchies in WordNet are built on heterogeneous subsumption relations (Gangemi et al., 2001; Gangemi et al., 2002; Guarino and Welty, 2001). The most common violation of the subsumption relation is the failure to distinguish Types and Roles (Guarino and Welty, 2002). Thus, WordNet lists as subordinates of the synset *dog, domestic_dog, Canis_familiaris* such synsets as *poodle, poodle_dog, Newfoundland*, and *corgi, Welsh_corgi* along with synsets like *cur, mongrel, mutt, lapdog, hunting_dog,* and *working_dog*. (Gangemi et al., 2001; Gangemi et al., 2002) propose eliminating from WordNet violations of strict subsumption (Type) relations and moving Roles like *student* to lower levels of the taxonomy.

Some of WordNet's verb hierarchies exhibit heterogeneous kinds of subordinates that seem intuitively similar to the Type/Role distinction among the nouns. For example, among the manner-subordinates of *clean*, we find *steam-clean* along with *brush, sweep*, and *wipe*. One of our goals here is to examine the heterogeneous manner-of relations in WordNet's verb component. Referring to work in progress, (Gangemi et al., 2002) briefly outline a clean ontology of events, categorizing them on the basis of criteria such as aspect and intentionality. Their examples are all complex events, such as *conducting a symphony* and *running a 100-meter race*. The number and nature of the event's participants as well as its spatial and temporal parts provide criteria for the ontological status of the events.

WordNet's verb entries are for the most part simple lexical items and do not include the kinds of complex events cited in (Gangemi et al., 2002). To the extent that WordNet is an ontology, it is a strictly lexical ontology whose entries are limited to concepts that are lexicalized in English[1]. WordNet resembles a traditional dictionary or thesaurus in that it does not explicitly account for aspectual or argument-taking properties of verbs (though verbs that are hierarchically related frequently share the same valency and aspectual properties). Therefore, the criteria for a clean ontology of events outlined by (Gangemi et al., 2002) are not applicable, and, indeed, may be complementary to the present discussion. Our treatment of simple verbs must necessarily be less ambitious, though we hope, no less interesting.

Besides offering some theroretical reflections, this paper attempts to outline how the different manner relations among the verbs could be constructively exploited and how corresponding links might be added to WordNet. Distinguishing and introducing a second manner relation parallel to the existing one would not only ensure semantically consistent relations but also yield a richer and more tighly interconnected network with a greater potential for NLP applications.

2. Hierarchies in WordNet's Verb Lexicon

In WordNet (Fellbaum, 1998), a word's meaning is represented by its membership in a group of cognitively synonymous words (a synset), and labelled pointers among the synsets that stand for semantic relations such as hyponymy, meronymy, and opposition.

The semantic relation that organizes most of the verbs in WordNet is the manner relation, or troponymy (Fellbaum, 1998). This relation allows one to build hierarchical structures akin to those found in the noun lexicon. Similar to the hyponymy relation expressable by the formula "X is a kind of Y", the formula for troponymically related verbs is (1):

(1) to X is to Y in some manner/way

For example, *stammer*, *lisp*, and *whisper* are among the many manner subordinates of *speak*, as the statement "to stammmer/lisp/whisper is to speak in some manner" shows.

Thus, WordNet expresses (part of) the meaning of verb X in terms of the meaning of its superordinate, Y. And the meaning of verb Y is expressed, in part, as the sum of the meaning of its subordinates (troponyms), such as X.

The manner relation is highly polysemous, as (Fellbaum, 1998) notes. Depending on the semantic domain, the differentiae distinguishing the superordinate from the more specific subordinate may be dimensions like speed (*walk-run*), direction (*move-rise*), volume (*talk-scream*), or intensity (*persuade-brainwash*). Despite these differences, the formula given in (1) seems to fit thousands of English verb senses and could be used to construct WordNet's extensive net, which currently includes well over 13,000 verb synsets.

3. Heterogenous Troponymy Relations

Most verbs fit neatly into a given hierarchy and can be assigned to a clearly identifiable superordinate (following

[1] WordNet's verb component contains a few non-lexicalized nodes that are arguably occupied by lexical gaps. See (Fellbaum and Kegl, 1989) for discussion.

an initial stage of identifying and coding top-level concepts, WordNet was constructed bottom-up). But if one examines specific hierarchies, it becomes clear that the relation is not just polysemous along the dimensions referred to above, but semantically heterogeneous.[2]

For example, *exercise* has subordinates like *jog*, *swim*, and *bike*. But these are clearly also manners of *moving/travelling*[3]. Both the following statements are true:

(2) to jog/swim/bike is to exercise in some manner

(3) to jog/swim/bike is to move in some manner

But clearly, there is a difference. The relation between *jog*, *swim*, *bike* and *exercise* is defeasible: Not every jogging/swimming/biking event is necessarily an exercising event. By contrast, every jogging/swimming/biking event is necessarily a moving event:

(4) She jogged/swam/biked but did not exercise

(5) *She jogged/swam/biked but did not move

The concept *exercise* is definable only by means of subordinates like *swim*, *jog*, and *bike* that are shared with another subordinate, *move*. But *move* has many subordinates that are not shared with *exercise*, such as *fly* and *drive*.

The relation of *jog*, *swim* and *bike* to their superordinates *move* and *exercise* is similar to that between, e.g., *dog*, *cat*, and *goldfish* to *animal* on the one hand and to *pet* on the other hand:

(6) A dog/cat/goldfish is a kind of pet.

(7) A dog/cat/goldfish is a kind of animal.

(8) That's my dog/cat/goldfish, but it is not a pet.

(9) *That's my dog/cat/goldfish, but it is not an animal.

Just as one can recognize dogs, cats, and goldfish as animals, but not (necessarily) as pets (Guarino, 1999), so one can recognize instances of biking, swimming, jogging as moving events, but not (necessarily) as exercising events. Unlike moving, the exercise component of biking, swimming, and jogging does not supply an identity criterion and is notionally dependent. Applying the terminology of (Guarino and Welty, 2001; Guarino and Welty, 2002) for nouns to verbs, we could say that *moving* is a rigid property, and *exercising* is an anti-rigid property of a biking/swimming/jogging event. Thus, verbs like *exercise* are similar to role nouns like *pet*, and *move* is similar to type nouns like *animal*.

[2]Some of the examples discussed here are not in fact coded in the current version WordNet, 1.7.

[3]For the sake simplification, we omit other nodes that may intervene; e.g., *jog* is linked to *move* via *run*.

3.1. Consequences for a Lexical Database

(Gangemi et al., 2002) propose an important criteria for "cleaning up" an ontology like WordNet: An anti-feature cannot subsume a feature. Thus, anti-rigidity cannot subsume rigidity. (Gangemi et al., 2002) advocate eliminating all violations of this principle found among WordNet's nouns. This would cut out hierarchical links between synset pairs like *animal* and *fictitious_animal*, while leaving intact the relation between pairs like *animal* and *horse*.

3.2. Arguments for Including Heterogeneous Troponymy Relations

The verb component of WordNet contains (perhaps many) cases of heterogeneous subsumption relations, and these must be recognized and distinguished. But we argue for retaining the corresponding pointers and, in fact, for coding more instances. Our arguments are grounded largely in a pragmatic view of WordNet as an NLP tool, rather than as an ontology that is perfectly consistent with strict logical principles.

First, if links between verbs like *bike* and *exercise* were eliminated in favor of links such as between *bike* and *move, travel*, important and potentially valuable information would be lost. In some cases, the semantic relation between words that are not conforming to strict subsumption principles is more salient than between words that are properly linked. This point will be discussed further later on.

Second, lexical databases that are useful for NLP gain from a tight network of relations. Word sense disambiguation, anaphor resolution, and applications relying on measures of textual cohesion can benefit from links such as between *bike* and *exercise*.

Finally, a random search in the WordNet shows up a fair number of subsumption violations of the *jog/swim/bike* as a manner of *exercise* kind. They are not simple lexicographic errors, as demonstrated by the goodness of the formula *to jog/bike/swim is to exercise in some manner*. But at present, we don't know how common such relations are, nor whether they are distributed evenly throughout the lexicon. Eliminating them when found would preclude a systematic study of the range, variety, and distribution of these relations and a better understanding of the structure of the lexicon.

4. Representing Different Kinds of Verb Hyponymy

Various possibilities exists for representing links between *bike, swim, jog* and superordinates like *move* on the one hand and *exercise* on the other hand.

First, each verb could be linked to multiple parents by means of the same labelled "manner" pointer. However, this "tangled hierarchy" approach is clearly unsatisfactory, as it implies that every jogging/swimming/biking event is both an exercising and a moving event, when in fact only the latter is true.

The second possibility is to posit two distinct senses each for verbs like *swim*, *bike* and *jog*, each sense with a different superordinate, here *move* and *exercise*. Some traditional dictionaries take this route; for exampe, *jog* is

represented in the *American Heritage Dictionary* as having distinct *running* and *exercising* senses. But this solution has the undesirable effect of increasing polysemy. More seriously, positing two distinct senses misses the fact that is every instance of jogging-as-exercise is necessarily also an instance of moving.

A better way to capture the relevant semantic facts is to introduce two distinct kinds of super-/subordinate relation linking a single verb to two superordinates. In addition to strict hyponymy, there would be a parallel hyponymy relation with the appropriate properties.

4.1. Para-troponymy

(Cruse, 1986) proposes a relation dubbed *para-hyponymy* for organizing nouns like *dog* and *pet* hierarchically. Like regular hyponymy, para-hyponymy admits the formula *Xs and other Ys*, where X is the subordinate and Y the superordinate: Both *roses and other flowers* and *dogs and other pets* are good. This formula can easily be adopted for verbs, and fits both strict hyponymy and para-hyponymy:

(10) Biking/swimming/jogging and other manners of moving/travelling

(11) Biking/swimming/jogging and other manners of exercising

To distinguish strict hyponymy from para-hyponymy among nouns, (Cruse, 1986) cites the *but*-test:

(12) It's a dog, but it's not a pet

This test shows that the hyponymy relation between *pet* and *dog* is first, expected, and second, defeasible.

Para-hyponymy can easily be applied to concepts expressed by verbs. The pairs *walk* and *exercise*, *jog* and *exercise*, *bike* and *exercise* etc. are all good in the *but not* frame:

(13) It's a walking/jogging/biking event but it's not an exercising event.

To distinguish this relation in the verb lexicon from para-hyponymy among nouns, we will call it para-troponymy. Our proposal for WordNet or a similar lexical database designed for NLP applications then is to include among the verb relations both strict troponymy and para-troponymy.

Other examples of verbs related by para-troponymy are listed below[4]. *Brush, wipe, sweep* are para-troponyms of *clean* and troponyms of *rub*; by contrast, *steam-clean, dry-clean* are strict troponyms of *clean*. *Nod, wink, scowl, frown, pout* are para-troponyms of *gesture*, *communicate* and troponyms of *move [a specific bodypart]* (omitting several intervening nodes).

[4]The examples of para-troponyms that we have found so far intuitively suggest a similarity to the telicity of Role nouns in para-hyponymic hierarchies; para-troponyms refer to events with a specific purpose or goal, as noted in (Fellbaum, 2002)

5. Expectation

(Cruse, 1986) notes that para-hyponymy is defined not by logical necessity but by "expectation." While intuitively convincing, this notion immediately raises several questions. How can expectation be characterized? Can it be quantified? How can pairs of verbs related by para-troponymy identified in the lexicon? And how do we know whether, say, a verb token *jog* in a corpus refers to an exercising event or (merely) to a running event?

To begin with, expectation is often context-dependent rather than inherent in the concept. In some contexts, a given verb's interpretation as a para-troponym is more salient, whereas in other context, its reading as a strict troponym of another superordinate is more appropriate:

For example, *move* is more salient in (14), but *exercise* is more salient in (15):

(14) a. The boat capsized and we had to swim to the shore.

(14) b. My car is in the repair shop so I'll bike to work.

(14) c. It started to rain heavily so she ran into the library.

(15) He swims/bikes/runs 3 miles every morning before work.

Some contexts allow for an underspecified reading:

(16) He jogged to the store.

More specifically, the nature of the verb's argument projection may play a role in setting up the expectation and the appropriate reading in some cases. *Clear dishes from the table*, where the Locatum entity is the direct object, seems to favor the *remove* reading (the strict superordinate) rather than the *clean* reading (the para-superordinate); *clear the table of dishes*, with the Location entity in direct object position, appears to favor the *clean* interpretation.

Second, the degree of expectation may differ across verbs independently of specific contexts. For some verbs, the para-relation is stronger than the strict relation, and the reverse may be true for other verbs. For example, *jog* intuitively is more strongly associated with its para-superordinate *exercise* than with its logical superordinate *run, move*. This is reflected in the fact that some dictionaries have distinct running and exercising senses for *jog*, as noted earlier. Conversely, *walk* seems be more strongly associated with *move* that with *exercise*. *Walk* seems like a less canonical form of exercise than *jog*, and thus exhibits a weaker association with its para-hypernym and a correspondingly stronger link to its strict superordinate.

The relative frequency of one reading as compared to another presumably influences expectation. Just as, say, hawks as pets may be more conventional in certain cultures than in others, there are probably cultures where jogging is not done for exercise purposes but, say, for pursuing game in a hunt.

Of course, the higher frequency of one reading as compared to the other makes the former more expected and thus stronger. It would therefore be desirable to firm up intuitions about the relative strength or weakness of the (para)troponymy relation with the aid of corpus data.

Almost any verb that is a hyponym of *move* could be made a para-troponym of *exercise*, just as any animal can be called a pet. If one wants to code para-relations in the database, it is important to avoid flooding it with links that reflect readings with very low expectancy. Here, too, corpus data would be useful to identify genuine from spurious para-links.

6. Para-tronomymy in the Lexicon

This paper has cited only a handful of examples of para-troponymy. At this point, we don't know how prevalent this relation is in the lexicon, or how many cases of concepts that exist merely by virtue of contingent subordinates are lexicalized in English. To find them, we need characteristic syntactic frames and a tool to search a corpus for appropriate occurrences of such patterns[5]. This section merely offers some thoughts and suggestions for future work.

We saw that para-troponyms pass the tests adapted from the one for para-hyponymy; in this respect, para-troponyms are indistinguishable from strict troponyms:

(17) X-ing and other manners/ways/methods of Y-ing.

(18) To X is to Y in some way/manner.

Using Google to search the Web for the string *and other manners/ways of*, we turned up quite a few examples of para-troponymy and para-hyponymy, as well as some cases of regular troponymy and noun hyponymy, in addition to cases of verbs co-occurring with nominalizations. Here are some cases of para-troponymy:

(19) Flirtation, courting and other manners of getting the attention of the opposite sex is certainly a form of manipulation ... www.mothersmagic.net/Goddess/maiden.html

(20) Befriending, listening and other ways of helping.... www.britishcouncil.org/sudan/science/ - 17k

(21) volunteering and other ways to help www.fcs-sf.org/page5.html

(22) Home Cooking and other ways to save Money. www.geocities.com/ dvsclothing/cooking.html

(23) Walking and other exercise use many muscles. www.lungusa.org/diseases/exercise.html

(24) activities that repeatedly flex the knee (ie, jumping, squatting, running and other exercise). orthoinfo.aaos.org/fact/thr_report.cfm? Thread_ID=252&topcategory=Knee

(25) Swimming, running, biking, walking and other exercise that are at a time length of over 20 minutes.. www.pmssolutions.com/Hiddentruth.html

To limit the search to para-troponyms, we searched for instances where the expected relation is negated, as in the pattern in (26):

(26) It's X-ing but not Y-ing
(e.g., it's swimming but not exercising)

We found:

(27) ...and then spraying the action with a little WD-40 is not cleaning. It is a slow methodical destruction of a considerable investment. Like everything ... www.doubleought.com/cleaning.html

(28) No, this is not "cleaning for the cleaning lady", it's picking up so that the cleaning lady can clean ... www.bitchypoo.com/2000/May/11.html - 7k

Similarly, on can search for cases where the para-hyponymy is asserted, possibly over a negative presupposition, as in the pattern in (29):

(29) This X-ing is Y-ing
(e.g., This swimming is exercising)

A web search turned up examples like these:

(30) Shotblasting is a way of cleaning or preparing surfaces for recoating, using an abrasive material forced through a jet nozzle... www.westshotblasting.co.uk/

(31) ... shake hands, using the right hand, and explain that this is a way of greeting one another. Pair up children and allow them to practice shaking hands. www.atozkidsstuff.com/math.html

(32) Tipping-leaving a gratuity-is a way of thanking people for their service. www.istudentcity.com/stages/3mannerstipping.asp

Another possibility is to examine co-occurrences of verbs in contexts for cases of (defeated) para-troponymy, without using any specific patterns. The following are actual examples:

(33) really get the job done. If the goal is to have clean sidewalks, they're going to have to be swept and bagged, not just blown. www.heartlight.org/two_minute/2min_971015.html

(34) will be swept by City crews. Residential streets are now swept once a month, while downtown streets are cleaned three times a week... www.ci.walnut-creek.ca.us/street

(35) These sociologists think that interrupting is a way of exercising power. They say, "Here we are dealing with a class of speakers ... www.glc.k12.ga.us/qstd-int/ancill/guidance/schoices/sc-f20.htm

We hope to develop more sophisticated and efficient ways for finding para-relations in the lexicon in the near future and to test their usefulness in applications.

[5]Resnik, Fellbaum, and Olsen are currently developing a tool to search the Web for specific syntactic patterns.

7. Summary and Conclusions

We have argued for retaining instances of paratroponymy in a lexical database like WordNet. Furthermore, we advocate collecting and adding naturally attested cases of this relation. Semantic relations that are not based on logical necessity but on expectations grounded in pragmatics or world knowledge are an interesting area for research in lexical semantics. Enriching a lexical database with para-relations can not only shed light on the organization of the lexicon, but may yield benefits for NLP applications relying on this database.

8. Acknowledgment

We thank Alessandro Oltramari for commenting on an earlier version of this paper. This work was supported by grant number IIS-ITR 0112429 from the National Science Foundation to the author.

On the Ontological Basis for Logical Metonomy

Telic Roles and WORDNET

Sandiway Fong

sandiway@research.nj.nec.com

Abstract

The analysis of examples of Logical Metonomy, where an event-taking verb is combined a non-eventive object, intuitively involves the recovery or insertion of a missing verb generally known as a Telic Role. For example, for *Mary enjoyed the meal*, an appropriate might be *eat*, i.e. *Mary enjoyed eating the meal*. The question for lexical semantics is where do telic roles reside and how are they accessed? In this paper, we investigate the use of WORDNET, a widely used semantic network, both as an appropriate repository and also as an organization suitable for the recovery or assignment of telic roles.

1. Introduction

The interaction of aspectual verbs such as *begin* or *finish* with simple, non-eventive noun phrases (NPs) has been used to motivate an account of *logical metonymy* in which telic (purpose/function) and agentive (creation) roles are distinguished components of the lexicon, see (Pustejovsky, 1995). Others, e.g. (Lascarides and Copestake, 1995) and (Verspoor, 1997), have highlighted the role of context and convention. Consider (1).

(1) a. John began the novel (*reading*/*writing*)
b. The author began the unfinished novel back in 1962 (*writing*)

(1a) can mean *John began reading the novel*, accessing the functional sense or telic role of *novel*, or *John began writing the novel*, accessing the specific means of creation or agentive role of *novel*. The telic/agentive role ambiguity seen in (1a) can be made less apparent in context, either within the same sentence, as in (1b) above, or through discourse or semantic inference, as in (11) and (12), to be discussed below. Note that there are important constraints, e.g. with respect to boundedness and aspect, on the possible NPs that can appear with *begin*. See (Verspoor, 1997) and the references cited therein for discussion of the relevant factors.

Other verbs such as the subject-experiencer psych verb *enjoy*, or verbs such as *refuse*, exclude the agentive role.[1] For example, contrast (2a) with (1a).

(2) a. Mary enjoyed the novel (*reading*)
b. Timmy refused the meal (*to eat*)

In (2b), *refuse* can access the telic role for *meal*, namely *to eat*. However, there is room for ambiguity here; (2b) is also compatible with the interpretation *Timmy refused* to accept *the meal*, cf. (3) below.

(3) Timmy refused the present (*accept*)

In (3), arguably the telic role of *present*, meaning *gift*, is *accept*. However, the same account cannot be posited for *meal*; its basic function (if one exists) is to be consumed or eaten; thus creating a problem for enumeration in lexical representation. In other cases, such as (4), there is no (felicitous) telic role at all.

(4) a. !John enjoyed the rock
b. !!John enjoyed the door

A physical object like *rock* has no obvious function. Yet (4a) can be marginally interpreted in the context that some (physical) aspect of the object gave *John* pleasure, e.g. its appearance as in *John enjoyed looking at the rock*. Or we can appeal to other perceptual properties, e.g. the tactile sense as in *the blind man enjoyed* touching *the rock*. To take one more example, consider (5):

(5) Mary enjoyed the garden

The prototypical definition of a garden as a pleasing arrangement of plants and other natural (or non-natural) objects admits not only the (putative) telic role *to see* but also a range of other possibilities, illustrated in (6).

(6) a. Mary enjoyed *seeing* the garden
b. Mary enjoyed *inspecting* the garden
c. Mary enjoyed *visiting* the garden
d. Mary enjoyed *strolling* through the garden
e. Mary enjoyed *rollerblading* in the garden
f. Mary enjoyed *sitting* in the garden
g. Mary enjoyed *dozing* in the garden

The ease of defeasibility of telic roles and the productivity of plausible alternatives is striking. In general, the recovery of appropriate contextual function falls outside the domain of local or specific lexical knowledge. It belongs more appropriately to systems that carry out reasoning and inference about the real world.

In fact, the recovery of contextual function is more ideally suited to ontological networks, which encode general semantic relations between abstract and concrete concepts

[1] *Enjoy* can take *write* explicitly, as in *Mary enjoyed writing the novel*. But this is not an instance of what Pustejovsky terms "coercion".

in the real world. This paper explores the application of such a network, WORDNET, to this problem. In particular, we will make use of the *isa*, or hypernymy, relation on, assuming (as required) the existence of certain commonsense, or real-world, properties of higher-level concepts, to account for a range of data.[2]

2. Hypernymy

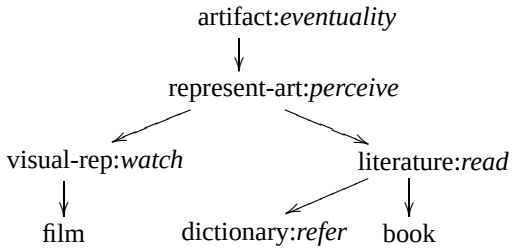
The idea that hypernymy may inform interpretation in logical metonymy has already been hinted at, or tacitly assumed, in several places in the literature. For example, this is apparent from the summary of logical metonymy in the BNC corpus, (Verspoor, 1997), excerpted in (7):

(7) eat FOOD/MEAL
drink LIQUID
tell STORY
play MUSIC
read/write WRITTEN_OBJECT
take MEDICINE/TREATMENT

(The capitalized terms in (7) denote semantically relevant concepts.)

(Lascarides and Copestake, 1995) assume the following telic roles for artifacts:

(8)



Finally, (Asher and Pustejovsky, forthcoming) assert the following complex types ($\otimes$ a type constructor):

(9) a. $p \otimes see$ and $p \otimes hear$ to encode the fact that objects with extension are typically visible, and objects involving sound are typically audible, respectively.
b. all artifacts inherit a general dependent type that gives their cause.
c. *wine*: liquid $\otimes_T$ drink ($\otimes_T$ introduces the telic role)
d. *class*: people $\otimes_T$ teach

In this paper, we explicitly test the hypothesis using the somewhat coarse-grained *isa*-relation available in WORDNET.[3] In conjunction with two principles, specificity and locality, defined with respect to hypernymy, we explain why telic/agentive roles are available for some cases but not for others. If this is the case, the locus of variation should be in ontological not lexical structure (as suggested by lexical entries such as the following):

(10) *novel*(y): telic:λx.*read*(x,y) agentive:λx.*write*(x,y)

In fact, in generative grammar, the lexicon is generally taken to be a repository of exceptions, see (Chomsky, 1965) citing Bloomfield. In this framework, non-idiosyncratic properties are factored out into grammar or further afield. Obviously, the evaluation of properties implicating mechanisms peculiar to language must stay within the domain of the language faculty. Non-language particular properties are perhaps best assimilated to general systems of reasoning and cognition.

Ontological relationships play a large role in lexical semantics and, more generally, semantic inference. Any account of language phenomenon involving the interaction of lexical entries with inheritance and (semantic) class-based behavior falls into this category. Computation involving defeasible reasoning and knowledge about the physical properties of objects in the real world should therefore fall outside the scope of the lexicon.

Furthermore, as (11), from (Lascarides and Copestake, 1995), illustrates, telic roles are easily overridden through discourse priming:

(11) a. He really enjoyed your book (*reading*)
b. My goat eats anything. He really enjoyed your book (*eating*)

Even in cases where arguably no felicitous telic role exists to be overridden, as in (12a), discourse may play a part in supplying the missing event, as in (12b):

(12) a. !He enjoyed your shoe[4]
b. My dog eats everything. He really enjoyed your shoe (*eating*)

3. The WORDNET Framework

3.1. The Hypernym Hierarchy

In WORDNET, nouns are grouped into synonym sets, known as "synsets", representing single concepts. For example, *cigarette*, *coffin nail*, *butt* and *fag* are generally substitutable, and thus belong to the same synset. Concepts are related through (possibly iterated) application of the hypernymy ("$\rightarrow$") or *isa*-relation, illustrated in (13).[5] Inheritance is strictly unidirectional in this model. For example, *tobacco* may be termed a *street drug*, but the reverse need not be true. Furthermore, multiple inheritance may obtain for some concepts. For example, *tobacco* is a *plant product* as well as a *street drug*.

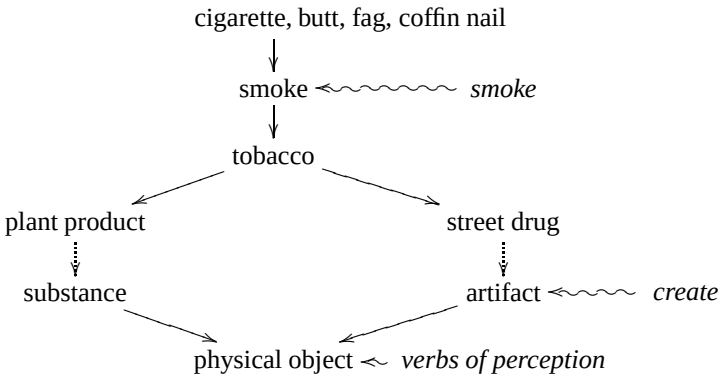
[2]The idea of using WORDNET on object NPs to pick out contexts in which those NPs represent events on a class-based model is not new. (Siegal, 1998) performed a (medical) corpus study in conjunction with WORDNET to distinguish eventive and stative *have*, e.g. *the patient had a fever* (stative)/*blood loss* (eventive).

[3]As (Gangemi et al., 2001), have noted, WORDNET's hypernymy relation is a heterogeneous one, merging functional and non-functional *isa*-relations alike, e.g. isa(tobacco,plant_product) and isa(tobacco,street_drug).

[4]In the framework described in this paper, *shoe* is a "foot covering". The telic role is cover(NP,FOOT), which is incompatible with prototype V(PRO,NP) defined in section 3.. The next higher concept is "footwear" with telic role *wear*, perhaps accessed in contexts like *He enjoyed the comfortable shoes you lent him*.

[5]For brevity, a dotted arrow ("$\dashrightarrow$") will sometimes be used to represent a hypernym sequence.

(13)

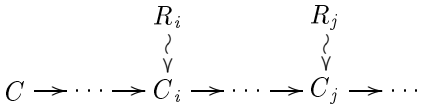


In this paper, we will assume annotation of concepts with characteristic verbs where relevant (to be indicated by "$\lesssim$"). For example, in (13) *artifact*, defined in the gloss as a "man-made object", is associated with the verb *create*. Similarly, the noun *smoke* is associated with the related verb *to smoke*.[6] Finally, the concept *physical object*, defined as "a tangible and visible entity", is characterized by verbs of perception such as *see*/*look at* and *touch*.

3.2. Contextual Function Search Rules

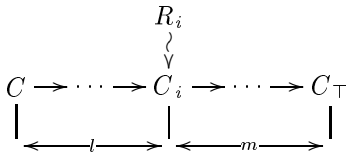
In this paper, we employ two simple principles of contextual function search over the hierarchy outlined above. In the following section, concepts will be denoted by (subscripted) C. R_i will denote a characteristic verb for a concept C_i. Given a noun $N \in C$, we have the rule of preference (14):

(14) **Principle of Specificity**: Prefer R_i to R_j in the sequence



In other words, prefer a closer role R_i over a more general one R_j in the concept chain. The (one-way) hypernymy relation relates a specific concept to a more general concept, so the closer a matching concept is in terms of the number of links, the more specific it will be. Next, given a noun $N \in C$ and $C_\top$ representing the top or most general concept relative to N, we have the rule of evaluation of the "goodness" of a characteristic verb R_i (15):[7]

(15) **Principle of Locality**: Plausibility of R_i scales with m and inversely with l in



Scalars l and m represent the length of sequences $< C, \ldots, C_i >$ and $< C_i, \ldots, C_\top >$, respectively. The closer C_i is to C (l small), the more plausible R_i will be. On the other hand, if C_i is close to $C_\top$, m will be small, encoding the intution that R_i (then) is a general characteristic that is not strongly associated with specific concept C. Rules (14) and (15) operate in tandem. Although the closest concept is always preferred, *ceteris paribus*, it will be deemed implausible or requiring of strong contextual support if it is many links from C or close to $C_\top$.

3.3. Grammatical Constraints

In what follows, we will consider the problem of determining the value of the verb V in the configuration (16b) given (16a), a restricted version of the telic role determination problem.

(16) a. EXP enjoy NP
b. EXP_i enjoy [PRO_i [V(ing) NP]]

In (16), EXP is the experiencer subject of *enjoy*, NP the object, PRO the controlled subject of V, and V a transitive verb V(PRO,NP). The twin requirements that the NP as must be the embedded object and that the subject be controlled limits the possibilities for telic roles to appear as V, as will be seen in the next section.

4. Worked Examples

Cigarette: Consider (17).

(17) Mary enjoyed the cigarette (*smoking*)

Given the hypernym hierarchy in (13), *smoke*(PRO,*cigarette*) is the strongly preferred interpretation since the concept *smoke* is highly specific (l small) and distant from general concepts *artifact* and *physical object* (m large).

Sonata: Consider the possibilities in (18).

(18) a. Mary enjoyed the sonata (*listening to*/*playing*)

[6] Concepts in WORDNET have associated glosses. A gloss will typically contain a brief definition and examples of use. In some cases, the characteristic verbs can be inferred from the gloss or from members of the synset. Further exploration of this idea is beyond the scope of this paper.

[7] In WORDNET's hypernym hierarchy there is no unique $C_\top$ concept. For example, *dirt* as *material* and as *gossip* have top concepts *entity* and *act*, respectively. See (34).

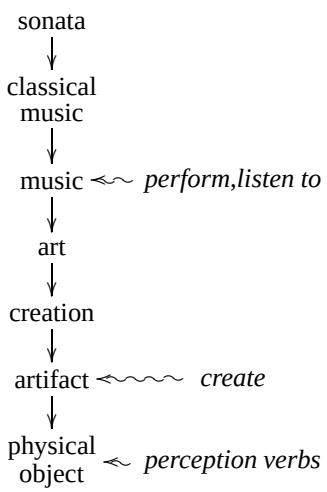
b. Mary began the sonata (*playing*/*composing*)

According to (Asher and Pustejovsky, forthcoming), the agentive and telic roles associated with *sonata* are *compose* and *play*, expressed in their type logic notation as (19).

(19) sonata: $(p \bullet i) \otimes_{A,T} (\text{compose}, \text{play})$

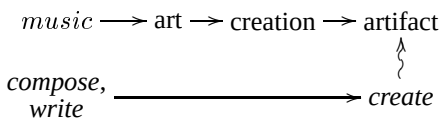
The hierarchy for *sonata* is given in (20).[8]

(20)



(20) predicts that *perform* and *listen to* are preferred in (18a). Verbs *begin* and *enjoy* differ in that *begin* allows an agentive role. This excludes subject-experiencer *listen to* but allows for *perform* and is also compatible with *create*. Note that *create* is associated with the general concept *artifact*. We can turn to WORDNET's verb hierarchy, shown superimposed in (21), to pick out the music-specific sense of *compose*.[9]

(21)

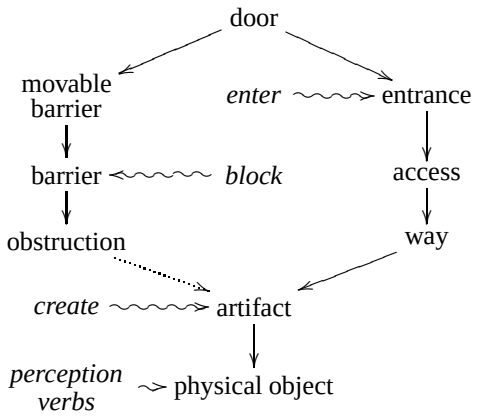


(18b) is explained since *compose* (or *write*) and *perform* are effectively equidistant from *sonata*.

Door: Consider (4b), repeated here as (22), with WORDNET hierarchy (23).

(22) !!John enjoyed the door

(23)

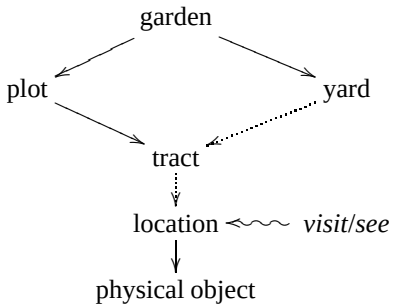


Specifically, a door can function both as an entrance (*enter*) and a barrier (*block*) to an enclosure. However, the telic verb *block* has form *block*(*door*,ENCLOSURE), which is incompatible with the prototype V(PRO,*door*), thus ruling out *block*. Similar reasoning applies to *enter*(PRO,ENCLOSURE). At the other end of the hierarchy, the canonical events associated with *physical object* are predicted to be implausible (l large, m small).

Garden: Consider (5), repeated here as (24), with WORDNET hierarchy (25).

(24) Mary enjoyed the garden (*seeing*/*visiting*)

(25)

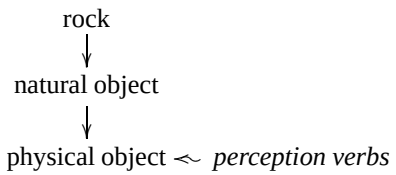


Assuming *visit* and visibility are characteristic of locations in general, (24) is accounted for. General mechanisms involved in reasoning about entailment may also play a large role in grounding *visit*. Note that the possibilities exemplified in (6) all entail *visit*.

Rock: Consider (4a), repeated here as (26).

(26) !John enjoyed the rock

(27)



Unlike *door* in (22), *rock* has no obvious function, as the simple hierarchy in (27) suggests. Hence, relatively speaking, we predict that (26), when picking out perceptual *looking at* or *touching*, is more acceptable than (22) (since l is smaller). However, the value of m is still small, indicating its acceptability can be improved significantly by contextual (discourse) support.

[8] Note, *physical object* $\rightarrow$ *entity* in WORDNET. $C_\top$ = *entity* has been omitted in (20) since *entity* has no possible characteristic functions.

[9] *Compose* and *write* belong to the same synset glossed as "*write music*". Thus the gloss locates this synset with the concept *music*.

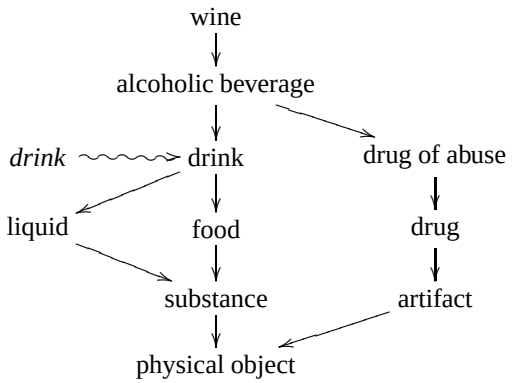
Note that WORDNET does not classify *rock* as a location, cf. *garden* in (5). Given the right context, the characteristic function *visit* may also be felicitous for *rock*, as in (28), where the rock in question is geographically significant.

(28) Mary enjoyed Ayer's Rock (*visiting*)

Wine: Consider (29) with hierarchy (30).

(29) Mary enjoyed the wine (*drinking*)

(30)

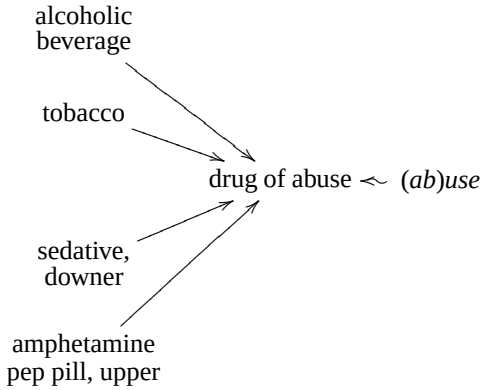


(30) strongly predicts (29) (l small, m large). However, this assumes the branch containing *drug of abuse* (with telic role (*ab*)*use*) is marginalized, i.e. *wine* as *drink* is preferred over *drug of abuse*. Contrast (29) with (31).

(31) Mary enjoyed the amphetamine/sedative (*using*)

(31) is also strongly predicted in our analysis as the elaborated WORDNET hierarchy fragment in (32) illustrates.

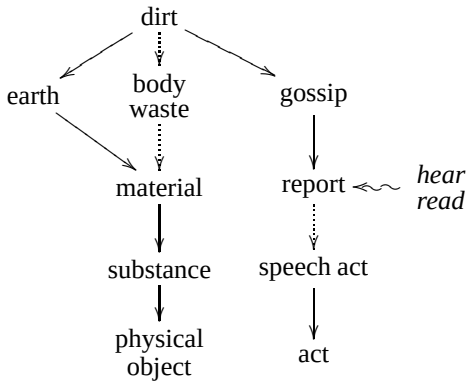
(32)



Dirt: Consider (33) with hierarchy (34).

(33) !John enjoyed the dirt

(34)



In (33), *dirt* as a natural substance has no plausible telic role. The corresponding WORDNET hierarchy is shown in (34). The relevant sense is given by the sequence <*dirt,earth,material,substance*>; the elements of which have no obvious purpose or function. Hence the status of (33).

According to WORDNET, *dirt* is also, perhaps little used, slang for fecal matter. Other (more common) words sharing the same synset are *crap*, *shit*, *poop* and *turd*. The telic role for *body waste*, perhaps *discharge*, is generally available for the synset, as can be seen by substitution of *dirt* in (33). So an appropriately annotated WORDNET makes essentially the right prediction for the synset as a whole. Finally, the right prediction is also made for *dirt* in the sense of malicious gossip, as in (35).

(35) John enjoyed the dirt on OJ Simpson (*hearing about*/*reading about*)

5. Conclusions

In this paper, we have argued for an ontological approach to the problem of logical metonymy using WORDNET's hypernymy relation for non-eventive nominals. That is, we interpret logical metonymy to be a phenomenon belonging to systems of semantic interpretation and general reasoning, governed by simple rules of specificity and locality with respect to concept hierarchy. We have shown, through worked examples, how such a mechanism accounts for data of the sort commonly cited in the literature.

Interesting questions remain for future work. For example, not all concepts in the WORDNET hierarchy have simple lexical realization satisfying the grammatical constraints, the question of what happens with lexical gaps remains. Since languages vary with respect to concept lexicalization, the question of whether the results obtained here generalize to other languages exhibiting logical metonomy remains open.

Differentiae Specificae in EuroWordNet and SIM*u*LLDA

Maarten Janssen

UiL-OTS, Utrecht University
Trans 10, 3512 ED Utrecht, The Netherlands
m.janssen@let.uu.nl

Abstract

(Euro)WordNet, like all other semantic network based formalisms, does not contain differentiae specificae. In this article, I will argue that this lack of differentiae specificae leads to a number of unsurmountable problems, not only from a monolingual point of view, but also in a multilingual setting. As an alternative, I will present the framework proposed in my thesis: SIM*u*LLDA. The SIM*u*LLDA set-up not just contains differentiae specificae (called definitional attributes), but differentiae specificae form the building blocks of the system: the relations between meanings are derived from the application of Formal Concept Analysis to the set of definitional attributes.

1. Introduction

Given the many shortcomings of systems based on semantic primitives, WordNet, like many other lexical databases and knowledge bases, is based on semantic networks (see for instance Miller (**?**)). In semantic networks, there is no need for anything like semantic markers or, as you would call them from a lexicographers point of view, differentiae specificae, since all information is formulated in terms of relations between (in the case of WordNet) synsets. In this article, I will argue that this lack of differentiae specificae leads to a number of insurmountable problems, not only from a monolingual point of view, but also in a multilingual setting.

As an alternative, I will present the framework proposed in my thesis (**?**): SIM*u*LLDA, a Structured Interlingua MultiLingual Lexical Database Application. The SIM*u*LLDA set-up not just contains differentiae specificae (which are called definitional attributes in the system), but differentiae specificae form the building blocks of the system: the relations between meanings are derived from the application of a logical formalism called Formal Concept Analysis (FCA) to the set of definitional attributes.

After the presentation of the framework, I will indicate why definitional attributes do not give these traditional problems by showing that the resulting framework should not be viewed as an ontological hierarchy, nor as a knowledge base, but as a modest lexical database.

In this article, the following notational conventions will be used: meaning-units, in the case of WordNet the synsets, will be typeset in SMALL-CAPS, word-forms are set in sans serif, differentiae specificae, as well as the relations in WordNet, in **bold-face**.

2. The Need for Differentiae Specificae

One of the main aspects of the WordNet system is its ontological hierarchy, provided by the **is_a** links. Although not de facto a separate system (the **is_a** link is just a link as any other), the hierarchy is often presented that way, and many applications of the WordNet database only make use of this ontology. So for the moment I will consider the (ontological) hierarchy of WordNet as a system on its own.

The **is_a** relation links a synset to its *genus proximum* (to use the lexicographer's term), hence strongly characterising the meaning of the synset by indicating what kind of meaning it is. But on its own, the **is_a** link does not fully characterise the meaning of the synset: it fails to distinguish the various hyponyms of the same synset. From the point of view of the hierarchy we also need *differentiae specificae* to keep the meanings/synsets within the same genus apart.

In the WordNet approach, this differentiation is done by means of the other links. As an example, one could define the synset ACTRESS by means of an **is_a** relation to ACTOR, and a **female** relation the other way around (or alternatively a **is** relation to FEMALE). But although the other links in WordNet do provide additional information about the synset, they are not designed to provide differentiae specificae. This shows in two ways: firstly, the other links give information independent of the **is_a** link, which means that they are independent of the information already provided by the **is_a** link. So they cannot structurally supplement the information lacking from the **is_a** link.

Secondly, not all differentiating information can be modelled by means of these other links. Consider for instance the word *millpond*, which **is_a** AREA OF WATER. But a millpond is not just any area of water, it is specifically one *used for driving the wheel of a watermill* (according to LDOCE). And there are no WordNet links for this type of differentiating information.

So differentiae specificae as such do not exist in WordNet, even though in some (or many) cases the differentiating information will be present or can be provided somehow. This absence of a structural modelling of differentiae specificae leads to serious problems. Let me illustrate this using three examples.

The first example is that, according to Vossen & Copestake (**?**), (Euro)WordNet has problems dealing with verb nominalisations: SMOKER is a hyponym of PERSON, but so are RUNNER, SLEEPER, JOGGER, etc. The point here is not so much that distinguishing these nominalisations is impossible in WordNet: in principle, these can be distinguished by means of the **involved_agent** relation. So we can express that the involved agent for SMOKE is SMOKER, and hence by means of backward search say that a smoker is a person *who smokes*. The point is that for synsets with large numbers of hyponyms, there is no structural way of telling them apart: WordNet in many cases depends on the ontological hierarchy, so the less layered it is, the less informative it is.

The second example makes a similar point: because of

the high dependence on hierarchy, WordNet is forced to accept as layered a structure as possible: to indicate the relation between ENEMY and MURDERER, WordNet has to introduce a synset for BAD PERSON, even though there are no words related to that synset. This introduction of 'empty synsets' is not really incorrect, but at least conceptually unattractive.

The lack of differentiae specificae is most disturbing when considered in a multilingual setting. As a third example, consider the Spanish word DEDO. It is a (translational) hyperonym of both the English FINGER, and the English TOE, since a finger is a *dedo del mano*, and a toe is a *dedo del pie*. The way this is modelled in EuroWordNet is as follows: the Spanish DEDO has an **eq_synonym** relation to an InterLingual Item (ILI) DEDO, and both the English FINGER and TOE are related to this same ILI with a relation **eq_has_hyperonym**[1]. In this way, the words finger and toe are correctly modelled as translational hyponyms of dedo.

But in this cross-linguistic linking, there is nothing keeping the two translational hyponyms *finger* and *toe* apart. That is to say, language internally, FINGER will have a **part_of** relation to HAND, and TOE to FOOT, but this information is not (directly) related to the cross-linguistic link to DEDO. Furthermore, if we would use these **part_of** relations to tell the translational hyponyms apart, they would be used as differentiae specificae. And there are other examples in which such differentiae specificae are not available. For instance, the French BIEF will be linked as a translational hyponym of CANAL, but the reason why bief is more specific (namely that it is a canal *bringing water from a stream to a hydraulic installation*) would not be modelled, because WordNet has no links to provide for it.

Such examples show that in a lexical database, there is a definite need for a structural modelling of differentiae specificae, especially in a multilingual setting. Although in this section, the criticism is specifically aimed at (Euro)WordNet, any hierarchy based system without a structural modelling of differentiae specificae will encounter the same problem, though they might show up in a different guise. Let me now turn to the system proposed in my thesis which does use differentiae specificae.

3. SIM*u*LLDA

In my thesis, I describe a multilingual lexical database set-up called SIM*u*LLDA, in which differentiae specificae play a crucial role. The differentiae specificae are modelled within the system by means of entities called *definitional attributes*. The SIM*u*LLDA system is designed to be a multilingual lexical database system from which bilingual definitions between arbitrary pairs of languages in the system can be derived.

The SIM*u*LLDA set-up consists of a number of steps: the data from monolingual dictionaries are reduced to sets of definitional attributes. These sets of definitional attributes are turned into a lattice structure by means of a logical formalism called Formal Concept Analysis (FCA). The result is a lattice structure, which can serve as a structured interlingua, connecting words from different languages. Let me show how this works using a simple example: the words for horses in English. This explanation is very brief; for a more complete explanation I refer to my thesis (**?**).

3.1. Creating Sets of Definitional Attributes

The hierarchical set-up of the SIM*u*LLDA system is best shown using a small and simple lexical field, such as the words for male, female, young, and adult horses in English. The SIM*u*LLDA system aims at modelling lexicographic data, so takes the definitions of these words as found in a monolingual dictionary as a starting point. The relevant definitions are given in table 1 (these are cleaned-up version of the definitions in the Longman Dictionary of Contemporary English, henceforth LDOCE).

colt	a young male horse
fil·ly	a young female horse
foal[1]	a young horse
mare	a fully-grown female horse
stal·lion	a fully-grown male horse

Table 1: Definitions of Words for Horses

The definitions in table 1 are analysed in the SIM*u*LLDA set-up as relating English words to defining aspects of the meanings expressed by these words. These defining attributes are called *definitional attributes*. As an example, the first definition in table 1 relates the word colt to the definitional attributes **male** and **young**. On top of these definitional attributes, colt is related to a sense of horse. But this meaning of horse is itself also related in the dictionary to definitional attributes and a further meaning of animal, etc. This will go on until the genus term is what you might call an *empty genus term*. The claim is that *thing* in a definition reading *a thing which ...* is just there because a lexical definition without a genus term is hard to formulate (in some cases). In this way, all lexical definition can be 'unravelled' into sets of definitional attributes. For simplicity, I will here ignore the relation of the words in table 1 to the word horse, and treat **horse** as if it were a definitional attribute. This leads to a situation in which the definitions in table 1 are analysed as in table 2.

	horse	**male**	**female**	**adult**	**young**
HORSE	×				
STALLION	×	×		×	
MARE	×		×	×	
FOAL	×				×
FILLY	×		×		×
COLT	×	×			×

Table 2: Definitional Attributes for Horses

So in the SIM*u*LLDA set-up, every word expresses a number of meanings, and these meanings are analysed in terms of sets of definitional attributes. And these defini-

[1]This situation is symmetrical in EuroWordNet: DEDO and FINGER are also related via the ILI FINGER. But that has no impact on the example.

tional attributes are nothing more than the accumulated differentiae specificae from their lexical definitions in monolingual dictionaries.

3.2. Formal Concept Analysis

The data in table 2 are organised within the SIM*u*LLDA set-up by means of a logical framework called Formal Concept Analysis (henceforth FCA). FCA was developed by Ganter and Wille in Darmstadt (**?**). It is an attempt to give a formal definition of the notion of a 'concept', within the boundaries of a model-theoretic framework. The idea behind FCA is the following: in a model, those objects that share a common set of attributes belong together; they form the extension of a concept, the intention of which is the set of attributes that they share.

The formal representation of FCA is follows. Take a set of objects *G*, a set of attributes *M*, and a relation *I* relating the objects to the attributes. We define the set of formal concepts $\mathfrak{B}$ over a context (G, M, I) in the following way:

$$B^{\downarrow} = \{g \in G \mid \forall b \in B \,.\, (g, b) \in I\} \quad (1)$$

$$A^{\uparrow} = \{m \in M \mid \forall a \in A \,.\, (a, m) \in I\} \quad (2)$$

$$\mathfrak{B}(G, M, I) = \{\langle A, B\rangle \mid A = B^{\downarrow} \wedge B = A^{\uparrow}\} \quad (3)$$

The way FCA is applied in SIM*u*LLDA is as follows: the meanings in table 2 are taken as formal objects (the elements of *G*), and the definitional attributes relation to them are taken as formal attributes (the elements of *M*). This lead to a set $\mathfrak{B}$ of formal concepts consisting of pairs of sets of meanings and sets of definitional attributes. There are ten such formal concepts in total, which are listed in table 3.

$\langle\{$HORSE, COLT, STALLION, MARE, FOAL, FILLY$\}, \{$**horse**$\}\rangle$
$\langle\{$MARE, FILLY$\}, \{$**horse, female**$\}\rangle$
$\langle\{$MARE$\}, \{$**horse, female, adult**$\}\rangle$
$\langle\{$STALLION, COLT$\}, \{$**horse, male**$\}\rangle$
$\langle\{$STALLION, MARE$\}, \{$**horse, adult**$\}\rangle$
$\langle\{$STALLION$\}, \{$**horse, male, adult**$\}\rangle$
$\langle\{$FOAL, COLT, FILLY$\}, \{$**horse, young**$\}\rangle$
$\langle\{$COLT$\}, \{$**horse, male, young**$\}\rangle$
$\langle\{$FILLY$\}, \{$**horse, female, young**$\}\rangle$
$\langle\emptyset, \{$**horse, female, young, male, adult**$\}\rangle$

Table 3: Formal Concepts for Horses

The formal concepts in $\mathfrak{B}$ have a natural order: formal concepts with more defining attributes are more specific those with less defining attributes. And also, all those objects that belong to a subconcept also belong to its superconcept. So we define an order relation $\leq$ over $\mathfrak{B}$ as follows:

$$\langle A_1, B_1\rangle \leq \langle A_2, B_2\rangle \Leftrightarrow A_1 \subseteq A_2 \Leftrightarrow B_2 \subseteq B_1 \quad (4)$$

The relation $\leq$ orders the formal concepts in table 3 into a lattice structure, which can be displayed in a Hasse-diagram as in figure 1. The nodes in this lattice represent the formal concepts, where the related sets of meanings and attributes can be found as follows: all formal concept below the node above which the definitional attribute **young** is placed have **young** in their set of definitional attributes, and conversely, all nodes above COLT have COLT in their set of meanings (i.e. a definitional attributes **a** is put above $\langle \mathbf{a}^{\downarrow}, \mathbf{a}^{\downarrow\uparrow}\rangle$, and a meaning A is depicted under $\langle \mathrm{A}^{\uparrow\downarrow}, \mathrm{A}^{\uparrow}\rangle$).

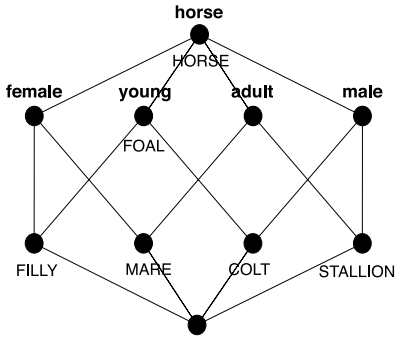

Figure 1: Concept Lattice for Horses

The construction of a concept lattice from a tabular representation of a context can be done automatically on-line by means of Java Applet written as part of my thesis. The Java-Applet is called JaLaBA (a Java Lattice Building Application). JaLaBA gives ask for a set of formal objects and a set of definitional attributes, and a relation between them, gives the related set of formal concepts, and then displays a 3D rotatable model of the corresponding Hasse diagram. JaLaBA can be found on the web-site of my thesis: `http://maarten.janssenweb.net/simullda`.

3.3. Interlingual Concept Lattice

The meanings in SIM*u*LLDA are abstracted from monolingual dictionaries. So the meanings STALLION in table 2 is derived from LDOCE. But the meaning STALLION as such is not an English meaning: the same meaning can be expressed by the French word étalon. Therefore the formal objects in SIM*u*LLDA are not taken to be language dependent meanings, but rather *interlingual meanings*, which can be expressed by words in various languages. It is clear that the definitional attributes defining these interlingual meanings cannot be language specific themselves. So also definitional attributes in SIM*u*LLDA are interlingual entities: **female** is a language independent definitional attribute, that can be lexicalised in English by the expression *female*, but also in French by the expression *femelle*, or in Dutch by the expression *mannelijk*.

Since the lattice in figure 1 thus contains only language independent entities, it can be taken as an interlingual structure, to which words of various languages can be related. This gives the situation as depicted in figure 2. Some notational conventions related to this figure: every interlingual meaning *y* has a (possibly empty) set of words lexicalising it in every language *X*, denoted by $\mathrm{wrd}_X(y)$, and every word *x* of every language has a set of interlingual meanings *Y* it expresses, denoted by $\mathrm{mng}(x)$.

In the set-up depicted in figure 2, it is possible to find translational synonyms: *x* is a translational synonym of *y*, iff $\mathrm{wrd}_Y(\mathrm{mng}(x)) \supseteq y$. To give an example:

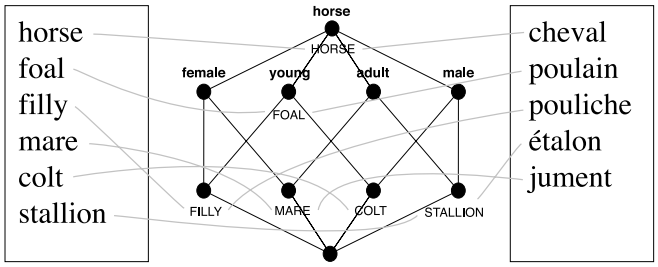

Figure 2: Concept Lattice with Words

mng(stallion) $\supseteq$ STALLION, and $\text{wrd}_{French}(\text{STALLION}) \supseteq$ étalon, so étalon is a translational synonym of stallion. In other words, just following the lines gives you translational synonyms.

More interesting is the situation when there is a lexical gap. In the SIM*u*LLDA set-up, there is a lexical gap iff $\text{wrd}(\text{mng}(x)) = \emptyset$. An example of a lexical gap in figure 2 is that there is no French translational synonym for colt. There only is the more general translational hyperonym poulain.

To find a translational hyperonym for a word *x*, first take mng*x*), and look up the lattice to find the first superconcept which has an interlingual meaning depicted under it for which there is a lexicalisation in the target language. So for colt, this interlingual meaning would be FOAL, and the fact hat poulain is a translational hyperonym of colt is modelled by the fact that COLT $\subseteq$ mng(colt), the related formal concept $\langle \text{COLT}^{\uparrow\downarrow}, \text{COLT}^{\uparrow} \rangle$ (I will use **COLT** as a name for this formal concept) is a subconcept of **FOAL**, and $\text{wrd}_{French}(\text{FOAL}) \supseteq$ poulain.

As claimed in the previous section, the things keeping colt and poulain apart should be the differentiae specificae. And differentiae specificae are implicitly present in the SIM*u*LLDA set-up: if we consider the formal concepts **COLT** and **FOAL**, then by the simple fact that **COLT** $\leq$ **FOAL**, we know that **COLT** has more definitional attributes than **FOAL**. If we define a function *ext* to give the set of definitional attributes of a formal concept ($\text{ext}(\langle A, B \rangle) = B$), then this *definitional surplus* will be $\text{ext}(\textbf{COLT}) \backslash \text{ext}(\textbf{FOAL}) =$ **male**. So **male** is the differentiam specificam distinguishing COLT from other hyponyms of FOAL such as FILLY.

The differentiae specificae, as well as the genus proximum, are hence modelled at the interlingual level. Within the interlingua, you could say that 'COLT = FOAL + **male**'. The language specific differentiae specificae are obtained by taking the lexicalisation in the desired language of this definitional surplus. We get the translation of our lexical gap by lexicalising both parts of the right-hand side of this equation in the target language. Since the French lexicalisation of **male** is *mâle*, we can conclude that colt in French is *poulain mâle*. This process of generating a translation for a lexical gap is called *lexical gap filling*. Notice that the lexical gap filling procedure renders what Zgusta (**?**) calls an *explanatory equivalent*, and not a *translational equivalent*.

We could also have opted to lexicalise all elements of the above equation within the same language, hence in English relating the word colt to the description *male foal*. In this way, also lexical definitions can be retrieved from the system. Notice that this lexical definition *male foal* is not the same definition as the one that formed the starting point of the analysis (see table 1): LDOCE does in fact not give the genus proximum, but a more remote genus term. But firstly, the rendered definition is nevertheless correct, and secondly, the LDOCE definition can also be rendered in the same way: we also have that **COLT** $\leq$ **HORSE**, with a larger definitional surplus: {**young, male**}. This leads to the original definition of colt as *young male horse*. The claim is that the generation of lexical definitions, as well as the lexical gap filling procedure, does not give a unique result, but does give only correct results.

Let me conclude this section by observing that not all definitional attributes are as 'simple' as the ones in this example. For instance, the Petit Robert definition of bief is *canal qui conduit les eaux d'un cours d'eau vers une machine hydraulique*[2]. There is no translational synonym in English for bief, but given an analysis of the data in SIM*u*LLDA, we would have that 'BIEF = CANAL + **qcled-cvumh**', where the lexicalisation in English of CANAL would be canal, and the English lexicalisation of **qcled-cvumh** would be *bringing water from a stream to a hydraulic installation*. So any differentiam specificam can be captured by a definitional attribute.

4. Definitional Attributes

As I have tried to show in the previous two sections, there is a definite need for differentiae specificae in a lexical database, especially in a multilingual one. That it is possible to set up a system using such differentiae specificae such as in the SIM*u*LLDA set-up. And that such a set-up leads to a correct modelling of lexical relations even in such problematic cases as lexical gaps. But of course the differentiae specificae introduced in a system, such as the definitional attributes in the case of SIM*u*LLDA, are at least reminiscent of the very thing WordNet reacted against: Katz & Fodor style semantics primitives (**?**). So naturally, from the perspective of semantic network theories, there is a reluctance to introduce differentiae specificae.

In the theory of Katz & Fodor, semantic markers are supposed to provide the foundation of knowledge, by their being innate building blocks to which all concepts can be reduced. But the presence of semantic primitives does not necessarily entail such a strongly reductionistic theory of meaning; there are more modest versions of semantic primitives, such as for instance in the French tradition of *sémantique interpretative*, as advocated by Rastier (**?**), Pottier (**?**) and others. The semantic primitives in this theory are called *sèmes*, which constitute meaning units calles *sémèmes*. Rastier explicitly discusses that sèmes do not have any of the strong properties semantic markers are supposed to have: they are not innate, not universal, not (interestingly) indivisible, they are not (necessarily) small in number, and they are not qualities of a referent or part of

[2]It actually is *canal de dérivation qui* ..., but I want to avoid here the for this point irrelevant question whether *canal de dérivation* should be taken as a complex genus term, or whether *de dérivation* counts as a differentiam specificam.

a concept. Especially in its description by Messelaar (**?**), sèmes have a striking resemblance to definitional attributes.

I do not want to give here an elaborate description of sèmes, their relation to semantic markers or a comparison to the SIM*u*LLDA set-up: definitional attributes are not sèmes either. But it is important to observe that the introduction of definitional attributes does not entail a strong theory of meaning. Definitional attributes are meant to be little more than what they are: theoretical entities that help to distinguish hyponyms of the same genus, and that make it possible to generate bilingual lexical definitions even for non-corresponding meanings. In my thesis, I give a lengthy discussion of the nature of the basic element of the SIM*u*LLDA set-up: words, word-forms, languages, interlingual meanings, and definitional attributes. For the moment, I will merely mention three properties definitional attributes are explicitly *not* supposed to have.

Firstly, definitional attributes do not form a special closed set of indivisible, innate semantic primitives. This should be clear from the example in section 2: the differentiam specificam *used for driving the wheel of a watermill* will constitute a definitional attribute, even though it has a clear internal structure. As a definitional attribute, it will count as an atomic entity, disregarding its internal structure[3]. So it is not an interestingly indivisible definitional attributes. And it would clearly be absurd to suppose that such a definitional attribute is in any way innate. New concepts arise every day, and new concepts can entail new definitional attributes, so there is not even a closed set of definitional attributes: new definitional attributes are introduced when need arises.

Secondly, sets of definitional attributes do not constitute a complete description of the concept related to the word that expresses the interlingual meaning in question. That is to say, interlingual meanings in the SIM*u*LLDA set-up are in a way defined in terms of sets of definitional attributes. But that does not result in saying that all information related to the word expressing that interlingual meaning is captured by the definitional attributes. For instance, stylistic information and other language-internal characteristics of the word are not modelled by the interlingual meaning, but handled at the level of the individual languages. Also, prototypes play an important role in the information/concept related to a word. But prototypes cannot be interlingual since, as shown by for instance Putnam (**?**), prototypes do not translate[4]. So the SIM*u*LLDA set-up is not supposed to provide a knowledge base: it is a lexical database, containing some aspects of word-meaning. In particular those aspects necessary for producing the kind of bilingual definition found in bilingual dictionaries.

Thirdly, definitional attributes are not denotational in nature. Definitional attributes are aspects of word meanings, not of (the) objects denoted by those words. And the interlingual meaning and/or the related set of definitional attributes are not supposed to fix the denotation of the word. Denotational semantics is very problematic, and it is even very dubious if every word(meaning) can be said to have a fixed denotation at any given moment. Furthermore, denotational semantics can never give a complete picture of word meaning. For instance, words can be metaphorically attributed to objects, where the meaning of the word is applied without the claim that the object to which it is attributed falls under the denotation of the word. So the fact that within the SIM*u*LLDA set-up, **COLT** is a subconcept of **FOAL** is not intended to express the ontological inclusion of the class of colts in the class of foals[5]: SIM*u*LLDA provides a lexical hierarchy, which should not be taken as an ontological hierarchy.

This last point is independent of the presence of differentiae specificae: also hierarchical systems without differentiae specificae, such as WordNet, should be taken as providing a lexical hierarchy, and not an ontological hierarchy. It is even dubious whether there really is an ontological ordering on the world. This is not to say that SIM*u*LLDA is not an ontology in the sense often used in computer science. For instance, the set-up is in many ways comparable to the *ontology clustering* set-up proposed by Visser & Tamma (**?**), which has a shared ontology and attributes over the concepts in it. Also in their set-up, a translation for a lexical gap is created after "*the attributes of the concept in the source ontology are compared with the attributes of the hypernym [found in the shared ontology] to select the distinguishing features.*" The point is that SIM*u*LLDA does not provide an ontological hierarchy in the philosophical sense.

Given the modest nature of definitional attributes, it will be clear that there are no strong claims concerning the meanings in the SIM*u*LLDA set-up. This is not surprising if you consider that SIM*u*LLDA aims at modelling lexicographic definitions, and lexicographic definitions do not really 'give' a description of the meanings of a word; they rely on knowledge of related words to 'hint at' the meaning of the word. A nice example of this is given by Hanks (**?**), who shows that a lexicographic definition of a chinaman (say *a left-hander's googly*) is only useful if you know about googlies, leg breaks, off-breaks and related cricket terms. Given the elusive nature of words, any theory that makes strong(er) claims is likely to runs into grave problems.

5. Conclusion

In this article, I hope to have shown the need for a structural modelling of differentiae specificae in a (multilingual) lexical database, and the advantages of the SIM*u*LLDA set-up which has such differentiae specificae by means of its definitional attributes. As already said, the criticism in this article was mainly directed at the EuroWordNet set-up, but applies equally to other hierarchical systems without differentiae specificiae. For instance, as far as I can tell, the

[3] In my thesis, I discuss some cases in which adopting a certain internal structure for definitional attributes proves beneficial, and also discuss order sets of definitional attributes, but in general, definitional attributes are atomic.

[4] Putnam goes on to claim that *perceptual prototypes may be psychologically important, but they just aren't* meanings – *not even "narrow" ones (op.cit. p.46).*. Although I am not unsympathetic with this point, it is not this strong claim I am aiming at here.

[5] This independently of the questions whether all colts are in fact foals.

SIMPLE framework, which in a way is a succesor of EuroWordNet, does not add structure to overcome the problems described in section 2.

Of course, the question whether SIM*u*LLDA could really provide a better alternative for a system like EuroWordNet is an (at least partly) empirical question: lexical databases and knowledge bases are designed for practical applicability. The SIM*u*LLDA approach is, however, a theoretical feasibility study, performed as a PhD-project, and the SIM*u*LLDA system has not (yet) been implemented or tested at large scale.

This is not to say that there is no empirical evidence for the applicability of the system: in my thesis, there is an empirical test whether the around 50 words for bodies of water from 6 different languages (English, French, Dutch, German, Italian, and Russian) can be correctly handled within the SIM*u*LLDA set-up. Describing the results of this test here would be too lengthy, and the test did bring forward some problems (or weaknesses) of the set-up. But the claim is that all the problems that have a solutions could be solved to satisfaction within the system. Although this does not provide a large-scale test, it does show that within an actual domain of lexical definitions, the systems works properly. The lexical field was not arbitrarily chosen, but was taken because it is a lexical field that is often quoted as problematic, both in terms of definability, as in terms of cross-linguistic differences, such as the often cited case of *river* and *fleuve*. So it is intended to provide some empirical evidence for the practical applicability of the system. But the only way to really test it is of course to build an application and fill it with data.

Abstract

There is an increasing interest in linguistic ontologies (e.g. WordNet) for a variety of content-based tasks, including conceptual indexing, word sense disambiguation and cross-language information retrieval. A relevant contribution in this direction is represented by linguistic ontologies with domain specific coverage, which are a crucial topic for the development of concrete application systems.
This paper tries to go a step further in the direction of the interoperability of specialized linguistic ontologies, by addressing the problem of their integration with global ontologies. This scenario poses some simplifications with respect to the general problem of merging ontologies, since it enables to define a strong precedence criterion so that terminological information overshadows generic information whenever conflicts arise. We assume the EuroWordNet model and propose a methodology to "plug" specialized linguistic ontologies into global ontologies. Experimental data related to an implemented algorithm, which has been tested on a global and a specialized linguistic ontology for the Italian language, are provided.

1. Introduction

Ontologies have become an important topic in research communities across several disciplines in relation to the key challenge of making the Internet and the Web a more friendly and productive place by filling more meaning to the vast and continuously growing amount of data on the net. The surging interest in the discovery and automatic or semi-automatic creation of complex, multi-relational knowledge structures, in fact, converges with recent proposals from various communities to build a Semantic Web relying on the use of ontologies as a means for the annotation of Web resources.

There is also an increasing interest in linguistic ontologies, such as WordNet, for a variety of content-based tasks, such as conceptual indexing and semantic query expansion to improve retrieval performance. More recently, the role of linguistic ontologies is also emerging in the context of distributed agents technologies, where the problem of meaning negotiation is crucial. A relevant perspective in this direction is represented by linguistic ontologies with domain specific coverage, whose role has been recognized as one of the major topics in many application areas.

This paper tries to go a step further in the direction of the interoperability of specialized linguistic ontologies, by addressing the problem of their integration with global linguistic ontologies. The possibility of merging information at different levels of specificity seems to be a crucial requirement at least in the case of large domains where terminologies include both very specific terms and a significant amount of common terms that may be shared with global ontologies.

The global-specialized scenario poses some simplifications with respect to the general problem of merging ontologies at the same degree of specificity (Hovy, 1998); in particular, in the case of conflicting information, it is possible to define a strong precedence criterion according to which terminological information overshadows generic information. We assume the EuroWordNet model and propose a methodology to "plug" specialized linguistic ontologies into global ontologies. The formal apparatus to realize this is based on plug relations that connect *basic concepts* of the specialized ontology to corresponding concepts in the generic ontology. We provide experimental data to support our approach, which has been tested on a global and a specialized linguistic ontology for the Italian language.

The paper is structured as follows. Section 2 presents the main features and uses of linguistic ontologies as opposed to formal ontologies. Section 3 introduces specialized linguistic ontologies, i.e. linguistic ontologies with domain specific coverage, as opposed to global linguistic ontologies containing generic knowledge. Section 4 deals with the problem of the interoperability of linguistic ontologies and describes the relations and the procedure enabling an integrated access of pairs of global and specialized linguistic ontologies.

2. Linguistic ontologies versus formal ontologies

In the recent years the increasing interest in ontologies for many natural language applications has led to the creation of ontologies for different purposes and with different features; therefore, it is worth pointing out the distinction between two main kinds of existing ontologies, i.e. formal and linguistic ontologies.

Linguistic ontologies are large scale lexical resources that cover most words of a language, while at the same time also providing an ontological structure where the main emphasis is on the relations between concepts; linguistic ontologies can therefore be seen both as a particular kind of lexical database and as particular kind of ontology.

Linguistic ontologies mainly differ from formal ontologies as far as their degree of formalization is concerned. Linguistic ontologies, in fact, do not reflect all the inherent aspects of formal ontologies. As Guarino et al. (1999) point out, for instance, WordNet's upper level structure shows no distinction between types and roles, whereas most of the original Pangloss (Knight and Luk, 1994) nodes in the Sensus ontology are actually types; to give a further example, WordNet's hierarchical structure lacks information about mutual disjointness between concepts.

Moreover, what distinguishes linguistic ontologies from formal ontologies, is their size: linguistic ontologies are very large (WordNet, for instance, has several dozen thousand synsets), while formal ontologies are generally much smaller.

The duality characterizing linguistic ontologies is reflected in their most prominent features. If we consider the linguistic level, they are strongly language-dependent, like electronic dictionaries, glossaries and all other linguistic resources, which focus on the words used in one specific language (in the case of monolingual resources) or in two or more specific language (in the case of bilingual or multilingual resources). On the other hand, if we consider the semantic level, we can observe that concepts denotated by different words in different languages can be shared, as it happens with the concepts in formal ontologies. In fact it is possible, at least for the core Indo-European languages, to identify a common ontological backbone behind the lexical surface of different languages (Guarino et al., 1999).

WordNet (Fellbaum, 1998), the best-known linguistic ontology, is an electronic lexical database where each sense of a lemma belongs to a different synset, i.e. a set of synonyms. Synsets are organized hierarchically by means of hypernymy and hyponymy relations. In WordNet other kinds of semantic relations among synsets are defined (e.g. role relation, part-of relation and cause relation), so as to build a more rich and complex semantic net. WordNet thus offers two distinct services: a lexicon, which describes the various word senses, and an ontology, which describes the semantic relationships among concepts.

As a linguistic ontology, WordNet is strongly language-dependent, but as an ontology it could also be adapted to a cross-language environment using the EuroWordNet multilingual database (Vossen, 1998) and mapping synsets into the EuroWordNet InterLingual Index, i.e. the index that links monolingual wordnets for all the languages covered by EuroWordNet. There are several examples of monolingual wordnets for many other languages, such as Dutch, Spanish, Italian, German and Basque.

A formal ontology based on linguistic motivation is the Generalized Upper Model (GUM) knowledge base (Bateman et al., 1995), an ontology primarily developed for Natural Language Processing applications. An upper model is an abstract linguistically motivated ontology meeting two requirements at the same time: i) a sufficient level of abstraction in the semantic types employed, as to escape the idiosyncrasies of surface realization and ease interfacing with domain knowledge, and ii) a sufficiently close relationship to surface regularities as to permit interfacing with natural language surface components.

2.1. Uses of formal ontologies

Recently ontologies have been used in the context of the Semantic Web. Ontologies can be employed to associate meaning with data and documents found on the Internet thus boosting diverse applications of information-retrieval systems. For the retrieval of information from the Web, Luke et al. (1996) propose a set of simple HTML Ontology Extensions to manually annotate Web pages with ontology-based knowledge, which performs high precision but is very expensive in terms of time.

OntoSeek (Guarino et al., 1999) is also based on content, but uses ontologies to find user's data in a large classical database of Web pages. Erdmann and Studer (1999) use an ontology to access sets of distributed XML documents on a conceptual level. Their approach defines the relationship between a given ontology and a document type definition (DTD) for classes of XML document. Thus, they are able to supplement syntactical access to XML documents by conceptual access.
However, as pointed out by Guarino et al. (1999), the practical adoption of ontologies in information-retrieval systems is limited by their insufficiently broad coverage and their need to be constantly updated; linguistic ontologies encompass both ontological and lexical information thus offering a way to partly overcome these limitations.

2.2. Uses of linguistic ontologies

Linguistic ontologies, and WordNet in particular, are proposed for content-based indexing, where semantic information is added to the classic word-based indexing. As an example, *Conceptual Indexing* (Woods, 1997) automatically organizes words and phrases of a body of material into a conceptual taxonomy that explicitly links each concept to its most specific generalizations. This taxonomic structure is used to organize links between semantically related concepts, and to make connections between terms of a request and related concepts in the index.

Mihalcea and Moldovan (2000) designed an IR system which performs a combined word-based and sense-based indexing exploiting WordNet. The inputs to IR systems consist of a question/query and a set of documents from which the information has to be retrieved. They add lexical and semantic information to both the query and the documents, during a preprocessing phase in which the input question and the texts are disambiguated. The disambiguation process relies on contextual information, and identifies the meaning of the words using WordNet.

The proble of sense disambiguation in the context of an IR task has been addressed, among the others, also by Gonzalo et al. (1998). In a preliminary experiment where disambiguation had been done manually, the vector space model for text retrieval gives better results if WordNet synsets are chosen as the indexing space, instead of word forms.

Desmontils and Jacquin (2001) present an approach where linguistic ontologies are used for information retrieval on the Internet. The indexing process is divided into four steps: i) for each page a flat index of terms is built; ii) WordNet is used to generate all candidate concepts which can be labeled with a term of the previous index; iii) each candidate concept of a page is studied to determine its representativeness of this page content; iv) all candidate concepts are filtered via an ontology, selecting the more representative for the content of the page.

More recently, the role of linguistic ontologies is also emerging in the context of distributed agents technologies, where the problem of meaning negotiation is crucial (Bouquet and Serafini, 2001).

3. Specialized linguistic ontologies

A particular kind of linguistic ontologies is represented by specialized linguistic ontologies, i.e. linguistic ontologies with domain specific coverage, as opposed to global linguistic ontologies, which contain generic knowledge. Focusing on one single domain, specialized linguistic ontologies often provide many sub-hierarchies of highly specialized concepts, whose lexicalizations tend to assume the shape of complex terms (i.e. multi-words); high level knowledge, on the other hand, tends to be simplified and domain oriented.

Many specialized linguistic ontologies have been developed, especially for practical applications, in domains such as art (see the Art and Architecture Getty Thesaurus), geography (see the Getty Thesaurus of Geographical Names), medicine (Gangemi et al., 1999), etc. and the importance of specialized linguistic ontologies is widely recognized in a number of works. The role of terminological resources for Natural Language Processing is addressed, for instance, by Maynard and Ananiadou (2000), who point out that high quality specialized resources such as dictionaries and ontologies are necessary for the development of hybrid approaches to automatic term recognition combining linguistic and contextual information with statistical information.

Buitelaar and Sacaleanu (2002) address the problem of tuning a general linguistic ontology such as WordNet or GermaNet to a specific domain (the medical domain, in the specific case). This involves both selecting the senses that are most appropriate for the domain and adding novel specific terms. Similarly, Turcato et al. (2000), describe a method for adapting a general purpose synonym database, like WordNet, to a specific domain (in this case, the aviation domain), adopting an eliminative approach based on the incremental pruning of the original database.

The use of domain terminologies also arises the problem of the (automatic) acquisition of thematic lexica and their mapping to a generic resource (Buitelaar and Sacaleanu, 2001; Vossen, 2001; Lavelli et al., 2002). As far as automatic term extraction is concerned, Basili et al. (2001) investigate whether syntactic context (i.e. structural information on local term context) can be used for determining "termhood" of given term candidates, with the aim of defining a weakly supervised "termhood" model suitably combining endogenous and exogenous syntactic information.

4. Merging global and specialized linguistic resources: the plug-in approach

One of the basic problems in the development of techniques for the Semantic Web is the integration of ontologies. Indeed the Web consists of a variety of information sources, and in order to extract information from such sources, their semantic integration is required.

Merging linguistic ontologies introduces issues concerning the amount of data to be managed (in the case of WordNet we have several dozen thousand synsets), which are typically neglected when upper levels are to be merged (Simov et al., 2001).

This paper tries to go a step further in the direction of the interoperability of linguistic ontologies, by addressing the problem of the integration of global and specialized linguistic ontologies. The possibility of merging information at different levels of specificity seems to be a crucial requirement at least in the case of domains, such as Economics or Law, that includes both very specific terms and a significant amount of common terms that may be shared by the two ontologies. We assume the EuroWordNet model and propose a methodology to "plug" specialized ontologies into global ontologies, i.e. to access them in conjunction through the construction of an integrated ontology.

4.1. Correspondences between global and specialized linguistic ontologies

A global linguistic ontology and a specialized one complement each other. The one contains generic knowledge without domain specific coverage, the other focuses on a specific domain, providing sub-hierarchies of highly specialized concepts. This scenario allows some significant simplifications when compared to the general problem of merging two ontologies. On the one hand, we have a specialized ontology, whose content is supposed to be more accurate and precise as far as specialized information is concerned; on the other hand, we can assume that the global ontology guarantees a more uniform coverage as far as high level concepts are concerned. These two assumptions provide us with a powerful precedence criterion for managing both information overlapping and inheritance in the integration procedure.

In spite of the differences existing between the two ontologies, in fact, it is often possible to find a certain degree of correspondence between them. In particular, we have information *overlapping* when the same concept belongs to the global and to the specialized ontology, and *over-differentiation* when a terminological concept has two or more corresponding concepts in the global ontology or the other way round. Finally, some specific concepts referring to technical notions may have no corresponding concept in the global ontology, which means there is a *conceptual gap*; in such cases a correspondence to the global ontology can be found through a more generic concept.

The sections highlighted in the global and the specialized ontology represented in Figure 1 reflect the correspondences we typically find between the two kinds on ontologies.

As for the global ontology (the bigger triangle), area *B1* is highlighted since it corresponds to the sub-hierarchies containing the concepts belonging to the same specific domain of the specialized ontology (the smaller triangle). The middle part of the specialized ontology, which we call *B* area, is also highlighted and it corresponds to concepts which are representative of the specific domain but are also present in the global ontology.

When the two ontologies undergo the integration procedure, an integrated ontology is constructed (Figure 2). Intuitively, we can think of it as if the specialized ontology somehow shifts over the global. In the integrated ontology, the information of the generic is maintained, with the exclusion of the sub-hierarchies containing the concepts belonging to the domain of the specialized ontology, which are covered by the corresponding area of the specialized. The

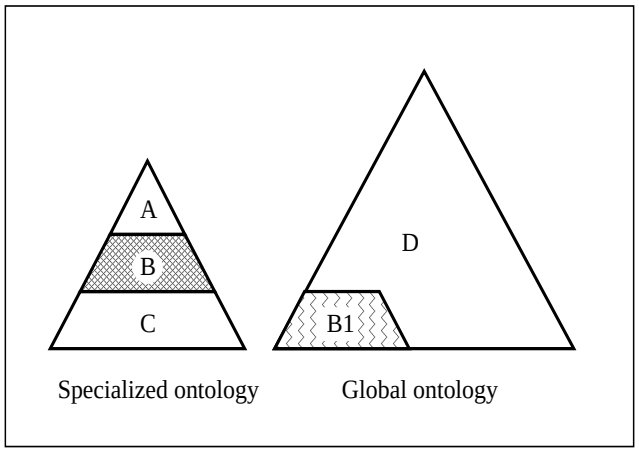

Figure 1: Separate specialized and global ontologies. Overlapping is represented in colored areas

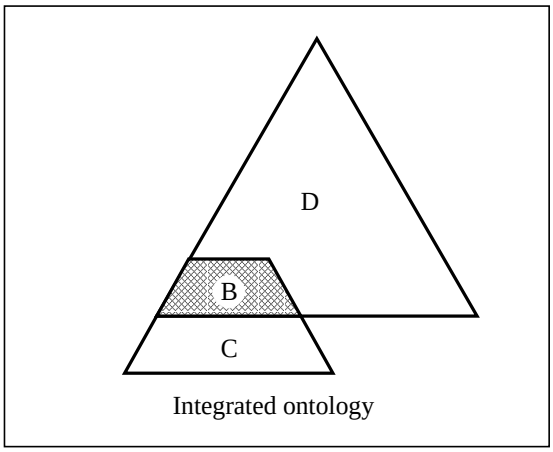

Figure 2: Integrated ontology. As to overlapping, precedence is given to the specialized ontology

integrated ontology also contains the most specific concepts of the specialized ontology (*C* area), which are not provided in the generic. What is excluded from the integrated ontology is the highest part of the hierarchy of the specialized ontology; it is represented by area *A* and contains generic concepts not belonging to a specialized domain, which are expected to be treated more precisely in the generic ontology.

4.2. Plug relations

The formal apparatus to realize an integrated ontology is based on the use of three different kinds of relations (plug-synonymy, plug-near-synonymy and plug-hyponymy) that connect basic concepts of the specialized ontology to the corresponding concepts in the global ontology, and on the use of eclipsing procedures that shadow certain concepts, either to avoid inconsistencies, or as a secondary effect of a plug relation.

A plug relation directly connects pairs of corresponding concepts, one belonging to the global ontology and the other to the specialized ontology. The main effect of a plug relation is the creation of one or more "plug concepts", which substitute the connected concepts, i.e. those directly involved in the relation. To describe the relations inherited by a plug concept, the following classification, adapted from Hirst and St-Onge (1998) is used: *up-links* of a concept are those whose target concept is more general (i.e. hypernymy and instance-of relations), *down-links* are those whose target is more specific (i.e. hyponymy and has-instance relations) and *horizontal-links* include all other relations (i.e. part-of relations, cause relations, derivation, etc.).

Plug-synonymy is used when overlapping concepts are found in the global ontology (hereafter *GO*) and in the specialized ontology (hereafter *SO*). The main effect of establishing a relation of plug-synonymy between concept *C* belonging to the global ontology (indicated as C^{GO}) and $C1^{SO}$ (i.e. concept *C1* belonging to the specialized ontology) is the creation of a plug concept $C1^{PLUG}$. The plug concept gets its linguistic forms (i.e. synonyms) from *SO*, up-links from GO, down-links from *SO* and horizontal-links from *SO* (see Table 1). As a secondary effect, the up relations of $C1^{SO}$ and the down relations of C^{GO} are eclipsed.

	$C1^{PLUG}$
Up links	*GO*
Down links	*SO*
Horizontal links	*GO* + *SO*

Table 1: Merging rules for plug-synonymy and plug-near-synonymy.

Plug-near-synonymy is used in two cases: (i) over-differentiation of the *GO*, i.e. when a concept in the *SO* has two or more corresponding concepts in the *GO*; this happens, for instance, when regular polysemy is represented in the GO but not in the SO; (ii) over-differentiation of the *SO*, i.e. when a concept in the *GO* corresponds to two or more concepts in the *SO*; this situation may happen as a consequence of subtle conceptual distinctions made by domain experts, which are not reported in the global ontology. Establishing a plug-near-synonymy relation has the same effect of creating a plug-synonymy (see Table 1).

Plug-hyponymy is used to connect concepts of the specialized ontology to more generic concepts in the case of conceptual gaps. The main effect of establishing a plug-hyponymy relation between C^{GO} (i.e. concept *C* of the global ontology) and $C1^{SO}$ (i.e. concept *C* of the specialized ontology) is the creation of the two plug concepts C^{PLUG} and $C1^{PLUG}$ (see Table 2). C^{PLUG} gets its linguistic forms from the *GO*, up-links from the *GO*, down-links are the hyponyms of C^{GO} plus the link to $C1^{PLUG}$ and horizontal-links from the *GO*. The other plug node, $C1^{PLUG}$, gets its linguistic form from the *SO*, C^{PLUG} as hypernym, down links from the *SO* and horizontal links from the *SO*. As a secondary effect, the hypernym of $C1^{SO}$ is eclipsed.

Eclipsing is a secondary effect of establishing a plug re-

	C^{PLUG}	$C1^{PLUG}$
Up links	*GO*	C^{PLUG}
Down links	*GO* + $C1^{PLUG}$	*SO*
Horizontal links	*GO*	*SO*

Table 2: Merging rules for plug-hyponymy

lation and is also an independent procedure used to avoid the case that pairs of overlapping concepts placed inconsistently in the taxonomies are included in the merged ontology; this could happen, for instance, when "whale" is placed under a "fish" sub-hierarchy in a common sense ontology, while also appearing in the mammal taxonomy of a scientific ontology.

4.3. Integration procedure

The plug-in approach described in the previous subsection has been realized by means of a semi-automatic procedure with the following four main steps.

(1) Basic concepts identification. The domain expert identifies a preliminary set of "basic concepts" in the specialized ontology. These concepts are highly representative of the domain and are also typically present in the global ontology. In addition, it is required that basic concepts are disjoint among each other and that they assure a complete coverage of the specialized ontology, i.e. it is required that all terminal nodes have at least one basic concept in their ancestor list.

(2) Alignment. This step consists in aligning each basic concept with the more similar concept of the global ontology, on the basis of the linguistic form of the concepts. Then, for each pair a plug-in configuration is selected among those described in Section 4.2.

(3) Merging. For each plug-in configuration an integration algorithm reconstructs the corresponding portion of the integrated ontology. If the integration algorithm detects no inconsistencies, the next plug-in configuration is considered, otherwise step 4 is called.

(4) Resolution of inconsistencies. An inconsistency occurs when the implementation of a plug-in configuration is in contrast with an already realized plug-in. In this case the domain expert has to decide which configuration has the priority and consequently modify the other configuration, which will be passed again to step 2 of the procedure.

5. Experiments

The integration procedure described in Section 4.3 has been tested within the SI-TAL project [1] to connect a global wordnet and a specialized wordnet that have been created independently. ItalWordNet (IWN) (Roventini et al., 2000), which was created as part of the EuroWordNet project (Vossen, 1998) and further developed through the introduction of adjectives and adverbs, is the lexical database involved in the plug-in as a generic resource and consists of about 45,000 lemmas. Economic-WordNet (ECOWN) is a specialized wordnet for the economic domain and consists of about 5,000 lemmas distributed in about 4,700 synsets. Table 3 summarizes the quantitative data of the two resources considered.

	Specialized	Generic
Synsets	4,687	49,108
Senses	5,313	64,251
Lemmas	5,130	45,006
Internal Relations	9,372	126,326
Variants/synsets	1.13	1.30
Senses/lemmas	1.03	1.42

Table 3: IWN and ECOWN quantitative data

As a first step, about 250 basic synsets (5.3% of the resource) of the specialized wordnet were manually identified by a domain expert, including, for instance "azione" ("share"), and excluding less informative synsets, such as "azione" ("action"). Alignment with respect to the generic wordnet (step 2 of the procedure) is carried out with an algorithm that considers the match of the variants. Candidates are then checked by the domain expert, who also chooses the proper plug relation. In the case of gaps, a synset with a more generic meaning was selected and a plug-hyponymy relation was chosen.

At this point the merging algorithm takes each plug relation and reconstructs a portion of the integrated wordnet. In total, 4,662 ECOWN synsets were connected to IWN: 577 synsets (corresponding to area *B* in Figure 2) substitute the synsets provided in the global ontology to represent the corresponding concepts (*B1* area in Figure 1); 4085 synsets, corresponding to the most specific concepts of the domain (*C* area in Figure 2) are properly added to the database. 25 high level ECOWN synsets (*A* area in Figure 1) were eclipsed as the effect of plug relations. The number of plug relations established is 269 (92 plug-synonymy, 36 plug-near-synonymy and 141 plug-hyponymy relations), while 449 IWN synsets with an economic meaning were eclipsed, either as a consequence of plug relations (when the two taxonomic structures are consistent) or through the independent procedure of eclipsing (when the taxonomies are inconsistent). Each relation connects on average 17,3 synsets.

6. Conclusions

After discussing the main features and uses of linguistic ontologies as opposed to formal ontologies, we have addressed the problem of the interoperability between linguistic ontologies. We have presented a methodology for the integration of a global and a specialized linguistic ontology. The global-specialized situation allows to define a strong precedence criterion to solve cases of conflicting information. The advantage of the approach is that a limited number of plug relations allows to connect a large amount of concepts (i.e. synsets) in the two ontologies.

Automatic Adaptation of WordNet to Domains

Roberto Navigli, Paola Velardi

Università di Roma "La Sapienza", Dipartimento di Scienze dell'Informazione, Via Salaria 113
00198 Roma, Italy, e-mail: velardi@dsi.uniroma1.it

Abstract

The objective of this paper is to present a method to automatically enrich WordNet with sub-trees of concepts in a given language domain. WordNet is then trimmed to reduce unnecessary ambiguity and singleton nodes. The process is based on the use of statistical method and linguistic processing to extract candidate domain *terms*. Multiword terms are semantically disambiguated and interpreted using ontological and contextual knowledge stored in WordNet on singleton words.

1. Introduction

As already pointed out by many researchers, WordNet is a very useful tool, but has some important drawbacks, namely, over-ambiguity and lack of domain terminology. Several published studies attempted to solve this problem in some automatic way, for example, (Vossen, 2001) (Harabagiu et al., 1999) (Milhalcea et al., 2001) and (Agirre et al. 1999). Other studies related to the work presented in this paper deal with the more general issue of automatic ontology construction. These contributions are collected in the web proceedings of two workshops dedicated to Ontology learning, (ECAI-OL, 2000) and (IJCAI-OL, 2001).

In many described approaches for ontology learning, domain terms are firstly extracted using a variety of statistical methods; then, taxonomic relations and other types of relations between terms are detected. In the literature, the notion of domain *term* and domain *concept* are used interchangeably, though no semantic interpretation of terms takes place. For example, in (Vossen, 2001) the "concept" *digital printing technology* is considered as a kind-of *printing technology* by virtue of simple string inclusion. However, *printing* has four senses in WordNet, and *technology* has two senses. There are hence 8 possible concept combinations for *printing technology*!

In this paper we propose a method for semantic interpretation of terms, using the information available in WordNet for the individual words that appear in a terminological string. Semantic interpretation allows us to detect non-trivial taxonomic relations between *concepts*, and other types of semantic relations.

The method described in this paper is implemented in a system called OntoLearn. OntoLearn is part of an Ontology Engineering architecture, described in (Missikoff et al., 2002), developed in the context of two European projects[1], aimed at improving interoperability in the Tourism sector.

Taxonomic information is extracted from the documents available in the considered domain in 5 steps: domain terminology is identified (section 2) and structured in syntactic trees (section 3), terms are mapped to concepts (section 4), that are arranged in a domain concept forest (section 5), and then used to create a domain-specific view of WordNet (section 6).

[1] ITS – 13015 (FETISH) and ITS- 29329 (HARMONISE).

2. Identification of Relevant Domain Terminology

The objective of this phase is to extract from the available documents a domain terminology. First, we use a linguistic processor, ARIOSTO[2], to extract from a corpus of documents a list of syntactically plausible terminological patterns, e.g. compounds (*credit card*), prepositional phrases (*board of directors*), adjective-noun relations (*manorial house*).

Then, two information theory based measures are used to filter out non-terminological (e.g. *last week*) and non-domain specific terms (e.g. *world wide web* in a Tourism domain). The first measure, called *Domain Relevance*, computes the probability of occurrence of a candidate term in the application domain (e.g. Tourism), as compared with other corpora that we use for a contrastive analysis (e.g. Medicine, Economy, Novels, etc.). The second measure, called *Domain Consensus*, computes the entropy of the probability of seeing a candidate term across the documents of the application domain. The underlying idea is that only terms that are *frequently* and *consistently* referred in the available domain documents reflect some *consensus* on the use of that term. These two measures have been formally defined and extensively evaluated in (Velardi et al, 2001).

3. Generation of Syntactic Trees

From the list of filtered terminology we generate *lexicalized trees*, on the basis of a simple inclusion relation. For example, given two strings x and wx (e.g. *telephone service* and *service*), we generate $wx \rightarrow^{@} x$, where '$\rightarrow^{@}$' stands for the hyperonymy relation. Figure 1 provides an example of a generated lexicalized tree $\mathfrak{I}$. It is clear that many taxonomic relations are not captured by this simple inclusion mechanism, like *bus service* $\rightarrow^{@}$ *public transport service*.

4. Semantic Disambiguation of Terms

The process of *semantic interpretation* is one that associates to each multiword term $t = w_n \cdot \ldots \cdot w_2 \cdot w_1$ (where w_i is an atomic word) the appropriate *concept name*.

[2] ARIOSTO is a joint effort of the Universities of Roma "La Sapienza" and "Tor Vergata".

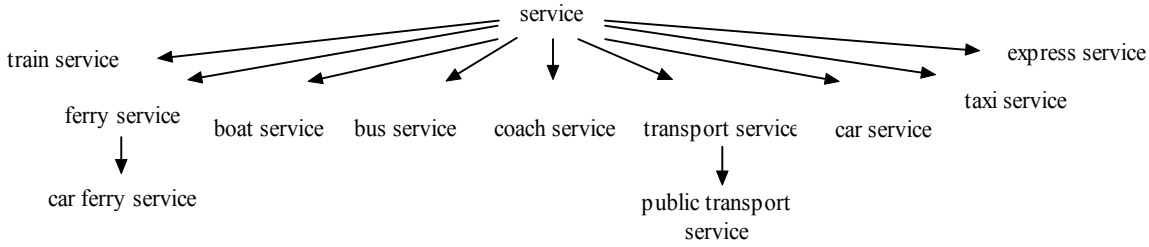

Figure 1. Example of a lexicalized tree.

Though complex terms are usually absent in WordNet, singleton words and occasionally word pairs included in a terminological string are mostly present. For example, *printing technology* as a unique term is not included, but *printing* and *technology* have an associated WordNet entry.

We derive the meaning of a complex terminological string *compositionally*, as explained hereafter.

Formally, a *semantic interpretation* is defined as follows: let $t = w_n \cdot \ldots \cdot w_2 \cdot w_1$ be a valid term belonging to a lexicalized tree $\mathfrak{I}$. The process of *semantic interpretation* is one that associates to each word w_k in t the appropriate WordNet synset S_i^k, the i-th synset ($i \in \{1,...,m\}$) associated to w_k in WordNet. The *sense* of t is hence defined as:

$$S(t) = \bigcup_k S^k,\ S^k \in Synsets(w_k) \text{ and } w_k \in t.$$

where $Synsets(w_k)$ is the set of synsets each representing a sense of the word w_k.

For instance: S("transport company") = { { transportation#4, shipping#1, transport#3 }, { company#1 } } corresponding to sense #1 of *company* ("*an institution created to conduct business*") and sense #3 of *transport* ("*the commercial enterprise of transporting goods and material*").

In order to disambiguate the words in a term $t = w_n \cdot \ldots \cdot w_2 \cdot w_1$ we proceed as follows:

a) If t is the first analyzed element of $\mathfrak{I}$, manually disambiguate the root node (w_1 if t is a compound) of $\mathfrak{I}$.

b) For any $w_k \in t$ and any synset S_i^k of w_k, create a *semantic net SN*. Semantic nets are automatically created using the following semantic relations: hyperonymy ($\rightarrow^{@}$), hyponymy ($\rightarrow^{\sim}$), meronymy ($\rightarrow^{\#}$), holonymy ($\rightarrow^{\%}$), pertonymy ($\rightarrow^{\backslash}$), attribute ($\rightarrow^{=}$), similarity ($\rightarrow^{\&}$), gloss ($\rightarrow^{gloss}$) and topic ($\rightarrow^{topic}$). The *gloss* and the *topic* relation are obtained parsing with ARIOSTO the WordNet concept definitions (*glosses*) and SemCor sentences (*topic*) including that sense. Every other relation is directly extracted from WordNet. To reduce the dimension of a SN, concepts at a distance of more than 3 relations from the SN centre, S_i^k, are removed. Figure 2a is an example of SN generated for sense #1 of *room*.

Let then $SN(S_i^k)$ be the semantic network for sense i of word w_k.

c) Starting from the "head" w_1 of t, and for any pair of words w_{k+1} and w_k (k=1,…,n-1) belonging to t, intersect alternative pairs of SNs. Let $I = SN(S_i^{k+1}) \cap SN(S_j^k)$ be one of such intersections for sense i of word w_{k+1} and sense j of word w_k. Note that, in each step k, the word w_k is already disambiguated, either manually (for k=1) or as a result of step k-1.

To identify common semantic patterns several heuristic rules are used, e.g.:

$$\exists G, M \in Synset_{wn} : S_1 \xrightarrow{gloss} G \xrightarrow{@^{\leq 3}} M \xleftarrow{@^{\leq 3}} S_2$$

The heuristic (named "gloss+parallelism") reads: "*given two central concepts S_1 and S_2, there exist two concepts G and M such that G appears in the gloss of S_1 and both G and S_2 reach the concept M in $SN(S_1) \cap SN(S_2)$ through a hyperonimy path.*

An example is the bold pattern in Figure 2b:

transport#3 $\xrightarrow{gloss}$ *enterprise*#2 $\xrightarrow{@^1}$ *organization*#1 $\xleftarrow{@^2}$ *company*#1.

5. Creating a Domain Concept Forest

Initially, all the terms in a tree $\mathfrak{I}$ are independently disambiguated. Subsequently, taxonomic information in WordNet is used to detect *is-a* relations between *concepts*, e.g. *ferry service* $\rightarrow^{@}$ *boat service*. In this phase, since all the elements in $\mathfrak{I}$ are jointly considered, some interpretation errors produced in the previous disambiguation step are corrected. In addition, certain concepts are *fused* in a unique concept name on the basis of pertonimy, similarity and synonymy relations (e.g. respectively: *manor house* and *manorial house*, *expert guide* and *skilled guide*, *bus service* and *coach service*).

Notice again that we detect semantic relations between *concepts*, not words. For example, *bus#1* and *coach#5* are synonyms, but this relation does not hold for other senses of these two words. Each lexicalized tree $\mathfrak{I}$ is finally transformed in a *domain concept* tree Υ.

Figure 3 shows the concept tree obtained from the lexicalized tree of Figure 1.

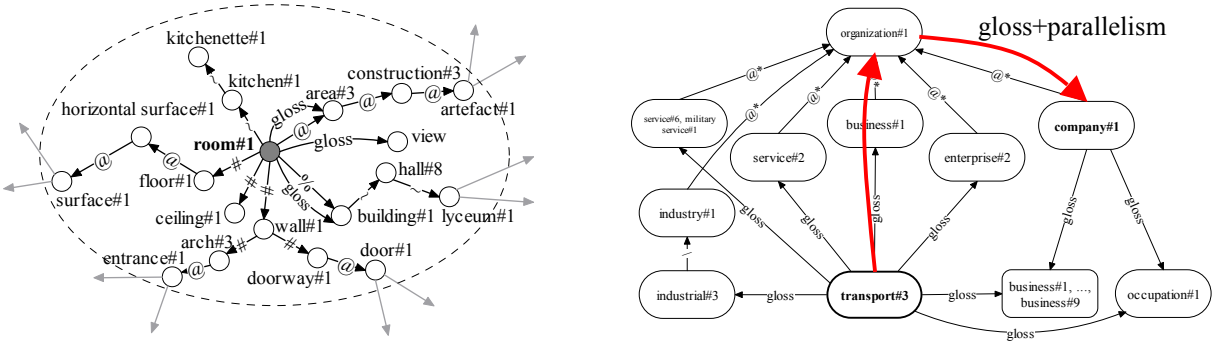

Figure 2. a) example of semantic net for *room#1*; b) example of intersecting semantic patterns for transport#3 and *company#1*.

For clarity, in Figure 3 concepts are labeled with the associated terms (rather than with synsets), and numbers are shown only when more than one semantic interpretation holds for a term, as for *coach service* and *bus service* (e.g. sense #3 of "bus" refers to "old cars").

6. Pruning and Trimming WordNet

The final phase consists in creating a domain-specialization of WordNet. In short, WordNet pruning and trimming is accomplished as follows:

1. The Domain Concept trees are attached under the appropriate nodes in WordNet.
2. An intermediate node in WordNet is pruned whenever the following conditions hold together

   i. it has no "brother" nodes;
   ii. it has only one direct hyponym;
   iii. it is not the root of a Domain Concept tree;
   iv. it is not at a distance ≤ 2 from a WordNet *unique beginner* (this is to preserve a "minimal" top ontology).

Figure 4 shows an example of pruning the nodes located over the Domain Concept tree with root *wine#1*. Appendix A shows an example of domain-adapted branch of WordNet in the tourism domain.

7. Evaluation

OntoLearn is a knowledge extraction system aimed at improving human productivity in the time-consuming task of building a domain ontology. Our experience in building a tourism ontology for the European project Harmonise reveals that, after one year of ontology engineering activities, the tourism experts were able to release the most general layer of the tourism ontology, comprising about 300 concepts.

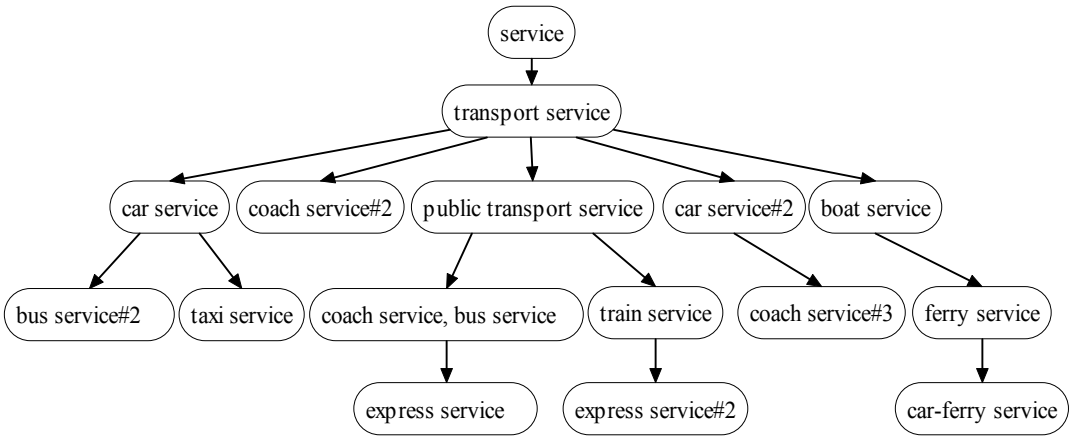

Figure 3. A Domain Concept Tree.

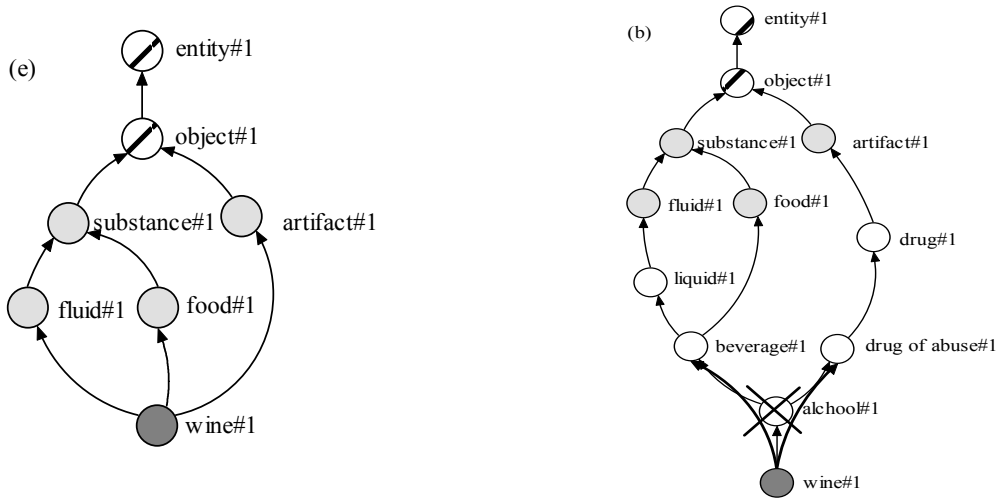

Figure 4. An intermediate step and the final pruning step over the Domain Concept Tree for "wine#1".

Then, we decided to speed up the process developing the *OntoLearn* system, aimed at supporting the ontology engineering tasks. This produced a significant acceleration in ontology building, since in the next 6 months[3] the tourism ontology reached about 3,000 concepts.

The OntoLearn system has been also evaluated independently from the ontology engineering process. We extracted from a 1 million-word corpus of travel descriptions (downloaded from Tourism web sites) a terminology of 3840 terms, manually evaluated[4] by domain experts participating in the Harmonise project. We obtained a precision ranging from 72.9% to about 80% and a recall of 52.74%. The precision shift is motivated by the well-known fact that the intuition of experts may significantly differ.

After this expert evaluation, we added few *ad hoc* heuristics that brought the precision to 97%. However, the use of heuristics limits the generality of the method.

The recall has been estimated by submitting a list of 6000 syntactic candidates to the experts, requiring them to mark truly terminological entries, and then comparing this list with that obtained by our statistical filtering method described in section 2.

We personally evaluated the semantic disambiguation algorithm using a test bed of about 650 extracted terms, which have been manually assigned to the appropriate WordNet concepts. These terms contributed to the creation of 90 syntactic trees. The entire process of semantic disambiguation and creation of domain trees has been evaluated, leading to an overall 84.5% precision. The precision grows to about 89% for highly structured sub-trees, as those in Figure 3. In fact, the phase described in section 5 significantly contributes at eliminating disambiguation errors (in the average, 5% improvement). We also analyzed the individual contribution of each of the heuristics mentioned in section 4 to the performance of the method, but a detailed performance report is omitted here for sake of space. The results of this performance analysis led to a refinement of the algorithm and the elimination of one heuristic.

[3] The time span includes also the effort needed to test and tune OntoLearn. Manual verification of automatically acquired domain concepts actually required few days.

[4] Here manual evaluation is simply deciding whether an extracted term is relevant, or not, for the tourism domain.

Abstract

Lexical knowledge databases such as WordNet contain much semantic information that is left implicit. In order to make maximal use of these resources it is important to make this implicit semantic information explicit. Metonymy and regular polysemy constitute a type of implicit ontological knowledge. This paper describes the semi-automatic extraction of systematically related word senses from WordNet by exploiting its hierarchical structure, and the identification of relations that link these on the basis of the glosses.

1. Introduction

WordNet (Fellbaum 1998) contains far more semantic information than its ontological organization shows. Word senses are related to senses of other words by means of a small number of basic semantic relations such as synonymy and hypernymy. Other types of encyclopaedic knowledge and semantic relations are implicitly present in the structure of WordNet in the form of taxonomic correspondences and glosses. This non-formalized semantic information in WordNet can be processed in order to distil more implicit knowledge (see e.g. Harabagiu 2000).

2. Relations between senses

Systematic relatedness between senses is one type of knowledge that is mostly left implicit in resources. This phenomenon is called metonymy, or, ore specifically, regular polysemy (Apresjan 1973).

Viewed traditionally, metonymy is a non-literal figure of speech in which the name of one thing is substituted for that of another related to it. It has been described as a cognitive process in which one conceptual entity, the vehicle, provides mental access to another conceptual entity (Radden 1999). In its basic form, it establishes a semantic relation between two concepts that are associated with word forms. The semantic shift expressed by the relation may or may not be accompanied by a shift in form. The semantic relation that is captured by metonymy is one of semantic contiguity, in the sense that in many cases there are systematic relations between metonymically related concepts that can be regarded as slots in conceptual frames (cf. Fillmore 1977).

Regular polysemy is a more specific instantiation of metonymy that covers the systematicity of the semantic relations involved. It can be defined as a subset of metonymically related senses of the same word displaying a conventional as opposed to novel type of semantic contiguity relation. Any systematic semantic relations between concepts are lexicalized, i.e. they are explicitly listed in dictionaries and independent of a pragmatic situation. For example, *The White House* is on the one hand an institution and on the other a building. The semantic relation between the two senses is 'is housed in'. It is a conventional pattern, not a nonce formation (a pragmatically defined novel metonymy), because it holds for related senses of two or more words (Apresjan, 1973) in the lexicon. It is this subtype of metonymy that we concentrate on in this paper.

3 Extraction from WordNet

A technique was developed (Peters 2000) for identifying sense combinations in WordNet where the senses involved potentially display a regular polysemic relation, i.e. where the senses involved are candidates for systematic relatedness.

In order to obtain these candidate patterns WordNet (WN) has been automatically analysed by exploiting its hierarchical structure for nouns. Wherever there are two or more nouns with senses in one part of the hierarchy, which also have senses in another part of the hierarchy, then we have a candidate pattern of regular polysemy. The patterns are candidates because there seems to be an observed regularity for two or more words. An example can be found in Figure 1 below.

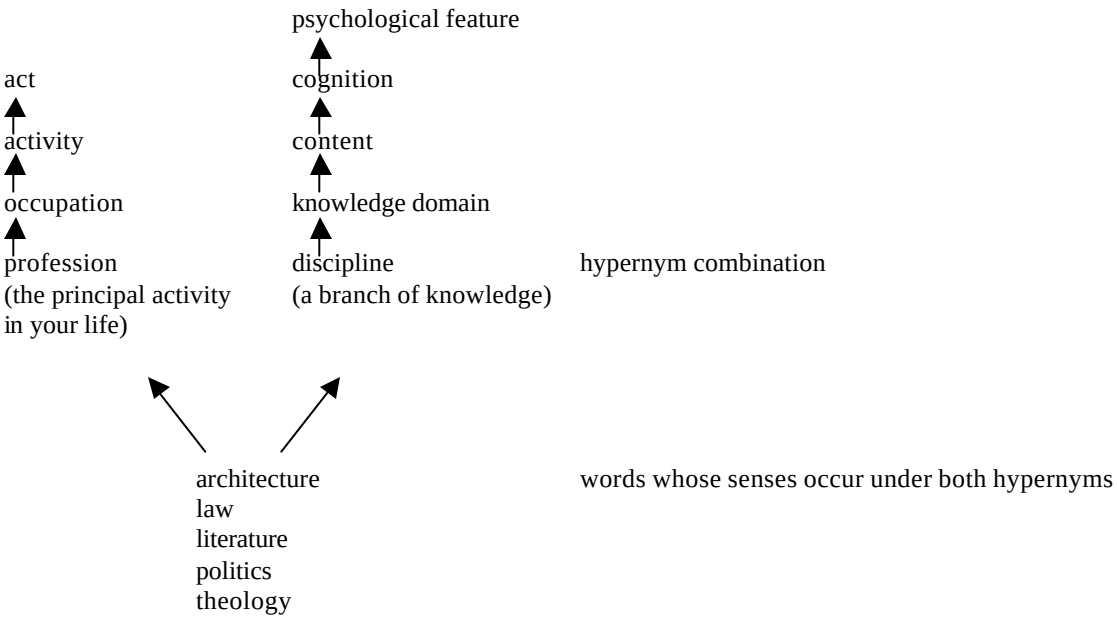

Figure 1: words in WordNet covered by the pattern profession/discipline

4 Relations

The results obtained from the manual analysis of reduced data sets according to (Peters 2001) and (Peters 2002) yields a set Regular Polysemic patterns. These patterns consist of combinations of the hypernymic nodes that subsume the words involved in the pattern. These combinations do not give any explicit information about the nature of the systematic relations that exist between them. This relationship can be determined by means of manual evaluation. The examination of the pair and the participating word senses will provide a human assessor with enough information to intuitively postulate a relationship. However, this is a costly and time consuming activity.

We have, up to a certain extent, automated this process of extracting explicit relations between the word senses involved in the regular polysemic pattern.

Our extraction process concentrates on the linguistic information available in the glosses associated with the word senses subsumed by the hypernymic pairs. The relations we have extracted take the form of verbs that link pairs of concepts. In each of these pairs one member is subsumed by member one of the hypernym pair and the other by number two. The glosses were first preprocessed. Part of speech tags were added and nominal and verbal content words were lemmatized.

For all nouns participating in the regular polysemic patterns listed above two bags of WordNet words were created, each associated with a sense captured by the regular polysemic pattern. The bag consisted of the noun under consideration, its synonyms and all the members of the hypernymic synsets. Then the words in the bag of the first word sense were matched against the processed gloss associated with the synset to which this sense belongs (henceforth synset 1).

If there was a match, the words from the bag of the second word sense (henceforth synset 2) were matched against the gloss.

If there was a match and the word from the synset 1 bag (word 1) preceded the word from the synset 2 bag (word 2) within the gloss, the text between the matches was extracted. If this span of text contained a verb, it was extracted, together with any associated prepositions. A distance of three positions between the matched nouns and the verb was applied in order to reduce spurious matches. Any extracted verb is considered to represent an instantiation of the relation(s) holding for the regular polysemic pattern.

The same matching process was repeated for the glosses associated with all hypernyms of synset 1. Then the whole process was repeated, looking for matches in the synset 2 gloss and all its hypernyms. Figure 2 below gives a graphical representation of the process.

The requirement that word 1 precedes word 2 is geared towards the extraction of transitive and prepositional verbs, both used in active form. The order constraint also determines the directionality of the relation, i.e. which hypernymic pair member is the subject and which is the object of an extracted verb.

We will illustrate this by means of an example.

The regular polysemic pattern **animal - food** is applicable to 172 words in WordNet. One of these words is '*herring*':

Sense 1: commercially important food fish of northern waters of both Atlantic and Pacific.

Sense 2: valuable flesh of fatty fish from shallow waters of northern Atlantic or Pacific; usually salted or pickled.

The bag of words associated with synset 1 contains 330 words (e.g. *fish, entity, life form, vertebrate, craniate*).

The synset 2 bag holds 518 words (*seafood, food, substance, food product, nutrient, object*). Only a subset of these words is related to *herring*, the rest are associated with the other words that are subsumed by the hypernymic pattern.
The concept 'food fish' is the hypernym of sense 1: "any fish used for food by human beings". Of the words in this gloss 'fish' is found in the synset1 bag and 'food' in the synset 2 bag. The intermediate text span is 'used for' which consists of a past participle and a preposition. The outcome is the relationship 'animal used for food'. This relation is found 37 times. The relation 'used for' is found 23 times.

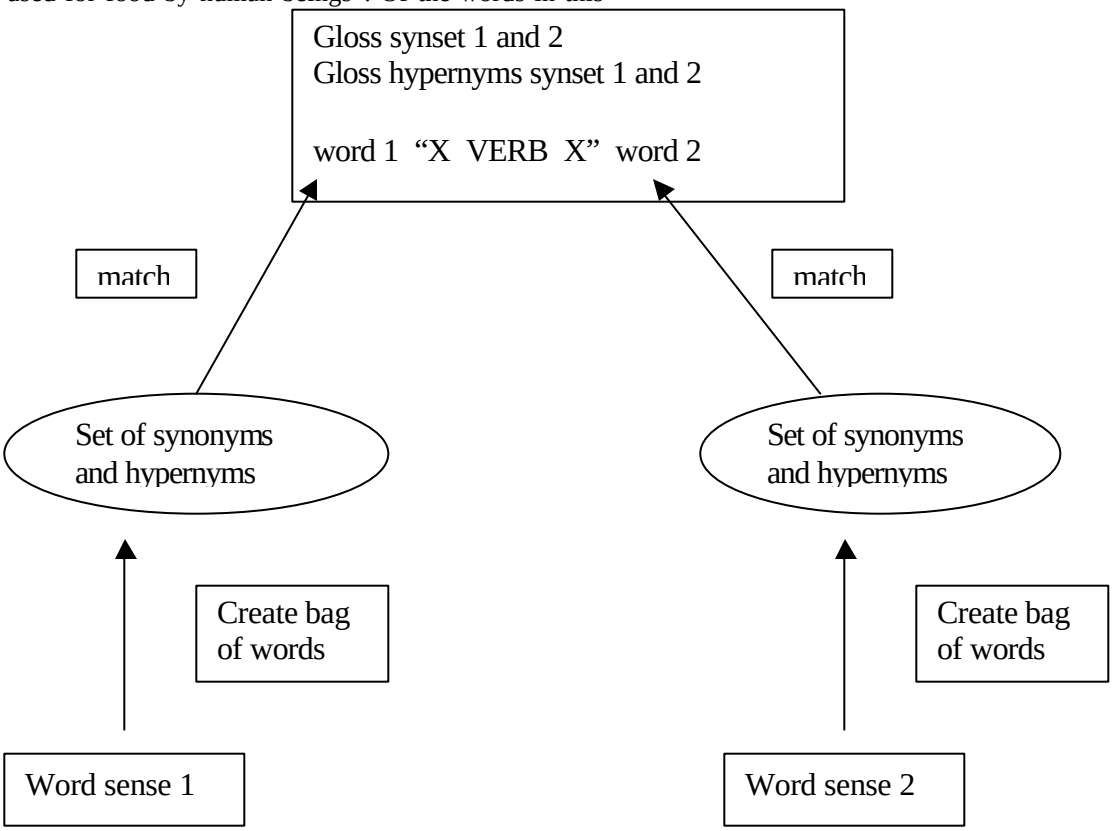

Figure 2: Mapping synset members onto glosses

The pattern **profession** and **discipline** (see figure 1) subsumes five words: *architecture, literature, politics, law* and *theology*.
Sense 6 of 'law' has the gloss 'the learned profession that is mastered by graduate study in a law school and that is responsible for the judicial system; "he studied law at Yale"'
Bag synset 1 contains 'profession', bag synset2 'study'. In between is the verb 'is mastered by' which yields the relation 'profession is mastered by discipline' for this regular polysemic pattern. This relation is found 2 times. One other relation was found: 'concerned with', which occurs only once.

Other relations are:

writing (reading matter; anything expressed in letters of the alphabet (especially when considered from the point of view of style and effect); "the writing in her novels is excellent")
message (what a communication that is about something is about)

This pattern covers 36 words. Examples are *account, conclusion, declaration, epitaph*. The relation 'express' occurs once, 'state' occurs 24 times.

fabric (something made by weaving or felting or knitting or crocheting natural or synthetic fibers)
covering (a natural object that covers or envelops)
This hypernymic combination subsumes 5 words: *fleece, hair, tapa, tappa, wool*.
'made from' occurs once.

person (a human being; "there was too much for one person to do")
language (a systematic means of communicating by the use of sounds or conventional symbols; "he taught foreign languages"; "the language introduced is standard throughout the text")
This pattern subsumes 257 words such as *Tatar, Assyrian, Hopi, Punjabi*.
The relation 'speak' occurs 132 times.

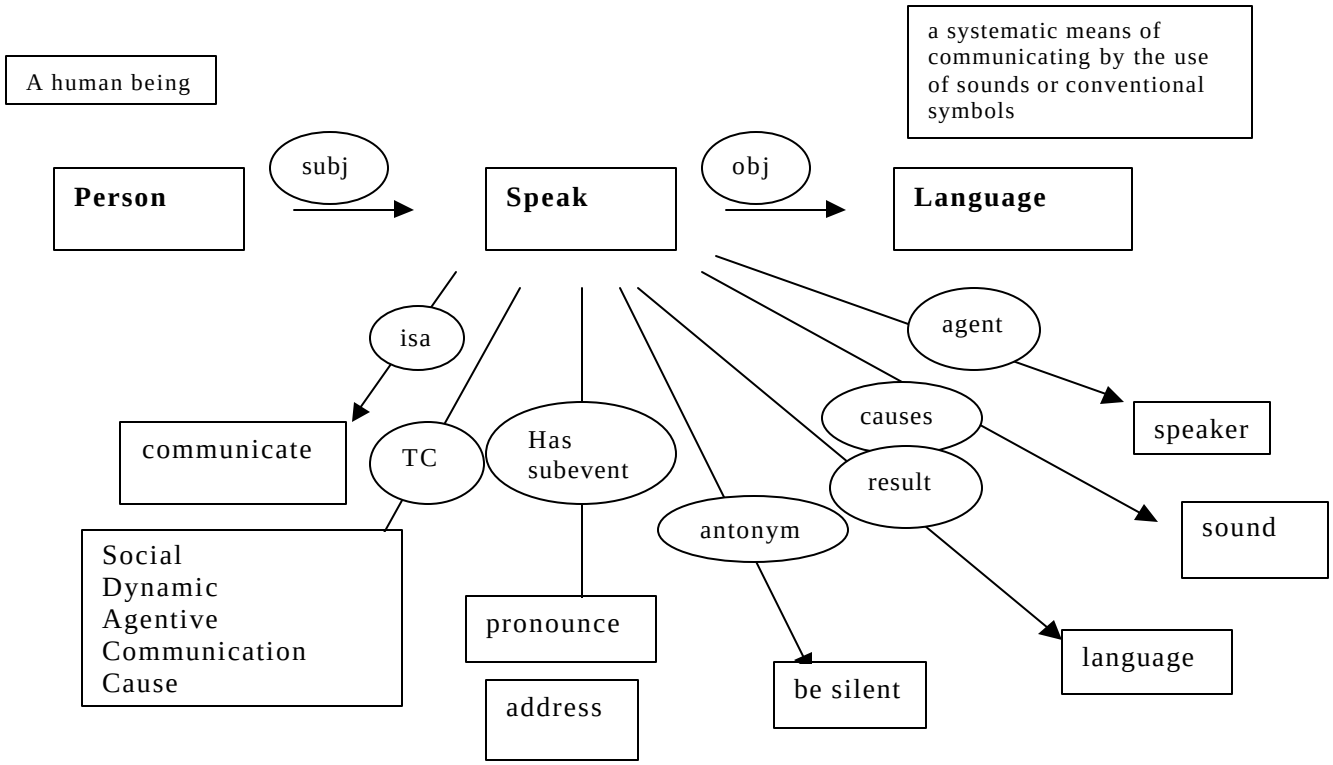

Figure 3: Expanded Ontological Fragment for the pattern person - speak - language

5 Expansion through EuroWordNet

Now we have obtained a number of patterns with specific relations it is possible to extend each ontological fragment consisting of concept triples (N-V-N) with explicit relations from EuroWordNet (Vossen, 1998). We have chosen this database over Wordnet because it contains more kinds of semantic relations than WordNet, such as thematic relations and links that hold between concepts lexicalized by different parts of speech.

First, the applicable verb senses was chosen manually. After that, relational chains in the database were extracted. Figure 3 and 4 exemplify this process for the verbs 'speak' associated with the pattern person - language and 'master' linking profession and discipline. The 'TC' relation indicates the EuroWordNet top concepts that are described in great detail in (Rodriguez et al., 1998).
The relations can all be considered additional slots in the partial knowledge frame that started as a regular polysemic pattern.
For instance, the additional knowledge fragments provided by EuroWordNet connect 'master' to 'knowledge', 'practice', 'learning' and 'teaching'. These can be used for inferencing purposes or knowledge extraction from texts.

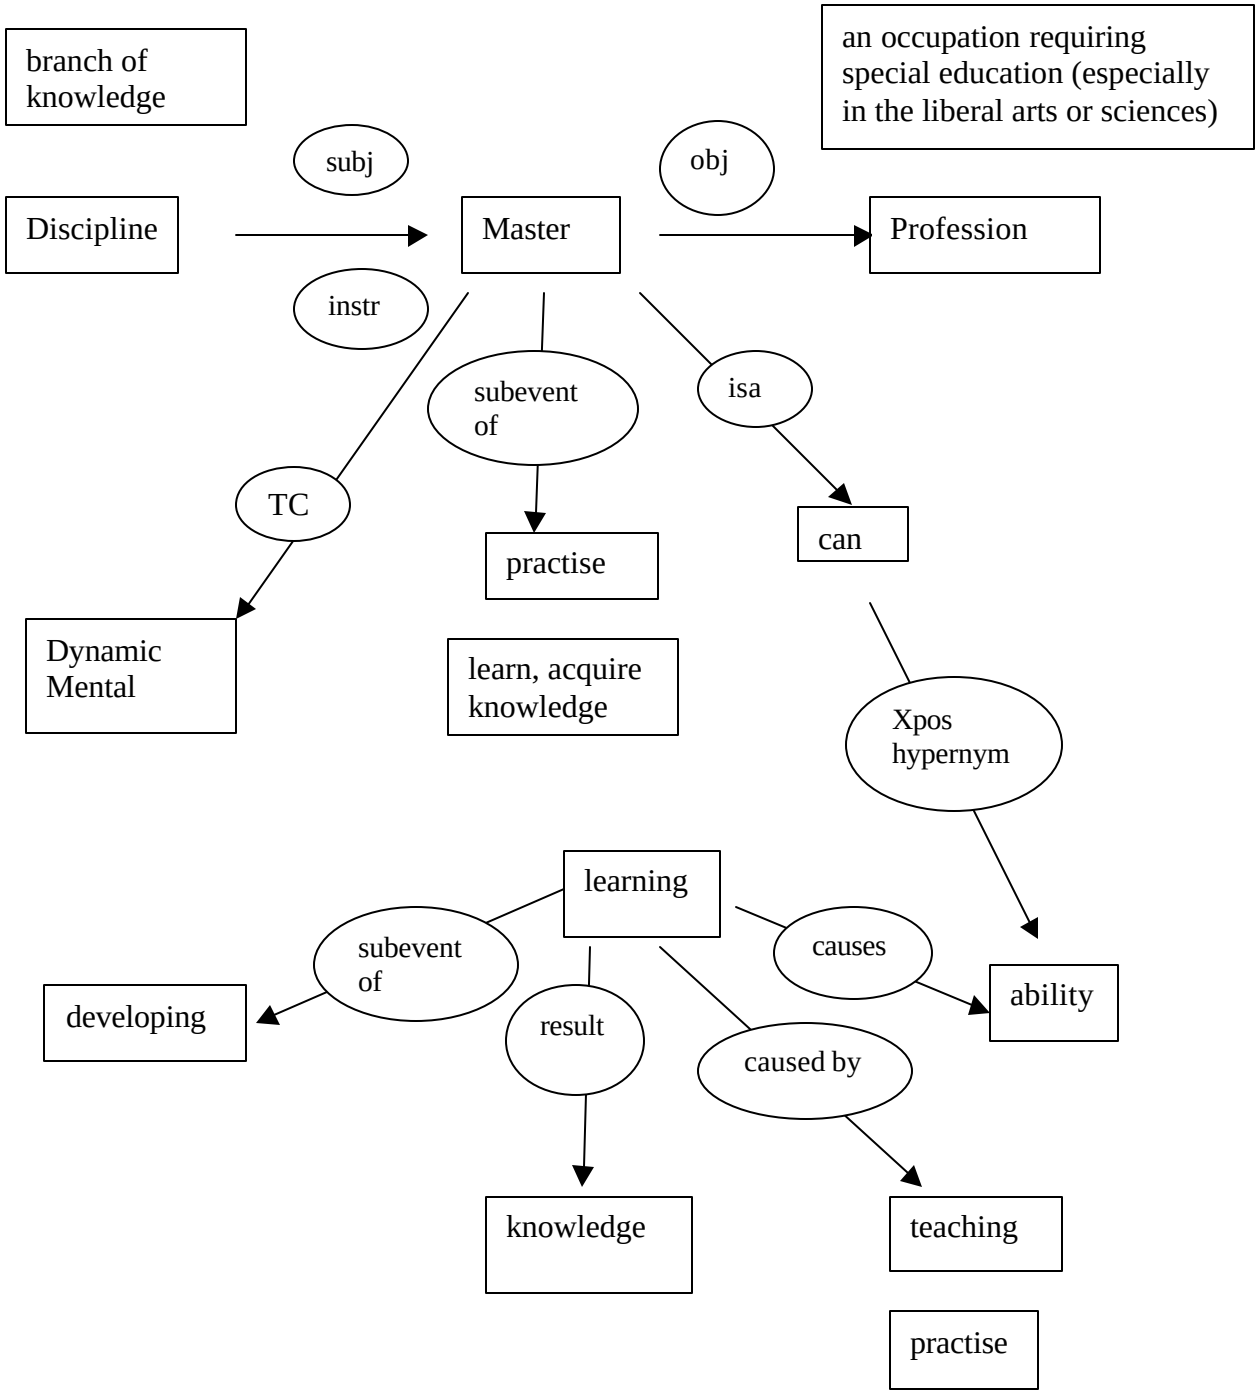

Figure 4: Expanded Ontological Fragment for the pattern **discipline - master - profession**

6 Discussion and conclusion

We have shown that the semi-automatic technique described above for extracting semantic relations between systematically related senses from WordNet glosses is feasible. There are cases, however, where no relations can be extracted, and where the extracted relations are wrong. Further experimentation with the syntactic properties of the glosses might improve results.

Rerendering Semantic Ontologies: Automatic Extensions to UMLS through Corpus Analytics

James Pustejovsky, Anna Rumshisky, José Castaño

Department of Computer Science, Brandeis University
Waltham, MA 02454
{jamesp, arum, jcastano}@cs.brandeis.edu

Abstract

In this paper, we discuss the utility and deficiencies of existing ontology resources for a number of language processing applications. We describe a technique for increasing the semantic type coverage of a specific ontology, the National Library of Medicine's UMLS, with the use of robust finite state methods used in conjunction with large-scale corpus analytics of the domain corpus. We call this technique "semantic rerendering" of the ontology. This research has been done in the context of Medstract, a joint Brandeis-Tufts effort aimed at developing tools for analyzing biomedical language (i.e., Medline), as well as creating targeted databases of bio-entities, biological relations, and pathway data for biological researchers (Pustejovsky et al., 2002). Motivating the current research is the need to have robust and reliable semantic typing of syntactic elements in the Medline corpus, in order to improve the overall performance of the information extraction applications mentioned above.

1. Introduction

Data mining and information extraction rely on a number of natural language tasks that require semantic typing; that is, the ability of an application to accurately determine the conceptual categories of syntactic constituents. Accurate semantic typing serves tasks such as relation extraction by improving anaphora resolution and entity identification. Domain-specific semantic typing also benefits statistical categorization and disambiguation techniques that require generalizations across semantic classes to make up for the sparsity of data. This applies, for example, to the problem of prepositional attachment, as well as identification of semantic relations between constituents within nominal compounds (see, for example, related discussion in Rosario & Hearst (2002)). Semantic typing has other direct applications, such as query reformulation, the filtering of results according to semantic type restrictions, and so on.

The set of categories used in semantic typing must be adequate enough to serve such tasks. In the biomedical domain, there are a number of efforts to develop specialized taxonomies and knowledge bases (UMLS, Gene Ontology, SWISS-PROT, OMIM, DIP). In this paper, we describe a method for adapting existing ontology resources for the natural language processing tasks and illustrate this technique on the National Library of Medicine's UMLS.

The UMLS, like many industry-standard taxonomies, contains a large number of word-concept pairings (over 1.5M typed terms), making it potentially attractive as a resource for semantic tagging information. However, these types are inadequate for NL tasks for two major reasons. First, the overall type structure is very shallow. For example, for the semantic tag "Amino Acid, Peptide, or Protein" (henceforth AAPP), there are 180,998 entries, for which there are dozens of functional subtypes that are routinely distinguished by biologists, but not in the UMLS.

One specific example of the type system deficiencies illustrates this point very clearly: the extraction of relations and their arguments from text is greatly improved with entity and anaphora resolution capabilities. However, entity and event anaphora resolution rely on (among other things) the semantic typing of the anaphor and its potential antecedents, particularly with sortal and event anaphora, as shown in (1) below.

(1) a. "For separation of nonpolar compounds, the prerun can be performed with *hexane*$_i$; ... The selection of *this solvent*$_i$ might be considered .."

b. [*p21*$_i$ inhibits the regulation of ...] ... [*This inhibitor*$_i$ binds to ...]

c. [A *phosphorylates*$_i$ B.] ... [*The phosphorylation*$_i$ of B ...]

Strict UMLS typing presents a problem for our anaphora resolution algorithm (Castaño et al., 2002). For example, for the case of anaphora in (1a), the UMLS Metathesaurus types *hexane* as either 'Organic Chemical' or 'Hazardous or Poisonous Substance'. However, *solvent* is typed as 'Indicator, Reagent, or Diagnostic Aid'. In the UMLS Semantic Network, these semantic types are not related. Therefore the resolution of the sortal anaphora would fail, due to the type mismatch. The fact is that hexane is a solvent, and this is simply not reflected in UMLS.

Functional subtyping is also missing, as (1b) illustrates. This example shows a known protein (p21) being subsequently referred to as an 'inhibitor' (a functional class of proteins). This type does not exist in UMLS and the noun 'inhibitor' is merely typed as 'Chemical Viewed Functionally', while p21 itself is typed as 'Gene or Genome', AAPP, or 'Biologically Active Substance'. It is therefore difficult to discriminate p21 from other proteins (as potential antecedents) for the sortal anaphor "this inhibitor".

A related difficulty is encountered with event anaphora cases such as (1c), where an event nominal anaphor binds to a tensed event as its antecedent, both of which are of different types in the UMLS. Hence, the existing UMLS system does not allow for recognition of type-subtype relations of the kinds that are needed in order to identify anaphoric bindings in Medline texts.

Given these motivations, we have developed a set of techniques for "rerendering" an existing semantic ontology to satisfy the requirements of specific features of a (set of) application(s). For the present case (i.e., the UMLS and bio-entity and relation extraction), we identify candidate subtypes for inclusion in the type system by two means: (a) corpus analysis on compound nominal phrases that express unique functional behavior of the compound head; (b) identification of functionally defined subtypes derived from bio-relation parsing and extraction from the corpus. The results of rerendering are evaluated for correctness against the original type system, and against additional taxonomies, should they exist, such as the GO ontology. In our preliminary experiments, we had domain experts partially verify it aganst the Gene Ontology. Full automatic verification will be done in the future.

2. Semantic Rerendering

Many NLP tasks in the service of information extraction can benefit from more accurate semantic typing of the syntactic constituents in the text. As mentioned above, the semantic taxonomy available from UMLS is lacking in several respects. With specific applications such as content summarization, anaphora resolution, and accurate relation identification in mind, we describe how an existing type system can be systematically adapted to better serve these needs, using a technique we call *semantic rerendering*. Semantic rerendering is a process that takes as input an existing type system (such as UMLS) and a text corpus, and proposes refinements to the taxonomy on the basis of two strategies:

- *Linguistic Rerendering*: Syntactic and semantic analysis of NP structures in the text;
- *Database Rerendering*: Analysis of "ad hoc abstractions" from a database of relations automatically derived from the corpus.

In the first strategy, we use the syntax of noun groups to identify candidate subtypes to an existing UMLS type. For example, categories that are of interest to biologists but which are not explicitly represented in the type system are functional categories such as *phosphorylators*, *receptors*, and *inhibitors*. These are each significant categories in their own right but also have a rich number of subtypes as well, as illustrated in (2) below.

(2)
```
CB(2) receptor
cannabinoid receptor
cell receptor
D1 dopamine receptor
epidermal growth factor receptor
functional GABAB receptor
gastrin receptororphan receptor
orphan nuclear receptor
major fibronectin receptor
mammalian skeletal muscle acetylcholine receptor
normal receptor
PTHrP receptor
protein-coupled receptor
ryanodine receptor
```

If individual proteins can be identified (i.e., semantically tagged) as belonging to a functionally defined class, such as *receptor*, then richer information extraction and textual binding is enabled.

There has been some recent research on extracting hyponym and other relations from corpora (Hearst, 1992; Pustejovsky et al., 1997; Campbell & Johnson, 1999; Mani, 2002). Our work extends the techniques described in (Pustejovsky et al., 1997) using more extensive corpus analytic techniques as developed in Pustejovsky & Hanks (2001).

2.1. Linguistic Rerendering

We first describe the linguistic rerendering procedure for inducing subtypes from corpus data, given an existing taxonomy such as the UMLS. We being by taking the strings classified as <*supertype*> in the current type system. On the basis of their behavior in the corpus, we identify candidate subtypes, derived from an analysis of the structure of nominal compounds and clusters. We use the RHHR (*righthand head rule*, cf. Pustejovsky et al. (1997)) for compound nominals (CN) and create subtype <*head-of-CN*> from the type of the head of CN. We then create a node for type N' and insert it into the existing UMLS hierarchy.

More explicitly, the procedure for identifying candidate subtypes from the structure of nominal compounds is given below.

(1) Acquire corpus C.

(2) Apply existing type system *UMLS*$_1$ over C:
TS-UMLS$_1(C) = C_{S-Tag}$.

(3) Select from the resulting semantically tagged corpus C_{S-Tag} all *NPs* with semantic tag A with $\theta > \delta$, where θ is a measure of how interesting semantic type is for rerendering:

(4) For a given noun *N* that is the headword of a phrase with semantic tag A, propose *N* as *name* of a subtype of *S-Tag A*, $N' \sqsubseteq A$, if:

- N appears as head in a certain number of NPs of length $l \geq 2$;
- N falls under the threshold set for the headwords above, but is an LCS (longest common subsequence) of a number of syntactic heads that achieve it when combined [1];
- there is sufficient variation in words comprising the remainder of phrase (so as to exclude using collocations as subtypes).

(We will refer to the nodes inserted into the ontology at this stage *first-level extension*)

(5) Nouns in the residue of *NP* with *N* as head α as modifier can be proposed as subtypes of $\alpha N' \sqsubseteq N'$ (*second-level extension*).

[1] E.g. For AAPP, *oxidase* might not achieve the threshold by itself. However, it does when all headwords containing it as a subsequence are combined (i.e.*myeloperoxidase, peroxidase, deepoxidase,* etc.)

Further subcategorization of induced types, based on the analysis of modifiers within the nominal phrases, uses a combination of template filtering of noun phrases and the LCS (longest common subsequence) algorithm (Cormen et al., 1990). Notice that one must use different thresholds for headwords and modifiers (in step (4) or step (5) of the algorithm). However, at step (4), a candidate subtype may replicate exactly the parent node ($receptor \sqsubseteq Receptor$). In that case, first-level extension types must derived from subphrase analysis, but using the threshold established for step (4).

Once the candidate subcategories are selected, the next step is to obtain the instances for the induced subtypes. These instances and their type bindings can be identified from the corpus using a number of standard methodologies developed in the field for the expansion of ontology coverage (Hearst, 1992; Campbell & Johnson, 1999; Mani, 2002). For the moment, in the experiments we conducted, we used syntactic pattern templates to identify the strings that map to the proposed extensions of UMLS types (see examples in Table 1 below).

This procedure will result in differential depth of UMLS extension for functionally defined vs. naming categories. For example no strings should map to $\{head, neck, arm, leg\} \sqsubseteq$ *<Body Location or Region>*, while string mappings are easily obtained for relational nouns such as $\{solvent, antibody, conjugate\} \sqsubseteq$ *<Indicator, Reagent, or Diagnostic Aid>*.

2.2. Database Rerendering

The second strategy uses a database of biological relations constructed through the application of robust natural language techniques as outlined in Pustejovsky et al. (2002) and Castaño et al. (2002). Over this database, "ad hoc" categories are created by projecting statistically thresholded arguments. More formally, for a particular relation, a typed projection is obtained:

$\pi X = \{X : T_1 | R(X, Y) \wedge T_1 \in UMLS_1\}$

R	X	Y
phosphorylate	"TNIK"	"Gelsolin"
phosphorylate	"GSK-3"	"NF-ATc4"
phosphorylate	"IKK-beta"	"IkappaB"
...	...	...
inhibit	"PD-ECGF"	"DNA synthesis"
inhibit	"BMP-7"	"terminal chondrocyte differentiation"
block	"DFMO"	"ODC activity"
abrogate	"Interleukin-4"	"hydrocortisone-induced apoptosis"
...	...	...

Table 2: A sample segment of relations database

The noun forms for such ad hoc categories are determined by checking each relation against the first-level extension subtypes derived through NP structure analysis as outlined above. Thus,

- For relation R and each subtype $N' \sqsubseteq T_1$, associate N' with πX if $Sim(N, \pi R) > \epsilon$.

e.g. $Sim($ "kinase", "phosphorylate" $)$,
$Sim($ "inhibitor", "inhibit" $)$, etc.

Note that the ad hoc category created through projection of the relation's argument can be matched with the types obtained at the second-level of NP-based ontology extension.

The similarity measure is constructed as a weighted combination of string similarity (e.g. *LCS*-based score), and an integrated composite measure derived from the training corpus and the outside knowledge sources. The latter might use standard IR similarity measures on contexts of occurrence of R and N in Medline abstracts, in definitions of R and N in domain-specific MRDs (such as the On-line Medical Dictionary), etc. Thus, we have:

$$Sim(N, \pi R) =$$
$$= z_0 * \text{ LCS-score } (N, \pi R) + \Sigma_{i=1}^{k} z_i * Sim_i(N, \pi R)$$

where $Sim_i(N, \pi R)$ is the similarity score derived from the source i, and z_i is the weight assigned to the source i.

3. Methodology

3.1. Seed Ontology

The Unified Medical Language System (UMLS) which was used as the seed ontology has three components: the UMLS Metathesaurus, the UMLS Semantic Network, and the SPECIALIST Lexicon (UMLS Knowledge Sources, 2001). The UMLS Metathesaurus maps single lexical items and complex nominal phrases into unique concept IDs (CUIs) which are then mapped to the semantic types from the UMLS Semantic Network. The latter type taxonomy is what was used in the experimental applications of rerendering procedure. It consists of 134 semantic types hierarchically arranged via the 'isa' relation and interlinked by a set of secondary non-hierarchical relations. UMLS Metathesaurus in the UMLS 2001 distribution contains over 1.5 million string mappings.

In the Metathesaurus, multiple semantic type bindings are specified for many of the concepts. Due to this ambiguity of UMLS concepts and to a lesser extent, the ambiguity of the strings themselves, the mappings obtained from the Metathesaurus give a number of semantic types for each lexical item or phrase. We intentionally avoid superimposing any disambiguation mechanism on this typing information while applying it in corpus analysis. Since corpus-based derivation of subtypes uses a frequency cutoff, this ambiguity essentially resolves itself. For example, if a given lexical item is typed as both T_1 and T_2 in the seed ontology, and occurs as a headword in $> 1\%$ of nominal phrases typed as T_1, but in $< 1\%$ of nominal phrases typed as T_2, it will only be proposed as a candidate subtype of T_1. Thus, under the 1% cutoff, *isozyme*, which the seed UMLS types as either $Enzyme$ or $AAPP$, will only be identified as a good candidate subtype for *Enzyme*.

3.2. Corpus preprocessing with UMLS types

The experimental application of the rerendering procedure was conducted on a relatively small corpus of Med-

Pattern Type	TEMPLATE	
apposition	"X, a Y inhibitor"	"X, the solvent
	"X, an inhibitor of Y"	"the solvent, X"
	"X, an inhibitor of Y"	"X, a common solvent for Y"
nominal compounds	"Y inhibitor"	"the solvent X"
definitional constructions	"X is an inhibitor of Y"	
aliasing constructions	"X (inhibitor of Y)"	"X (the solvent)"
	"an inhibitor of Y (X)"	"the solvent (X)"
enumeration	"Y inhibitors such as X, ..."	"solvents (e.g. X)"
		"solvents, e.g. X"
		"the following solvents: X, .."
relative clauses	"X which is an inhibitor of Y"	"the solvent used was X"
		"X proved to be a suitable solvent"
adjuncts		"in X and Y as solvents"
		"X as solvent"

Table 1: Sample syntactic patterns for string-to-semantic type mappings

line abstracts (around 40,000). Medline abstracts were tokenized, stemmed, and tagged. They were then shallow-parsed, with noun phrase coordination and limited prepositional attachment (only *of*-attachment) using finite-state techniques. The shallow parse was obtained using five separate automata each recognizing a distinct family of grammatical constructions, very much in the spirit of Hindle (1983), McDonald (1992) and Pustejovsky et al. (1997). The machinery used in preprocessing is described in more detail in Pustejovsky et al. (2002).

Semantic type assignment of the resulting nominal chunks is determined through lookup as follows. Each noun phrase is put through a cascade of hierarchically arranged type-assignment heuristics. Higher priority heuristics take absolute precedence; that is, if a semantic typing is possible, it is assigned. In this implementation, we use the full UMLS semantic type hierarchy, including the mappings to both leaves and intermediate nodes.

During direct lookup, a string is assigned a given semantic type if the UMLS Metathesaurus contains a mapping of that string to a concept so typed. If a semantic type for the whole phrase is not found in UMLS, we attempt to identify its syntactic head using a modification of RHHR (*righthand head rule*), and determine the semantic type of the headword. For chunks with *OF*-attachment, i.e. phrases of the form, *<NP-1> of <NP-2>*, the lookup is first attempted on *NP-1* as a whole.

If the lookup on a particular prospective head fails, it is tested for a match with morphological heuristics recognizing semantically vacant categories, such as 'NUMERIC', 'ABBREVIATION', 'SINGLE CAPITAL LETTER', 'SINGLE LOWER-CASE LETTER', etc. These, and phrases headed by common words occurring in a non-specialized dictionary are filtered out. The last layer of heuristics applied to a prospective syntactic head successively attempts to strip a groups of suffixes and prefixes and perform lookup on the remaining stem.

3.3. Inducing candidate subtypes

In these initial series of tests, we experimented primarily with the first part of the rerendering procedure as it is outlined in Section 2.1. In the first stage of identifying the subtypes based on the syntactic analysis of noun phrase structure, a headword was considered a candidate subtype of type T if it occured in more that 1% of all nominal chunks tagged as T. Note that the same chunk is frequently tagged with several UMLS types.

The candidate subtypes for the second (NP modifier-based) level of UMLS extension were identified using a combination of template and frequency-based filtering of noun phrases and the LCS (longest common subsequence) algorithm. Thus, for a given headword proposed as subtype at first level of extension (e.g., *kinase*) the LCS algorithm was run on all phrases with that headword that matched a certain template (e.g. <Indefinite Article> <Modifier>* N). The substrings that occurred in the corpus in more than a certain percentage of phrases with that headword were identified as candidate subtypes for insertion into the ontology at the next level. The cut-off threshold had to be kept very low for this series of experiments, as it was conducted over a relatively small corpus. In working with a larger corpus the thresholds are set separately for each template, so e.g. it is much higher for the unfiltered set of nominal compounds than for those occurring with an indefinite article. Frequency-based filtering involves discarding as potential candidates noun phrases with modifiers that occur frequently in separate non-specialized corpus, which allows to automatically discard phrases such as 'multiple receptors', 'specific kinase', etc. [2]

Identification of sample instances for the induced types was performed over shallow-parsed text using syntactic pattern templates. The definitional construction patterns were extracted using relation extraction machinery (see Pustejovsky et al. (2002) for details). It was applied to our test corpus and another sample set of Medline abstracts (approx. 60,000).

4. Results

Semantic typing over our sample set of Medline data produced type bindings for over 1 million noun phrases.

[2] Similar filtering was also applied to the first-level extensions

4.1. NP analysis-based subtypes

The choice of particular UMLS categories as supertypes for extension of the seed UMLS semantic type taxonomy is dictated by the particular natural language application. Semantic types given below are derived from nominal phrase analysis for some of the supertypes that have been used in anaphora resolution tasks (cf Castaño et al. (2002)). Each UMLS type is shown with the number of noun phrases of that type which occurred in our test corpus, followed by a list of derived candidate subtypes with their respective frequencies. The subtypes shown below were derived as described above in step 4 of the rerendering procedure specification in Section 2.1.

```
Enzyme 4724
      dehydrogenase 140
      protease 160
      reductase 73
      metalloproteinase 48
      isozyme 54
      oxidase 79
      phosphatase 111
      enzyme 1142
      kinase 741

Amino Acid, Peptide, or Protein 20830
      receptor 2444
      protein 4521
      peptide 947
      kinase 741
      cytokine 287
      isoform 412

Cell 16348
      macrophage 251
      clone 350
      neuron 1094
      lymphocyte 412
      fibroblast 257
      cell 11586

Cell Component 2508
      cytosol 84
      nucleus 469
      liposome 43
      organelle 40
      vacuole 35
      ribosome 28
      cytoskeleton 55
      dendrite 53
      cytoplasm 195
      soma 26
      granule 80
      chromatin 36
      microtubule 45
      chromosome 319
      axon 99
      microsome 132
```

Notice that the categories derived in this manner would include functionally defined types (e.g. *isoform*).

4.2. NP modifier-based extension (second-level)

As mentioned above, some of the UMLS extension candidates that are derived according to the procedure are replicas of the supertype category, e.g. $enzyme \sqsubseteq Enzyme$, or $receptor \sqsubseteq Receptor$. For example, among the lexical items tagged as *Receptor* in UMLS Metathesaurus, NPs headed by the word "receptor" comprise 87% of all NPs tagged as *Receptor* in our test corpus:

```
Receptor 2820
      integrin 91
      receptor 2444
```

The appropriate extensions to the comparable level within the type taxonomy in this case are derived from subphrase analysis. Thus, for the case of $enzyme$, the candidate subtypes so derived would be:

```
cytosolic enzyme
heterologous enzyme
male enzyme
metalloenzyme
multifunctional enzyme
proof-reading enzyme
proteolytic enzyme
rate-limiting enzyme
recombinant enzyme
rotary enzyme
tetrameric enzyme
```

These are identified at step 5 of rerendering procedure through a combination of template filtering of noun phrases and longest common substring identification. They are then added to the same level of the type taxonomy as all $N' \sqsubseteq Enzyme$ (see Figure 1).

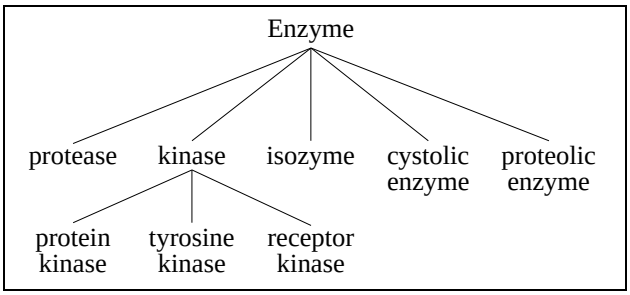

Figure 1: Extension subtree for $Enzyme$ (partial)

The results produced at this stage by the automated processing described above need further filtering before good subtype candidates can be identified. This can be achieved by fine-tuning the use of corpus frequencies, as well as type filtering of modifiers using the seed ontology type system. Table 3 below shows UMLS types for selected NP modifier-based subcategories of $receptor$.

4.3. Corpus-based identification of the instances of induced semantic categories

The rerendering procedure gives different results for different segments of the taxonomy, depending on the class of supertype category. Thus, for functionally defined semantic types, such as, "Chemical Viewed Functionally", or "Indicator, Reagent, or Diagnostic Aid", corpus-based derivation of instances for the induced subcategories is clearly much more feasible. Consider the first level extension types for the categories below:

```
Indicator, Reagent, or Diagnostic Aid 3424
      buffer 151
      conjugate 112
      stain 75
      agar 38
      antibody 1640
      indicator 373
      solvent 38
      tracer 53
      dye 95
      reagent 113
      nitroprusside 51
      hydrogen peroxide 58
```

Candidate Subtypes $\alpha N' \sqsubseteq N'$	**Seed UMLS Type for Modifier** α
cell surface receptor	'Cell Component'
membrane receptor	'Tissue'
adhesion receptor	'Acquired Abnormality', 'Disease or Syndrome'
	'Natural Phenomenon or Process'
activation receptor	no type binding
contraction receptor	'Functional Concept'
estrogen receptor	'Steroid', 'Pharmacologic Substance', 'Hormone'
dopamine receptor	'Organic Chemical', 'Pharmacologic Substance',
	'Neuroreactive Substance or Biogenic Amine'
adenosine receptors	'Nucleic Acid, Nucleoside, or Nucleotide',
	'Pharmacologic Substance', 'Biologically Active Substance'
insulin receptor	'Amino Acid, Peptide, or Protein',
	'Pharmacologic Substance', 'Hormone'
TSH receptor	'Amino Acid, Peptide, or Protein', 'Hormone'
	'Neuroreactive Substance or Biogenic Amine'
EGF receptor	'Amino Acid, Peptide, or Protein', 'Hormone',
	'Pharmacologic Substance',
transferrin receptor	'Amino Acid, Peptide, or Protein', 'Biologically Active Substance',
	'Indicator, Reagent, or Diagnostic Aid', 'Laboratory Procedure'
receptor	**'Amino Acid, Peptide, or Protein', 'Receptor'**

Table 3: UMLS Typing of modifiers α for some sample subtypes $\alpha N' \sqsubseteq N'$ for N' =*receptor*

```
Chemical Viewed Functionally 3494
      inhibitor 1668
      prodrug 62
      basis 1075
      vehicle 107
      radical 144
      base 265
      pigment 36
      surfactant 36

Pathologic Function 17752
      impairment 383
      stenosis 274
      other 450
      illness 209
      problem 1133
      dysfunction 493
      block 244
      carrier 219
      inflammation 243
      pathogenesis 497
      cavity 273
      hemorrhage 180
      occlusion 266
      lesion 1820
      infarction 449
      regression 237
      pathology 242
      infection 1782
      complication 1248
      separation 320
      degeneration 180
      stress 487
```

Table 4 shows the derivation of instances for the categories induced through noun phrase analysis (step 5), using the definitional construction template. The first column shows the actual strings that get the new type binding as $kinase$ (in blue) and their original UMLS types (in black). Notice that for many of the strings that can be so typed, the seed UMLS type is either generic $AAPP$ or the type binding is absent altogether.

If the candidate subtype is a valid semantic category, such corpus-based identification of instances should work equally well irrespective of the level at at which the induced type is inserted. For example, see Table 5 below for NP modifier extensions of *receptor*.

cell-surface receptors:
polycystin-1 is a *cell surface receptor*
Fas is a *cell surface* death $receptor$
CD40 is a *cell surface receptor*
CD44 is a *cell surface receptor*
The scavenger receptor BI is a *cell surface* lipoprotein $receptor$
membrane receptors:
Neuropilin-1 is a trans*membrane receptor*
APJ is a seven trans$membrane$ domain G-protein-coupled $receptor$
HER2 is a *membrane receptor*

Table 5: Sample semantic type instances derived with the definitional construction template for subtypes of *receptor*

5. Evaluation of Rerendering Procedure

The evaluation of the performance for rerendering essentially boils down to whatever improvement is produced in precision and recall for the client applications. However, in order to do an earnest evaluation of performance of the rerendering algorithm, we would need to run it on a much larger corpus. This would allow for better candidate choices for the portions of the procedure that have been plagued by sparsity (e.g., in NP modifier-based candidate subtype selection). But most importantly, it would increase the coverage in terms of instances for which the type bindings are produced in the new type system.

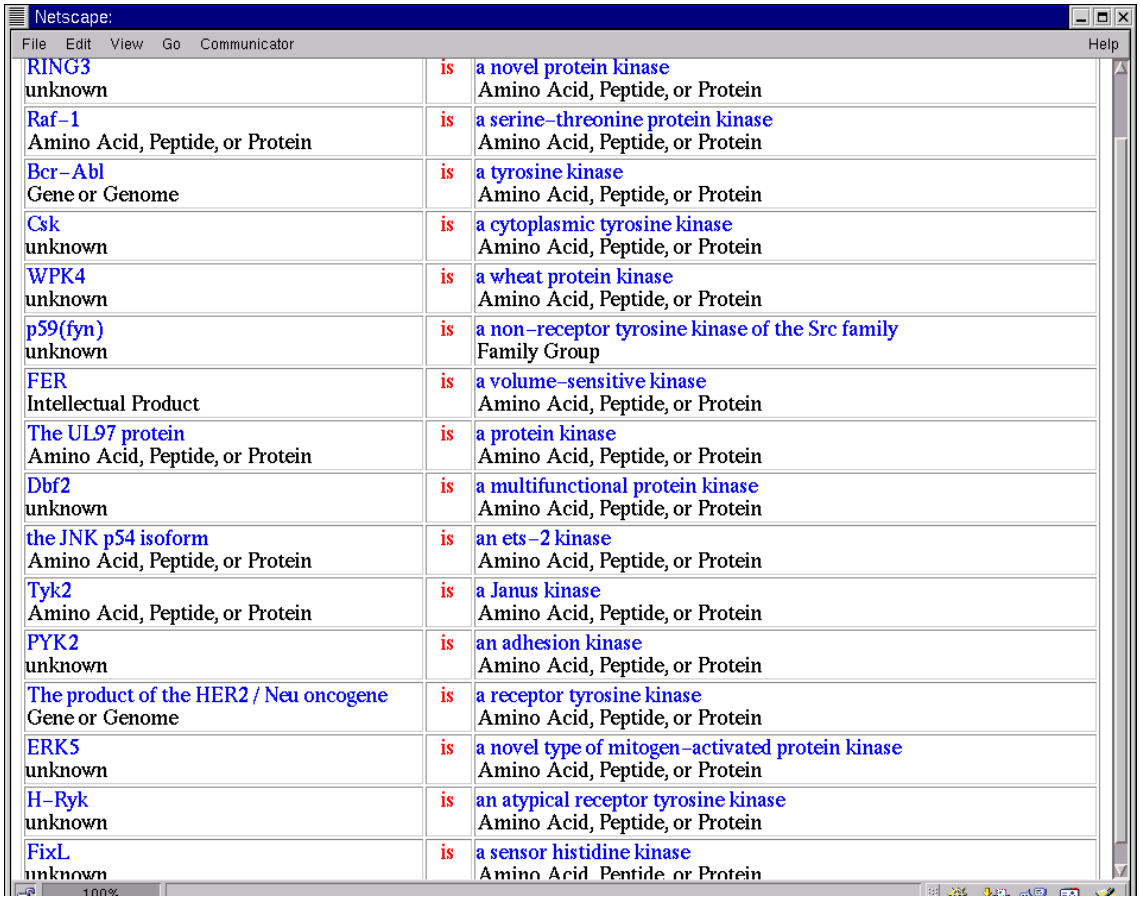

Table 4: Definitional construction template at work for the $N' = kinase$

5.1. Usability in natural language applications

One of the client applications for the experiments we report here is coreference resolution. The anaphora examples in (3) below illustrate the impact of using the derived types. Even the test corpus we used actually contained enough information to produce the type bindings for some of the strings used in (3).

(3) a. "Assays were conducted in *chloroform, toluene, amyl acetate, isopropyl ether, and butanol*. ... In *each solvent*,"

b. "The extracts were prepared separately in *methanol, ethanol, phosphate buffer saline (PBS), and distilled water* as part of our study to look at ... Our results have shown that *all four solvents* were ..."

c. "A 47-year-old man was found dead in a factory where *dichloromethane (DCM)* tanks were stocked. He was making an inventory of t he annual stock of DCM contained in several tanks (5- to 8000-L capacity) by transferring *the solvent* into an additional tank with the help of compressed air."

(emphasis added)

The seed ontology induces a type mismatch between the anaphor and the antecedent. For example, in (3c), the original type bindings are:

- *TS-UMLS*$_1$(solvent)= 'Indicator, Reagent, or Diagnostic Aid';
- *TS-UMLS*$_1$(dichloromethane)= {'Organic Chemical', 'Pharmacologic Substance', 'Injury or Poisoning'}

The rerendered ontology allows the induced semantic type *solvent* $\sqsubseteq$*<Indicator, Reagent, or Diagnostic Aid>* to be included in the type bindings for "dicloromethane".

5.2. Evaluation against existing ontologies

We performed some test evaluations of the second-level extension subtypes against the Gene Ontology. Despite the very modest side of our test corpus, we observed significant overlap in some categories. Thus, for example, the 388 second-level extension subtype candidates for *receptor*, 12% were identified as concept names in the Gene Ontology.

In general, the preliminary results of applying the first step of the rerendering procedure algorithm to the UMLS semantic type taxonomy appear quite encouraging. In the future, better automated methods for the evaluation of rerendering results against the existing ontologies must be developed. And most importantly, the utility and usefulness of the rerendering algorithm must be evaluated vis-a-vis achieving improvement in precision and recall for client NLP applications.

Abstract

It is very costly to build up lexical resources and domain ontologies. Especially when confronted with a new application domain lexical gaps and a poor coverage of domain concepts are a problem for the successful exploitation of natural language document analysis systems that need and exploit such knowledge sources. In this paper we report about ongoing experiments with 'bootstrapping techniques' for lexicon and ontology creation.

1. Introduction

It is very costly to build up lexical resources and domain ontologies. Especially when confronted with a new application domain lexical gaps and a poor coverage of domain concepts are a problem for the successful exploitation of natural language document analysis systems that need and exploit such knowledge sources.

We are confronted with such a situation very often in our work with the XDOC document suite, a collection of tools created to support intelligent processing of corpora of interesting textual documents taken from domains like engineering and medicine. The XDOC document workbench is currently employed in a number of applications. These include:

- knowledge acquisition from technical documentation about casting technology,
- extraction of company profiles from WWW pages,
- analysis of autopsy protocols.

The latter application is part of a joint project with the institute for forensic medicine of our university. The paper is organised as follows: We start with background information about XDOC. Then we sketch characteristics of the sublanguage of autopsy protocols and describe the core idea of our experiments. This is followed by a description of syntactic structures that are currently processed. Then clustering of co-occurrence data and its exploitation is described. A discussion of results and problems and an outlook on future work completes the paper.

2. Background: the XDOC document suite

We have designed and implemented the XDOC document suite as a workbench for the flexible processing of electronically available documents in German. The tools in the XDOC document suite(Kunze and Rösner, 2001a), (Kunze and Rösner, 2001b) can be grouped according to their function:

- preprocessing
- structure detection
- POS tagging
- syntactic parsing
- semantic analysis
- tools for the specific application: e.g. information extraction

In the semantic analysis, similar to the POS tagging, the tokens are annotated with their meaning and a classification in semantic categories like e.g. concepts and relations. For the semantic tagging we apply a semantic lexicon. This lexicon contains the semantic interpretation of a word and its case frame combined with the syntactic valence requirements. When we are confronted with a new application domain, the lexical resources must be completed with the domain specific terms. Even semantic resources with broad coverage like the semantic lexicon GermaNet for German (GermaNet-Project-Site, 2002) and Wordnet(Wordnet-Project-Site, 2002) for English, can not cover all terms of all different domains.

2.1. Design principles

The work in the XDOC project is guided by the following design principles:

- The tools shall be usable for 'realistic' documents.
  One aspect of 'realistic' documents is that they typically contain domain-specific tokens that are not directly covered by classical lexical categories (like noun, verb, ...). Those tokens are nevertheless often essential for the user of the document (e.g. an enzyme descriptor like EC 4.1.1.17 for a biochemist).
- The tools shall be as robust as possible.
  In general it can not be expected that lexicon information is available for all tokens in a document. This is not only the case for most tokens from 'nonlexical' types – like telephone numbers, enzyme names, material codes, ... –, even for lexical types there will always

be 'lexical gaps'. This may either be caused by neologisms or simply by starting to process documents from a new application domain with a new sublanguage. In the latter case lexical items will typically be missing in the lexicon ('lexical gap') and phrasal structures may not or not adequately be covered by the grammar.

- The tools shall be usable independently but shall allow for flexible combination and interoperability.
- The tools shall not only be usable by developers but as well by domain experts without linguistic training.

2.2. XML as unifying framework

We have decided to exploit XML (Bray et al., 1998) and its accompanying formalisms (e.g. XSLT (Site, 2002)) and tools (e.g. xt (Clark, 2002)) as a unifying framework. All modules in the XDOC system expect XML documents as input and deliver their results in XML format.

This decision has positive consequences for many aspects in XDOC. Take e.g. the desideratum that the tools of XDOC shall not only be usable by developers but as well by domain experts without linguistic training. Here XML and XSLT play a major role: XSL stylesheets can be exploited to allow different presentations of internal data and results for different target groups; for end users the internals are in many cases not helpful, whereas developers will need them for debugging.

2.3. Bridging lexical gaps

We do not expect extensive lexicon coding at the beginning of an XDOC application. XDOC's POS tagger and syntactic parser have therefore been augmented with a number of techniques for dealing with such 'lexical gaps'.

For POS tagging we exploit the morphology component MORPHIX (Finkler and Neumann, 1988): If a token in a German text can be morphologically analysed with MORPHIX the resulting word class categorisation is used as POS information. Note that this classification need not be unique. Since the tokens are analysed in isolation multiple analyses are often the case. Some examples: the token 'der' may either be a determiner (with a number of different combinations for the features case, number and gender) or a relative pronoun, the token 'liebe' may be either a verb or an adjective (again with different feature combinations not relevant for POS tagging).

MORPHIX's coverage can be characterised as follows: most closed class lexical items of German as well as all irregular verbs are covered. The coverage of open class lexical items is dependent on the amount of coding. The paradigms for e.g. verb conjugation and noun declination are fully covered but to be able to analyze and generate word forms their roots need to be included in the MORPHIX lexicon.

Due to lexical gaps some tokens will not get a MORPHIX analysis, at least at the beginning of an XDOC application. We then employ two techniques: We first try to make use of heuristics that are based on aspects of the tokens that can easily be detected with simple string analysis (e.g. upper-/lowercase, endings, ...) and/or exploitation of the token position relative to sentence boundaries (detected in the structure detection module). If a heuristic yields a classification the resulting POS class is added together with the name of the employed heuristic (marked as feature SRC, cf. example 1). If no heuristics are applicable we classify the token as member of the class unknown (tagged with XXX).

To keep the POS tagger fast and simple the disambiguation between multiple POS classes for a token and the derivation of a possible POS class from context for an unknown token are postponed to syntactic processing (cf. below).

3. Bootstrapping in a new domain

XDOCs most recent application is part of a joint project with the institute for forensic medicine of our university. The medical doctors there are interested in tools that help them to exploit their huge collection of several thousand autopsy protocols for their research interests. The confrontation with this corpus from a new domain has stimulated experiments with 'bootstrapping techniques' for lexicon and ontology creation.

3.1. The core idea

The core idea is the following:

When you are confronted with a new corpus from a new domain, try to find linguistic structures in the text that are easy to detect automatically and that allow to classify unknown terms in a robust manner both syntactically as well as on the knowledge level. Take the results from a run of these simple but robust heuristics as an initial version of a domain dependent lexicon and ontology. Exploit these initial resources to extend the processing to more complicated linguistic structures in order to detect and classify more terms of interest automatically.

An example: In the sublanguage of autopsy protocols (in German) a very telegrammatic style is dominant. Condensed and compact structures like the following are very frequent:

- Harnblase leer. (Urinary bladder empty.)
- Harnleiter frei. (Ureter free.)
- Nierenoberflaeche glatt. (Surface of kidney smooth.)
- Vorsteherdruese altersentsprechend. (Prostate corresponding to age.)
- ...

These structures can be abstracted syntactically as <Noun><Adjective><Fullstop> and as semantically <Anatomic-entity><Attribute-value><Fullstop>. Furthermore they are easily detectable.

In our experiments we have exploited this characteristic of the corpus extensively to automatically deduce an initial lexicon (with nouns and adjectives) and an initial ontology (with concepts for anatomic regions or organs and their respective features and values).

3.2. A sublanguage analysis of autopsy protocols

The telegrammatic style of autopsy protocolls results in a preference for 'verbless' structures. It is e.g. much more likely that a finding like 'the mouth was open' is expressed as 'Mund geoeffnet.' (mouth open) although a more verbose paraphrase like 'Der Mund ist geoeffnet.' may occur sometimes.

Another consequence of the style is a preference for noun compounds in contrast to semantically equivalent noun phrases.

When referring to a concept like 'weight of the liver' the noun compound 'Lebergewicht' is more likely than the noun phrase 'Gewicht der Leber'. This generalizes for the weight of other organs: 'Organgewicht' is more likely than the noun phrase 'Gewicht des/der X'.

The need for contextual interpretation of terms may be seen as another consequence of the style. In local context with an organ as topic generic terms like 'Gewicht' (weight) or 'Durchmesser' (diameter) have to be interpreted as referring to the object in focus, i.e. the organ.

3.3. Refinements of the initial approach

In our corpus it is very likely that a syntactic structure of the type <Noun><Adjective><Fullstop> can semantically be interpreted as <Anatomic-entity><Attribute-value><Fullstop>, but there are exceptions. An example: 'Flachschnitt unauffaellig.' Here the noun does not denote an anatomic entity, but is referring to a diagnostic procedure in autopsy. On the other hand the adjective co-occurs with anatomic entities as well.

So the initial approach needs refinement: as long as the number of exceptions of a simple pattern (here: <Noun> <Adjective> <Fullstop>) in a heuristic remains small the exceptions (here: noun 'Flachschnitt') are simply checked first before the heuristic is applied for all cases in which the exceptions are not present.

3.4. Exploitation of syntactic constraints

Pattern based analysis is a first step only. For full syntactic parsing we apply a chart parser based on context free grammar rules augmented with feature structures. The output of a robust POS tagger is used as input to parsing. The POS tagger works on token in isolation. Its output may contain:

- multiple POS classes,
- unknown classes of open world tokens and
- tokens with POS class, but without or only partial feature information.

Example 1 *unknown token classified as noun with heuristics*

```
<NP TYPE="COMPLEX" RULE="NPC3" GEN="FEM"
        NUM="PL" CAS="_">
  <NP TYPE="FULL" RULE="NP1" CAS="_"
           NUM="PL" GEN="FEM">
       <N SRC="UNG">Blutanhaftungen</N>
  </NP>
  <PP CAS="DAT">
    <PRP CAS="DAT">an</PRP>
    <NP TYPE="FULL" RULE="NP2" CAS="DAT"
           NUM="SG" GEN="FEM">
      <DETD>der</DETD>
      <N SRC="UC1">Gekroesewurzel</N>
    </NP>
  </PP>
</NP>
```

The latter case results from some heuristics in POS tagging that allow to assume e.g. the class noun for a token but do not suffice to detect its full paradigm from the token (note that there are approximately two dozen different morphosyntactic paradigms for noun declination in German).

For a given input the parser attempts to find all complete analyses that cover the input. If no such complete analysis is achievable it is attempted to combine maximal partial results into structures covering the whole input (Rösner, 2000).

A successful analysis may be based on an assumption about the word class of an initially unclassified token (tagged XXX). This is indicated in the parsing result (feature AS) and can be exploited for learning such classifications from contextual constraints. In a similar way the successful combination from known feature values from closed class items (e.g. determiners, prepositions) with underspecified features in agreement constraints allows the determination of paradigm information from successfully processed occurrences. In example 2 features of the unknown word "Mundhoehle" (mouth) could be derived from the features of the determiner within the PP (e.g. gender feminine).

Example 2 *unknown token classified as adjective and features derived through contextual constraints*

```
<NP TYPE="COMPLEX" RULE="NPC3" GEN="MAS" NUM="SG"
    CAS="NOM">
  <NP TYPE="FULL" RULE="NP3" CAS="NOM" NUM="SG"
        GEN="MAS">
    <DETI>kein</DETI>
    <XXX AS="ADJ">ungehoeriger</XXX>
    <N>Inhalt</N>
  </NP>
  <PP CAS="DAT">
    <PRP CAS="DAT">in</PRP>
    <NP TYPE="FULL" RULE="NP2" CAS="DAT" NUM="SG"
        GEN="FEM">
      <DETD>der</DETD>
      <N SRC="UC1">Mundhoehle</N>
    </NP>
  </PP>
</NP>"
```

The grammar used in syntactic parsing is organised in a modular way that allows to add or remove groups of rules. This is exploited when the sublanguage of a domain contains linguistic structures that are unusual or even ungrammatical in standard German.

Example 3 *Excerpt from syntactic analysis*

```
<PP CAS="AKK">
  <PRP CAS="AKK">auf</PRP>
  <NP TYPE="COMPLEX" RULE="NPC3" GEN="MAS" NUM="SG"
   CAS="AKK">
    <NP TYPE="FULL" RULE="NP1" CAS="AKK" NUM="SG"
    GEN="MAS">
      <N>Flachschnitt</N>
    </NP>
    <PP CAS="AKK">
      <PRP CAS="AKK">in</PRP>
      <NP TYPE="FULL" RULE="NP2" CAS="AKK" NUM="SG"
      GEN="NTR">
        <DETD>das</DETD>
        <N>Gewebe</N>
      </NP>
    </PP>
  </NP>
</PP>
```

3.5. Beyond simple patterns

At the time we work with a 'light' grammar of 40 rules. This grammar contains basic rules (for the analysis of noun phrases and preposition phrases) and specific rules, based on the patterns of the sublanguage.

We have just started to extract binary relations from completely parsed sentences. Following patterns of the sublanguage are analysed in this manner: Simple structures like: <NP> <Adjective> <Fullstop> will be analysed as <Anatomic-entity> <Attribute-value> <Fullstop>.

Example 4 *For example: 'Gehirngaenge frei.'. The Analysis returns:*

```
<RATT-V>
   <ENTITY>Gehoergaenge</ENTITY>
   <VALUE CNT="1">frei</VALUE>
</RATT-V>
```

All results of this analysis are also marked as XML structure. The attribute 'CNT' contains the number of occurences of the attribute value in context with the anatomic entity. A similar pattern is the structure <NP> 'ist|sind'[1] <Adjective>|<Verb> <Fullstop>.

Example 5 *For example: 'Gangsysteme sind frei.' or 'Augen sind geschlossen'. The Analysis returns:*

```
<RATT-V>
   <ENTITY>Gangsysteme</ENTITY>
   <VALUE CNT="1">frei</VALUE>
</RATT-V>
<RATT-V>
   <ENTITY>Augen</ENTITY>
   <VALUE CNT="1">geschlossen</VALUE>
</RATT-V>
```

Further on we analyse structures which contain more than attribute and domain entity. We extended our analyses to structures, which e.g. contain a modifier like 'sehr' (very) or a negator like 'nicht' (not) and other adjectives.

Example 6 *Result of the example: 'Brustkorb nicht sehr breit.*'

```
<RATT-V>
   <ENTITY>Brustkorb</ENTITY>
   <VALUE CNT="1">nicht-sehr-breit</VALUE>
</RATT-V>
```

Here the attribute is compounded of a series of words from different wordclasses, because at the time we work with binary relations only. In ongoing work we will further detail this semantic interpretation. In addition we analyse complex structures like coordinated structures. There exist various pattern, e.g. <NP> <Adjective>|<Verb> 'und' <Adjective>|<Verb><Fullstop>. These structures are interpreted as <Anatomic-entity> <Attribute-value1> 'and' <Anatomic-entity> <Attribute-value2><Fullstop>.

Example 7 *For example: 'Beckengeruest festgefuegt und unversehrt.'. The result is:*

```
<RATT-V>
   <ENTITY>Beckengeruest</ENTITY>
   <VALUE CNT="1">festgefuegt</VALUE>
   <VALUE CNT="1">unversehrt</VALUE>
</RATT-V>
```

[1] is|are, | expresses alternatives in pattern

The inverse structure (the coordination at the beginning of the pattern) e.g. <Adjective> 'und' <Adjective> <NP> <Fullstop> can also be analysed.

Example 8 *For example: 'Akute und chronische Erweiterung des Herzens.*'

```
<RATT-V>
   <ENTITY>Erweiterung des Herzens</ENTITY>
   <VALUE CNT="1">akute</VALUE>
   <VALUE CNT="1">chronische</VALUE>
</RATT-V>
```

Another coordinated pattern is <NP> 'und' <NP> <Adjective>|<Verb> <Fullstop>. The semantic interpretation is similar to the analysis of the simple structures: <Anatomic-entity1> <Attribute-value> 'and' <Anatomic-entity2><Attribute-value><Fullstop>.

Example 9 *For example: 'Rippen und Wirbelsaeule intakt.' The result is:*

```
<RATT-V>
   <ENTITY>Rippen</ENTITY>
   <VALUE CNT="1">intakt</VALUE>
</RATT-V>
<RATT-V>
   <ENTITY>Wirbelsaeule</ENTITY>
   <VALUE CNT="1">intakt</VALUE>
</RATT-V>
```

The pattern, like the example 'Leber und Niere ohne Besonderheiten.'('Liver and kidney without findings.'), differs from the last described structures in the kind of the attribute. In this structure the attribute is described by a preposition phrase. The analysis returns

Example 10 *Result of 'Leber und Niere ohne Besonderheiten.':*

```
<RATT-V>
   <ENTITY>Leber</ENTITY>
   <VALUE CNT="1">ohne Besonderheiten</VALUE>
</RATT-V>
<RATT-V>
   <ENTITY>Niere</ENTITY>
   <VALUE CNT="1">ohne Besonderheiten</VALUE>
</RATT-V>
```

4. Ontology creation

4.1. Analysis of co-occurrence data

Co-occurrence data are used for clustering: We start e.g. with an adjective token that is related to a single noun type only in the analysed data.

If - again within the corpus given - this noun co-occurs only with this very adjective then the relation between the noun's concept and the property denoted by the adjective is very strong. It may even be the case that the adjective-noun-combination is a name like fixed phrase.

If the noun co-occurs with other adjectives as well it is interesting to uncover the relation between the adjectives and denoted properties respectively.

There are a number of possibilities:

- Two adjectives may be used as 'quasi-synonyms',
- Adjectives may be in an antinomy relation,
- Adjectives may refer to discrete values of a property that are linearly ordered on a scale,

- Adjectives refer to values of different properties.

We can proceed in a zig-zag-manner:

We have started with a single adjective and checked for its co-occurring noun. We then asked for other adjectives co-occurring with this noun. In the next step we extend the set of nouns with those nouns that co-occur with at least one of the adjectives in the adjective set.

Then we can extend the adjective set accordingly. The process will definitely stop if in a step the set to be expanded (either the noun or the adjective set) is no longer growing and has thus reached a fixed point.

As soon as the zig-zag-procedure adds an adjective to the adjective set thats co-occurs with many nouns of different type then in the next step, when the co-occurring adjectives of all these nouns are added, we may produce (nearly) a full covering of all adjectives and of all nouns respectively.

4.2. Exploiting co-occurrence information

4.2.1. Concept detection

A noun phrase of the type <Adj> <Noun> may be like the name of a concept but this does not always hold and depends on usage.

An example: 'fluessige Galle' as in 'In der Gallenblase fluessige Galle' is a property value, not a name. On the other hand 'harte Hirnhaut' is to be treated as nameing a concept. This can be inferred from the usage of the NP 'harte Hirnhaut' in structures of the type

<NP><Adj> like 'harte Hirnhaut perlmuttergrau'.

4.2.2. Concept classification

Currently linguistic structures are mapped into binary relations. An example:

Harte Hirnhaut grauweiss.

is an application of the grammar rule with

<NP> <Adjective> <Fullstop>

as right hand side. This establishes a <Property> <Concept> pair.

If we invert this relation (i.e. give a listing of all property values that co-occur – with number of occurrences above a threshold – with the concept) this yields:

Harte Hirnhaut: glaenzend, grauweiss, perlmuttergrau, weisslich-gelblich-verfaerbt, intakt, grauroetlich, blaeulich-durchscheinend

If we analyze these adjectives (and compounded adjective groups) we find the following:

- there is one very generic property 'intakt' (engl. 'intact') that is usable with almost any anatomic-entity
- the adjective 'glaenzend' is characterising the visual appearance of the brain skin as shiny
- all other adjectives denote a variety colors

Thus the brain skin can be classified as an anatomic-entity whose color values are relevant in autopsy reports.

4.2.3. Concept grouping

Clustering of co-occurrence data allows to detect candidates for semantic groups as well as synonyms and/or paraphrases.

- 'spiegelnd': 'Herzueberzug', 'Lungenueberzug'
- 'unversehrt': 'Haut des Rueckens', 'Stirnhaut'
- 'frei': 'Gehoergange', 'Ausfuehrungsgang', 'Kehlkopfeingang'

All concepts co-occurring with 'frei' are of the type tube.

4.3. Ontological relations

What ontological relations can be inferred?

- Is-a: Leber Is-a Organ
- Part-of: Schleimhaut Part-of Magen (generalized Schleimhaut Part-of Organ)
- other n-nary relations: e.g. 'nicht widernatuerlich beweglich'

Further on we can find a classification of relations resp. the domain range of an relation. For example the relation 'geoeffnet' (opened) can be changed by modifier in the attribute-value

- 'geoeffnet'
- 'spaltweit-geoeffnet'
- 'spaltfoermig-geoeffnet'
- 'geschlossen' (as opposite to 'geoeffnet')

5. Discussion

Our current work is of an investigative nature. The size of the corpus is still small. It is planned to apply the techniques developed with the initial corpus to the collection of several thousand protocols. The number of occurrences is still small and statistical methods are therefore not yet adequate. Even if quantitative measures are not applicable on the basis of this corpus occurrence data can be interpreted qualitatively.

Since we have just recently started with the domain of autopsy protocols there are e.g. still gaps in grammar coverage and in the tagging process (not every unknown word can be classified by heuristics). In the corpus currently approx 37 % of the sentences and telegrammatic structures can be fully processed (i.e. get at least one reading covering the structure as a whole; multiple readings are possible.) Experiments with the full corpus will allow to evaluate how reliable the results are.

The telegrammatic style results in shorter and – on the first sight – 'simpler' linguistic structures. As a trade-off these structures are less constrained and this e.g. complicates the derivation of morphosyntactic features from context or makes inferred results less reliable.

An example: If 'Nieren' is an unknown token the full sentence 'Die Nieren sind unversehrt' allows to infer that the token is a plural form, the same inference is not possible from the telegrammatic version 'Nieren unversehrt'.

5.1. XDOC as a workbench

We are aiming at a workbench with a rich functionality but we do not expect a fully automatic and autonomous solution. The user shall be supported as good as possible but s/he will still be involved in the process.

Our approach is interactive. The user has to confirm suggestions from the system. He is accepting or refusing, but can delegate searching, comparing, counting etc. to the system.

5.2. Acquisition of domain knowledge

Some findings in autopsy protocols are results of measurements: values of weights, sizes, diameters etc. are reported.

This allows to collect 'typical values' and to gain distributions for ranges of values.

For weights a typical pattern is:

<organ>gewicht <number> g.

'Lebergewicht ... g'

From the texts we derived the range of the weight-relation for example for the organ kidney as 135 g to 270 g (in a medical manual the weight of the kidney is defined in the range of 120 g to 300 g).

Sometimes contextual interpretation is necessary:

<organ><property-value>. Gewicht <number> g.

Here the generic term 'Gewicht' (weight) has to be interpreted as referring to the organ in focus.

Similar constructions are employed for other indicators like diameters.

5.3. Future work:

For the quality of inferences the detection of synonyms and paraphrases plays a major role, e.g. 'Blase' and 'Harnblase' do refer to the same organ, 'Stirnhaut' and 'Haut der Stirn' denote the same region: the skin of the forehead.

A general solution for coordinated structures will be necessary.

A subtype of coordinated structures includes truncation of compounds. An example: 'Wangen- und Kinnpartie unauffaellig.' The reconstruction of the untruncated term is not always as simple as in the example. For this task we need an approach similar to the one described in (Buitelaar and Scaleanu, 2002). It must not only be analysed which is the semantic meaning of the word, but rather which is the word, which was truncated. One criterion is, that the words must have the same semantic category.

A general component for the semantic treatment of noun compounds is needed. This will have to interact with contextual interpretation. In an example like

24. Hirngewicht 1490 g. Windungen abgeflacht, Furchen verstrichen. ...

it has to be detected that with the reference to the weight of the brain ('Hirngewicht') the brain is established as topic and that the terms 'Windungen' and 'Furchen' are referring to findings about the brain's visible appearance.

Autopsy protocols are written in a way such that the course of the autopsy is directly reflected in discourse structure. The autopsy on the other hand follows anatomic structures and their neighbourhood relations. In local contexts we both find part-of relations between anatomic structures as well as neighbourhood relations.

The analysis of noun phrases needs to be more fine grained. Structures like 'Haut des Rueckens' or 'Haut ueber der Nase' should e.g. be interpreted as localisation information that is specifying regions of the skin (here: 'skin of the back' and 'skin of the nose').

Supports

This workshop has been organised in part with support from the ISLE Project – International Standards for Language Engineering (IST-10647). The ISLE Project is funded by the European Union, the National Science Foundation of the USA, and the Swiss Government.

Workshop Programme

9:00 – 9:15	Introduction and welcome to the workshop – *Maghi King*
9:15 – 9:45	Introduction to the ISLE taxonomy for MT evaluation – *Maghi King* and *Andrei Popescu-Belis*
9:45 – 10:15	Overview of human-based metrics for MT evaluation – *Florence Reeder*
10:15– 10:45	The DARPA 2001 automated metric and its relation to IBM's BLEU – *George Doddington*
10:45 – 11:00	Summary of the proposed evaluation tasks – *Andrei Popescu-Belis*
11:00 – 11:40	**Coffee break** and extra evaluation time [general LREC break: 11:00-11:20]
11:40 – 12:00	Summary of the goals of our collective hands-on experiment – *Andrei Popescu-Belis*
12:00 – 13:00	Reports on individual evaluations (human vs. automatic) – *All workshop participants*
13:00 – 14:30	**Lunch break**
14:30 – 15:30	Reports on individual evaluations (human vs. automatic, *continued*) – *All workshop participants*
15:30 – 16:40	Synthesis of evaluation exercises: reliability and correlation of the metrics used in the hands-on exercises – *Workshop organisers*
16:40 – 17:00	**Coffee break** [synchronised with general LREC break]
17:00 – 18:30	Roundtable discussions of the observed results. Conclusions – *All workshop participants*

Abstract

This section of the workbook describes the principles and mechanism of an integrative effort in machine translation (MT) evaluation. Building upon previous standardization initiatives, above all ISO/IEC 9126, 14598 and EAGLES, we attempt to classify into a coherent taxonomy most of the characteristics, attributes and metrics that have been proposed for MT evaluation. The main articulation of this flexible framework is the link between a taxonomy that helps evaluators define a context of use for the evaluated software, and a taxonomy of the quality characteristics and associated metrics. The document overviews these elements and provides a perspective on ongoing work in MT evaluation.

1. Introduction

Evaluating machine translation is important for everyone involved: researchers need to know if their theories make a difference, commercial developers want to impress customers, and users have to decide which system to employ. Given the richness of the literature, and the complexity of the enterprise, there is a need for an overall perspective, something that helps the potential evaluator approach the problem in a more informed way, and that might help pave the way toward an eventual theory of MT evaluation.

Our main effort is to build a coherent overview of the various features and metrics used in the past, to offer a common descriptive framework and vocabulary, and to unify the process of evaluation design. Therefore, we present here a parameterizable taxonomy of the various attributes of an MT system that are relevant to its utility, as well as correspondences between the intended context of use and the desired system qualities, i.e., a quality model. Our initiative builds upon previous work in the standardization of evaluation, while applying to MT the ISO/IEC standards for software evaluation.

We first review (Section 2) the main evaluation efforts in MT and in software engineering (ISO/IEC standards). Then we describe the need for two taxonomies, one relating the context of use (analyzed in Section 3) to the quality characteristics, the other relating the quality characteristics to the metrics. In Section 4 we provide a brief overview of these taxonomies, together with a view on their dissemination and use. We finally outline (Section 5) our perspectives on current and future developments.

2. Formalizing Evaluation: from MT to Software Engineering

2.1. Previous Approaches to MT Evaluation

The path to a systematic picture of MT evaluation is long and hard. While it is impossible to write a comprehensive overview of the MT evaluation literature, certain tendencies and trends should be mentioned. First, throughout the history of evaluation, two aspects – often called quality and fidelity – stand out. Particularly MT researchers often feel that if a system produces syntactically and lexically well-formed sentences (i.e., high quality output), and does not distort the meaning (semantics) of the input (i.e., high fidelity), then the evaluation is sufficient. System developers and real-world users often add evaluation measures, notably system extensibility (how easy it is for a user to add new words, grammar, and transfer rules), coverage (specialization of the system to the domains of interest), and price. In fact, as discussed in (Church and Hovy, 1993), for some real-world applications quality may take a back seat to these factors.

Various ways of measuring quality have been proposed, some focusing on specific syntactic constructions (relative clauses, number agreement, etc.) (Flanagan, 1994), others simply asking judges to rate each sentence as a whole on an N-point scale (White et al., 1992 1994; Doyon et al., 1998), and others automatically measuring the perplexity of a target text against a bigram or trigram language model of ideal translations (Papineni et al., 2001). The amount of agreement among such measures has never been studied. Fidelity requires bilingual judges, and is usually measured on an N-point scale by having judges rate how well each portion of the system's output expresses the content of an equivalent portion of one or more ideal (human) translations (White et al., 1992 1994; Doyon et al., 1998). A proposal to measure fidelity automatically by projecting both system output and a number of ideal human translations into a vector space of words, and then measuring how far the system's translation deviates from the mean of the ideal ones, is an intriguing idea whose generality still needs to be proved (Thompson, 1992). In

similar vein, it may be possible to use the above mentioned perplexity measure also to evaluate fidelity (Papineni et al., 2001).

The Japanese JEIDA study of 1992 (Nomura, 1992; Nomura and Isahara, 1992), paralleling EAGLES, identified two sets of 14 parameters each: one that characterizes the desired context of use of an MT system, and the other that characterizes the MT system and its output. A mapping between these two sets of parameters allows one to determine the degree of match, and hence to predict which system would be appropriate for which user. In similar vein, various companies published large reports in which several commercial MT systems are compared thoroughly on a few dozen criteria (Mason and Rinsche, 1995; Infoshop, 1999). The OVUM report includes usability, customizability, application to total translation process, language coverage, terminology building, documentation, and others.

The variety of MT evaluations is enormous, from the influential ALPAC Report (Pierce et al., 1966) to the largest ever competitive MT evaluations, funded by the US Defense Advanced Research Projects Agency (DARPA) (White et al., 1992 1994) and beyond. Some influential contributions are (Kay, 1980; Nagao, 1989). Van Slype (1979) produced a thorough study reviewing MT evaluation at the end of the 1970s, and reviews for the 1980s can be found in (Lehrberger and Bourbeau, 1988; King and Falkedal, 1990). The pre-AMTA workshop on evaluation contains a useful set of papers (AMTA, 1992).

2.2. The EAGLES Guidelines for NLP Evaluation

The European EAGLES initiatives (1993-1996) came into being as an attempt to create standards for language engineering. It was accepted that no single evaluation scheme could be developed even for a specific application, simply because what counted as a "good" system would depend critically on the use of the system. However, it did seem possible to create a general framework for evaluation design, which could guide the creation of individual evaluations and make it easier to understand and compare the results. An important influence here was the 1993 report by Sparck-Jones and Galliers, later published in book form (1996), and the ISO/IEC 9126 (cf. next section).

These first attempts proposed the definition of a general quality model for NLP systems in terms of a hierarchically structured set of features and attributes, where the leaves of the structure were measurable attributes, with which specific metrics were associated. The specific needs of a particular user or class of users were catered for by extracting from the general model just those features relevant to that user, and by allowing the results of metrics to be combined in different ways in order to reflect differing needs. These attempts were validated by application to quite simple examples of language technology: spelling checkers, then grammar checkers (TEMAA, 1996) and translation memory systems (preliminary work), but the EAGLES methodology was also used outside the project for dialogue, speech recognition and dictation systems.

When the ISLE project (International Standards for Language Engineering) was proposed in 1999, the American partners had also been working along the lines of taxonomies of features (Hovy, 1999), focusing explicitly on MT and developing in the same formalism a taxonomization of user needs, along the lines suggested by the JEIDA study (Nomura, 1992). The evaluation working group of the ISLE project (one of the three ISLE working groups) therefore decided to concentrate on MT systems.

2.3. The ISO/IEC Standards for Software Evaluation

2.3.1. A Growing Set of Standards

The International Organization for Standardization (ISO) together with the International Electrotechnical Commission (IEC) have initiated in the past decade an important effort towards the standardization of software evaluation. In 1991 appeared the ISO/IEC 9126 standard (ISO/IEC-9126, 1991), a milestone that proposed a definition of the concept of quality, and decomposed software quality into six generic quality characteristics. Evaluation is the measure of the quality of a system in a given context, as stated by the definition of quality as "the totality of features and characteristics of a product or service that bear on its ability to satisfy stated or implied needs" (ISO/IEC9126, 1991, p. 2).

Subsequent efforts led to a set of standards, some still in draft versions today. It appeared that a new series was necessary for the evaluation process, of which the first in the series (ISO/IEC-14598, 1998 2001, Part 1) provides an overview. The new version of the ISO/IEC 9126 standard will finally comprise four inter-related standards: standards for software quality models (ISO/IEC-9126-1, 2001), for external, internal and quality in use metrics (ISO/IEC 9126- 2 to 4, unpublished). Regarding the 14598 series (ISO/IEC14598, 1998 2001), now completely published, volumes subsequent to ISO/IEC 14598-1 focus on the planning and management (14598-2) and documentation (14598-6) of the evaluation process, and apply the generic organization framework to developers (14598-3), acquirers (14598-4) and evaluators (14598-5).

2.3.2. The Definition of a Quality Model

This subsection situates our proposal for MT evaluation within the ISO/IEC framework. According to ISO/IEC 14598-1 (1998 2001, Part 1, p. 12, fig. 4), the software life-cycle starts with an analysis of user needs that will be answered by the software, which determine in their turn a set of specifications. From the point of view of quality, these are the external quality requirements. Then, the software is built during the design and development phase, when quality becomes an internal matter related to the characteristics of the system itself. Once a product is obtained, it is possible to assess its internal quality, then the external quality, i.e., the extent to which it satisfies the specified requirements. Finally, turning back to the user needs that were at the origin of the software, quality in use is the extent to which the software really helps users fulfill their tasks (ISO/IEC-9126-1, 2001, p. 11).

Quality in use does not follow automatically from external quality since it is not possible to predict all the results of using the software before it is completely operational. In addition, for MT software, there seems to

be no straightforward link, in the conception phase, from the external quality requirements to the internal structure of a system. Therefore, the relation between external and internal qualities is quite loose.

Following mainly (ISO/IEC-9126-1, 2001), software quality results from six quality characteristics:

- functionality
- reliability
- usability
- efficiency
- maintainability
- portability

These characteristics have been refined into software sub-characteristics that are still domain-independent (ISO/IEC 9126-1). These form a loose hierarchy (some overlapping is possible), but the terminal entries are always measurable features of the software, that is, attributes. Following (ISO/IEC-14598, 1998-2001, Part 1), "a measurement is the use of a metric to assign a value (i.e., a measure, be it a number or a category) from a scale to an attribute of an entity".

The six top level quality characteristics are the same for external as well as for internal quality. The hierarchy of sub-characteristics may be different, whereas the attributes are certainly different, since external quality is measured through external attributes (related to the behavior of a system) while internal quality is measured through internal attributes (related to intrinsic features of the system).

Finally, quality in use results from four characteristics: effectiveness, productivity, safety, and satisfaction. These can only be measured in the operating environment of the software, thus seeming less prone to standardization (see however (Daly-Jones et al., 1999) and ISO/IEC 9126-4).

2.3.3. Stages in the Evaluation Process

The five consecutive phases of the evaluation process according to (ISO/IEC-9126, 1991, p. 6) and (ISO/IEC-14598, 1998 2001, Part 5, p. 7) are:

- establish the quality requirements (the list of required quality characteristics);
- specify the evaluation (specify measurements and map them to requirements);
- design the evaluation, producing the evaluation plan that documents the procedures used to perform measurements);
- execute the evaluation, producing a draft evaluation report;
- conclude the evaluation.

During specification of the measurements, each required quality characteristic must be decomposed into the relevant sub-characteristics, and metrics must be specified for each of the attributes arrived at in this process. More precisely, three elements must be distinguished in the specification and design processes; these correspond to the following stages in execution:

- application of a metric (*a*);
- rating of the measured value (*b*);
- integration (assessment) of the various ratings (*c*).

It must be noted that (a) and (b) may be merged in the concept of 'measure', as in ISO/IEC 14598-1, and that integration (c) is optional. Still, at the level of concrete evaluations of systems, the above distinction, advocated also by EAGLES (EAGLES-Evaluation-Workgroup, 1996), seems particularly useful: to evaluate a system, a metric is applied for each of the selected attributes, yielding as a score a raw or intrinsic score; these scores are then transformed into marks or rating levels on a given scale; finally, during assessment, rating levels are combined if a single result must be provided for a system.

A single final rating is often less informative, but more adapted to comparative evaluation. However, an expandable rating, in which a single value can be decomposed on demand into several components, is made possible when the relative strengths of the component metrics are understood. Conversely, the EAGLES methodology (EAGLES-Evaluation-Workgroup, 1996, p. 15) considers the set of ratings to be the final result of the evaluation.

3. Relation between the Context of Use, Quality Characteristics, and Metrics

Just as one cannot determine "what is the best house?", one cannot expect to determine the best MT system without further specifications. Just like a house, an MT system is intended for certain users, located in specific circumstances, and required for specific functions. Which parameters to pay attention to, and how much weight to assign each one, remains the prerogative of the user/evaluator. The importance of the context for effective system deployment and use has been long understood, and has been a focus of study for MT specifically in the JEIDA report (Nomura, 1992).

3.1. The Context of Use in the ISO/IEC Standards

While a good definition of the context of use is essential for accurate evaluation, in ISO/IEC the context of use plays a somewhat lesser role. The context of use is considered at the beginning of the software's life-cycle (ISO/IEC-14598, 1998 2001, Part 1), and appears in the definition of quality in use. No obvious connection between quality in use metrics and internal or external ones is provided. There is thus no overall indication how to take into account the context of use in evaluating a product.

There are however two interesting mentions of the context of use in ISO/IEC. First, the ISO/IEC standard for acquirers (ISO/IEC-14598, 1998 2001, Part 4, Annex B, pp. 21-22) exemplifies the link between the desired integrity of the evaluated software (integrity pertains to the risk of using the software) and the evaluation activities, in particular the choice of a quality model: for higher integrity, more evaluation procedures have to be fulfilled. The six ISO/IEC 9126 characteristics are also ordered differently according to the required integrity. Second, (ISO/IEC-14598, 1998 2001, Part 5, Annex B, pp. 22-25) gives another relation between "evaluation techniques" and the acceptable risk level. These proposals attempt thus to fill the gap between concrete contexts of use and generic quality models.

3.2. Relating the Context of Use to the Quality Model

When specifying an evaluation, the external evaluator – a person or a group in charge of estimating the quality of MT software – must mainly provide a quality model based on the expected context of use of the software. Guidelines for MT evaluation must therefore contain the following elements:

1. A classification of the main features defining a context of use: the user of the MT system, the task, and the nature of the input to the system.
2. A classification of the MT software quality characteristics, detailed into hierarchies of sub-characteristics and attributes, with internal and/or external attributes (i.e., metrics) at the bottom level. The upper levels coincide with the ISO/IEC 9126 characteristics.
3. A mapping from the first classification to the second, which defines (or at least suggests) the characteristics, sub-characteristics and attributes or metrics that are the most relevant for each context of use.

This broad view of evaluation is still, by comparison to ISO/IEC, focused on the technical aspect of evaluation. Despite the proximity between the taxonomy of contexts of use and quality in use, we do not extend our guidelines to quality in use, since this must be measured fully in context, using metrics that have less to do with MT evaluation than with ergonomics and productivity measures. Therefore, we have proposed elsewhere (Hovy, King and Popescu-Belis, 2002) a formal model of the mapping at point (3) above.

To summarize, building upon the definitions in Section 2.3.3., we consider the set of all possible attributes for MT software $\{A_1, A_2, \ldots, A_n\}$, and the process of evaluation is defined using three stages and the corresponding mappings: m_{Ai} (application of metrics), r_{Ai} (rating of measured value), and α (assessment of ratings).

From this point of view, the correspondence described at point (3) above holds between a context of use and the assessment or averaging function α. Point (3) is thus addressed by providing, for each context of use, the corresponding assessment function, i.e. the function that assigns a greater weight to the attributes relevant to that particular context. In the formal model, α is simplified by choosing a linear selection function.

4. The Contents of the Two Taxonomies

The schema below gives a general view of the contents of the two taxonomies. The first one enumerates non exclusive characteristics of the context of use grouped in three complementary parts (task, user, input). The second one develops the quality model, and its starting point is the six ISO/IEC quality characteristics. The reader will notice that our efforts towards a synthesis have not yet succeeded in unifying internal and external attributes under these six characteristics. As mentioned in Section 2.3.2., the link between internal features and external performance is not yet completely clear for MT systems. So, the internal attributes are structured here in a branch separate from the six ISO/IEC characteristics, which are measured by external metrics.

For lack of space, the hierarchies below represent a brief snapshot of the actual state of our proposal, which may be revised under feedback from the community. The full version available over the Internet (`http://www.issco.unige.ch/projects/isle/taxonomy2`) has about 30 pages, and expands each taxon with the corresponding metrics extracted from the literature. The website provides an interactive version and a printable version of the taxonomy.

- Specifying the context of use
  - Characteristics of the translation task
    - Assimilation
    - Dissemination
    - Communication
  - Characteristics of the user of the MT system
    - Linguistic education
    - Language proficiency in source language
    - Language proficiency in target language
    - Present translation needs
  - Input characteristics (author and text)
    - Document / text type
    - Author characteristics
    - Sources of error in the input
      - Intentional error sources
      - Medium-related error sources
      - Performance-related errors
- Quality characteristics, sub-characteristics and attributes
  - System internal characteristics
    - MT system-specific characteristics (translation process)
    - Model of translation process (rule-based / example-based / statistical / translation memory)
    - Linguistic resources and utilities
    - Characteristics related to the intended mode of use
      - Post-editing or post-translation capacities
      - Pre-editing or pre-translation capacities
      - Vocabulary search
      - User performed dictionary updating
      - Automatic dictionary updating
  - System external characteristics
    - Functionality
      - Suitability (coverage – readability – fluency / style – clarity – terminology)
      - Accuracy (text as a whole – individual sentence level – types of errors)
      - Interoperability
      - Compliance
      - Security
    - Reliability
    - Usability
    - Efficiency
      - Time behavior (production time / speed of translation – reading time – revision and post-editing / correction time)
      - Resource behavior
    - Maintainability
    - Portability
    - Cost

Practical work using the present taxonomy was the object of a series of workshops organized by the

Evaluation Work Group of the ISLE Project. There has been considerable continuity between workshops, with the result that the most recent in the series offered a number of interesting examples of using the taxonomy in practice. A very wide range of topics was covered, including the development of new metrics, investigations into possible correlation between metrics, ways to take into account different user needs, novel scenarios both for the evaluation and for the ultimate use of an MT system and ways to automate MT evaluation. The four workshops took place in October 2000 (at AMTA 2000), April 2001 (stand-alone hands-on workshop at ISSCO, Geneva), June 2001 (at NAACL 2001) and September 2001 (at MT Summit VIII).

Among the first conclusions drawn from the workshops is the fact that evaluators tend to favor some parts of the second taxonomy – especially attributes related to the quality of the output text – and to neglect some others – for instance the definition of a user profile. It appears that the sub-hierarchy related to the "hard problem", i.e. the quality of output text, should be better developed. Sub-characteristics such as the translation quality for noun phrases (which is further on split into several attributes) attracted steady interest.

The proposed taxonomies can be accessed and browsed through a computer interface. The mechanism that supports this function also ensures that the various nodes and leaves of the categories are stored in a common format (based on XML), and simplifies considerably the periodic update of the classifications (Popescu-Belis et al., 2001). A first version of our taxonomies is visible at `http://www.isi.edu/natural-language/mteval` and the second one at `http://www.issco.unige.ch/projects/isle/taxonomy2` – the two sites will soon mirror a third, updated version.

5. Towards the Refinement of the Taxonomies

The taxonomies form but the first step in a larger program – listing the essential parameters of importance to MT evaluation. But for a comprehensive and systematic understanding of the problem, one also has to analyze the nature and results of the actual evaluation measures used. In our current work, a primary focus is the analysis of the measures and metrics: their variation, correlation, expected deviation, reliability, cost to perform, etc. This section outlines first a theoretical framework featuring coherence criteria for the metrics, then lists the (unfortunately very few) examples from previous research.

5.1. Coherence Criteria for Evaluation Metrics

We have defined coherence criteria for NLP evaluation metrics in an EAGLES-based framework (Popescu-Belis, 1999). The following criteria, applied to a case where there is no golden standard to compare a system's response to, enable evaluators to choose the most suitable metric for a given attribute and help them interpret the measures.

A metric m_{Ai} for a given attribute A_i is a function from an abstract 'quality space' onto a numeric interval, say [0,1] or [0%, 100%]. With respect to definition (a) in Section 2.3.3., each system occupies a place in the quality space of A_i, quantified by that metric. Since the goal of evaluators is to quantify the quality level using a metric, they must poll the experts to get an idea of what the best and the worst quality levels are for A_i.

It is often easy to find the best quality of a response, but there are at least two kinds of very poor quality levels: (a) the worst imaginable ones (which a system may rarely actually descend to) and (b) the levels attained by simplistic or baseline systems. For instance, for the capacity to translate polysemous words, a system that always outputs the most frequent sense of source words does far better than the worst possible system (the one that always gets it wrong) or than a random system. Once these limits are identified, the following coherence criteria should be tested for:

- **UL – upper limit**: A metric for an attribute A_i must reach 1 for best quality of a system, and (reciprocally) only reach 1 when the quality is perfect;

- **LL – lower limit:** A metric for an attribute A_i must reach 0 for the worst possible quality of a system, and only reach 0 when the quality is extremely low. Since it is not easy to identify the set of lowest quality cases, one can alternatively check that:
  - receiving a 0 score corresponds to low quality;
  - all the worst quality responses receive a 0 score;
  - the lowest theoretical scores are close or equal to 0 (a necessary condition for the previous requirement).

- **M – monotonicity**: A metric must be monotonic, that is, if the quality of system A is higher than that of system B, then the score of A must be higher than the score of B.

One should note that it is difficult to prove that a metric does satisfy these coherence criteria, and much easier to use counter-examples to criticize a measure on the basis of these criteria. Finally, one can also compare two metrics, stating that m_1 is more severe than m_2 if it yields lower scores for each possible quality level.

5.2. Analyzing the Behavior of Measures

Since our taxonomy gathers numerous quality attributes and metrics, there are basic aspects of MT that may be rated through several attributes, and each attribute may be scored using several metrics. This uncomfortable state of affairs calls for investigation. If it should turn out, for a given characteristic, that one specific attribute correlates perfectly with human judgments, subsumes most or all of the other proposed measures, can be expressed easily through one or more metrics, and is cheap to apply, we should have no reason to look further: that aspect of the taxonomy would be settled.

The full list of desiderata for a measure is not immediately clear, but there are some obvious ones. The measure:

- must be easy to define, clear and intuitive;
- must correlate well with human judgments under all conditions, genres, domains, etc.;

- must be `tight', exhibiting as little variance as possible across evaluators, or for equivalent inputs;
- must be cheap to prepare (i.e., not require a great deal of human effort for training data or ideal examples);
- must be cheap to apply;
- should be automated if possible.

Unexpectedly, the literature contains rather few methodological studies of this kind. Few evaluators have bothered to try someone else's measures too, and correlate the results. However, there are some advances. In recent promising work using the DARPA 1994 evaluation results (White et al., 1992 1994), White and Forner have studied the correlation between intelligibility (syntactic fluency) and fidelity (White, 2001) and between fidelity and noun compound translation (Forner and White, 2001). As one would expect with measures focusing on aspects as different as syntax and semantics, some correlation was found, but not a clear one. Papineni et al. (2001) compared the scores given by BLEU, an algorithm mentioned above, with human judgments of the fluency and fidelity of translations. They found a very high level of agreement, with correlation coefficients of 0.99 (with monolingual judges) and 0.96 (bilingual ones).

Another important matter is inter-evaluator agreement, reported on by most careful evaluations. Although the way one formulates instructions has a major effect on subjects' behavior, we still lack guidelines for formulating the instructions for evaluators, and no idea how variations would affect systems' scores. Similarly, we do not know whether a 3-point scale is more effective than a 5- or 7-point. Experiments are needed to determine the optimal point between inter-evaluator consistency (higher on a shorter scale) and evaluation informativeness (higher on a longer scale). Still another important issue is the number of measure points required by each metric before the evaluation can be trusted, a figure that can be inferred from the confidence levels of past evaluation studies.

In the ISLE research we are now embarking on the design of a program that will help address these questions. Our very ambitious goal is to know, for each taxon in the taxonomy, which measure(s) are most appropriate, which metric(s) to use for them, how much work and cost is involved in applying each measure, and what final level of score should be considered acceptable (or not). Armed with this knowledge, a would-be evaluator would be able to make a much more informed selection of what to evaluate and how to go about it.

5.3. A View to the Future

It can be appreciated that building a taxonomy of features is an arduous task, made more difficult by the fact that few external criteria for correctness exist. It is easy to think of features and to create taxonomies; we therefore have several suggestions for taxonomy structure, and it is unfortunately very difficult to argue for the correctness of one against another. We therefore explicitly do not claim in this work that the present taxonomy is correct, complete, or not subject to change. We expect it to grow, to become more refined, and to be the subject of discussion and disagreement – that is the only way in which it will show its relevance. Nonetheless, while it is possible to continue refining the taxonomy, collecting additional references, and classifying additional measures, we feel that the most pressing work is only now being started. The taxonomy is but the first step toward a more comprehensive and systematic understanding of MT evaluation in all its complexity, including a dedicated program of systematic comparison between metrics.

The dream of a magic test that makes everything easy – preferably an automated process – always remains. A recent candidate, proposed by (Papineni et al., 2001), has these desirable characteristics. Should it be true that the method correlates very highly with human judgments, and that it really requires only a handful of expert translations, then we will be spared much work. But we will not be done. For although the existence of a quick and cheap evaluation measure is enough for many people, it still does not cover more than a small portion of the taxonomy; all the other aspects of MT that people have wished to measure in the past remain to be measured.

A general theme running throughout this document is that MT evaluation is simply a special, although rather complex, case of software evaluation in general. An obvious question then is whether the work described here can be extended to other fields. Some previous experience has shown that it applies relatively straightforwardly to some domains, for example, dialogue systems in a specific context of use. However, as the systems to be evaluated grow more complex, the contexts of use become potentially almost infinite. Trying to imagine them all and to draw up a descriptive scheme as we are doing for MT systems becomes a challenging problem, that must be addressed in the future. It is nevertheless our belief that the basic ISO notion of building a quality model and associating appropriate metrics to it should carry over to almost any application.

Abstract

This section of the workbook provides the description of the MT evaluation exercise that is proposed to the workshop participants, including the specification of the metrics for MT evaluation that the participants are suggested to use at the workshop.

1. A Collective Hands-on Exercise

1.1. Motivation

The motivations behind the LREC 2002 MT Evaluation workshop are grounded in previous work in the field, described at length in the previous section. The workshop is the sixth in a series of hands-on workshops on MT Evaluation, organized in the framework of the ISLE Project.

The goal of these hands-on evaluation workshops is to carry on a collective effort towards the standardization of MT evaluation. The ISLE taxonomy has been designed for standardization, but it would have not reached the present state without feedback from the participants at the workshops. Conversely, the participants have broadened their view of MT Evaluation, through the concrete use of the ISLE taxonomy for the design of toy evaluations, but also through extensive discussions with the organizers and other participants.

Some of the workshops have focused more on the setup of an evaluation depending on the desired context of use, others on metrics, others on reporting results obtained in this framework. As pointed out in the previous section, the need for a clear view of the performances of various metrics has prompted the organization of the present workshop, "Machine Translation Evaluation: Human Evaluators Meet Automated Metrics". Through hands-on application of selected metrics from the present workbook, the participants will be able to familiarize themselves with the current problems of MT Evaluation, to get a first-hand experience with recent metrics and to contribute to research in this field by their own observations of the metrics' behaviors.

1.2. Description of the exercise

The participants to the workshop are suggested to register with the organizers well before the day the workshop will take place (May 27, 2002). Thus, both organizers and participants will be able to prepare in advance an evaluation exercise (requiring several hours of work), so that the workshop itself can be devoted to the exploitation of those results.

The evaluation study that all participants are kindly required to carry on can be summarized as follows:

1. Select two evaluation metrics among those described below, preferably one "human-based" and one "automated" (more than two is welcome!).

2. Optionally, add one of the metrics that you have used before in MT evaluation, or any personal suggestion for a metric.

3. Using the test data provided by the organizers, apply the selected metrics and compute the scores of each translation, on a 0%–100% scale.
   The test data is described in the next document of the workbook and can be downloaded from `http://www.issco.unige.ch/projects/isle/mteval-may02/`. It consists in two source texts in French, each with a reference translation and about a dozen translations to be evaluated, from various systems and humans.

4. Send the results by email to the organizers (e.g., `Andrei.Popescu-Belis@issco.unige.ch`), together with any comments you believe useful.

5. Prepare a brief account of the evaluation (about 10–15 minute talk) to be presented at the workshop, for instance by first answering the question "what are the strongest and the weakest points in the measures that you used?"

1.3. Exploitation of the Results

The results of these evaluations will be discussed and highlighted at the workshop from the perspective of present research goals. Regarding individual metrics, the scores obtained by different evaluators using the same metric will inform the community about the reliability of that metric (cf. preceding document, 5.2), by computing standard deviation and inter-annotator agreement.

The other important result of the pre-workshop evaluations will be data on cross-metric correlation, i.e. the agreement between pairs of metrics. This is important both for metrics based on human judges (it illustrates how well the specifications are defined or how coherent the judges are) and for automated metrics (for which agreement with a reliable human judgement is almost the only proof of coherence). These meta-evaluation

considerations will be analyzed at the workshop by the organizers, based on the results sent to them by the participants. These considerations will constitute the basis for discussion and conclusions of the workshop.

2. Specifications of the Metrics

2.1. Preamble

The metrics that are proposed in this application illustrate a broad spectrum of those that were synthesized for the ISLE MT evaluation framework. The two categories identified below parallel of course the title of the workshop, "Human Evaluators Meet Automated Metrics". In the history of MT evaluation, given the difficulty of the task, most of the quality judgments, and later 'metrics', we carried on by humans. However, as explained in the previous chapter, the utility of automatic measures has always been clear: they provide cheap, quick, repeatable and objective evaluation. 'Objective' means here that the same translation will always receive the same score, as opposed to human judges that may have fluctuating opinions. However, since human judges are the final reference in MT evaluation, the results of automated metrics must correlate well with (some aspect of) human-based metrics.

The metrics specified below must of course be integrated in a broader view of evaluation, since none of them is sufficient to determine the overall quality of a system. As stated in the ISLE taxonomy, it is the desired context of use of the evaluated system that determines a 'quality model', namely a set of useful features, to which several metrics are associated. It is only the combination of these scores that provides a good view of the quality of the system in the given context.

Documentation about the metrics below (apart from the references quoted) can be found in several papers available over the Internet. The ISLE evaluation workgroup has a webpage at `http://www.issco.unige.ch/projects/isle/ewg.html`, with links to previous workshop material for MT Evaluation, and to electronic versions of Van Slype's (1979) report and of the MT Evaluation workshop held at the MT Summit VIII conference. The ISLE taxonomy can be found at `http://www.issco.unige.ch/projects/isle/taxonomy2/`.

Below is a synopsis of the metrics that will be described in the remaining part of this document.

(A1)	IBM's BLEU and the NIST version
(A2)	EvalTrans
(A3)	Named entity translation
(A4a)	Syntactic correctness
(A4b)	X-Score / parsability
(A5a)	Dictionary update / number of untranslated words
(A5b)	Translation of domain terminology
(A6)	Evaluating syntactic correctness from the implementation of transfer rules
(H1)	Reading time
(H2)	Correction / post-editing time
(H3)	Cloze test
(H4a)	Intelligibility / fluency
(H4b)	Clarity
(H5)	Correctness / adequacy / fidelity
(H6)	Informativeness: comprehension task

2.2. Automated/automatable metrics

2.2.1. IBM's BLEU and the NIST version (A1)

We mention first the most recent proposal of an automated metric for MT Evaluation, namely the BLEU algorithm proposed by a team from IBM (Papineni et al., 2001; Papineni, 2002). The principle of this metric, which was fully implemented, is to compute a distance between the candidate translation and a corpus of human "reference" translations of the source text. The distance is computed averaging *n*-gram similitude between texts, for $n = 1, 2, 3$ (higher values do not seem relevant). That is, if the words of the candidate translation, the bi-grams (couples of consecutive words) and tri-grams are close to one or more of those in the reference translations, then the candidate scores high on the BLEU metric.

Apart from intuitive arguments, the method to find out whether this metric really reflects translation quality is to compare its results with human judgements, on the same texts. In-house data (Papineni et al., 2001), as well as the DARPA 1994 data (Papineni et al., 2002), were used to test the coherence between human scores and BLEU scores, and this was found acceptable.

The metric was also adapted for the recent NIST MT Evaluation campaign (Doddington, 2001). The main changes were: text preprocessing, a differentiated weight associated to N-grams based on their frequency, and the use of tri-grams only. These modifications must still be discussed by the community, but the NIST provides yet the scripts implementing the BLEU metric as well as its adaptation, at: `http://www.nist.gov/speech/tests/mt/mt2001/resource/`.

We do not describe further this metric, but would like to refer the participants to the documentation quoted above, which provides enough resources to apply it.

2.2.2. EvalTrans (A2)

Automatic corpus evaluation extrapolation using EvalTrans (Niessen et al., 2000) gives statistics, such as the average Levenshtein distance standardized to the length of the target sentence. The tool can be downloaded at `http://www-i6.informatik.rwth-aachen.de/HTML/Forschung/Uebersetzung/Evaluation/`.

The first step is to load and save the human translations. For the present workshop, the reference translation as well as the other human translations of the same source text will constitute the "reference set". When the system is set up to work automatically, it will search this reference database for sentences which are most similar to the machine translated sentence that must be scored.

However, in order for the extrapolation to be performed, the Levenshtein distance algorithm needs to be seeded with scores for some (at least one) manually evaluated sentence. For this, a baseline machine translation (for instance) needs to be loaded and some sentence pairs need to be evaluated.

Next, the "test corpus" sentences need to be loaded. These are the machine translations for each source text. For each set of "test corpus" sentences, which comprise each machine translation of a source text, subjective sentence error rate (SSER) and multi-reference word error rate (mWER) will be calculated by the automatic metric.

- Several statistics of interest will be produced:
- Average number of "perfect" (scored 10) reference sentences per evaluation sentence pair (to indicate how reliable the mWER is).
- (average-score) / (value of all (evaluated/ extrapolated) sentence pairs)
- Standard deviation of the score
- Subjective sentence error rate (i.e., 100% * (1 – average-score)). An average score of 0.0 results in a SSER of 100%, an average score of 10.0 in a SSER of 0%.
- Subjective sentence error rate weighted by the length of the target sentences
- Average extrapolation distance: average Levenshtein distance (per target word) of all extrapolated sentences

The SSER indexes each sentence, then uses the mWER, the number of perfect reference sentences, the absolute Levenshtein distance to each sentence, and the Levenshtein distance to that sentence v. the length of current sentence.

The mWER is the word error rate against the most similar reference sentence which has been evaluated as "perfect" (i.e., has been assigned a score of ten). It is calculated as Levenshtein operations per reference word (and can thus exceed 100%). Average mWER for an evaluation corpus is calculated word-wise, not sentence-wise.

Another measure, the information item error rate, is not included because it relies heavily on manual scores, use of which would defeat the purpose of the automated metric.

2.2.3. Named entity translation (A3)

The NEE metric (Named Entity Evaluation) is described for instance in (Reeder et al., 2001). Since automated software to support this metric is available, it has been considered here an automated metric. Participants to the workshop may of course apply it manually, given the small amount of test data.

The process for utilizing this metric is relatively straightforward: a) identify the named entities within a given test corpus; b) pull unique entities from the document; c) find the entities in the system output text; and d) compare entities in the output text with those identified in the reference text (see Figure 1 below). Identifying the named entities in the reference translation requires human annotation, and is the only stage of the process to do so.

In a concrete example of this metric, to prepare the corpora for evaluation, two expert annotators used the Alembic Workbench (Day et al., 1997; see also `http://www.mitre.org/technology/alembic-workbench/`) annotation tool to tag occurrences of named entities according to the MUC annotation guidelines. After the named entities are tagged in the reference translation (designated here by ANNO), the metric can be applied.

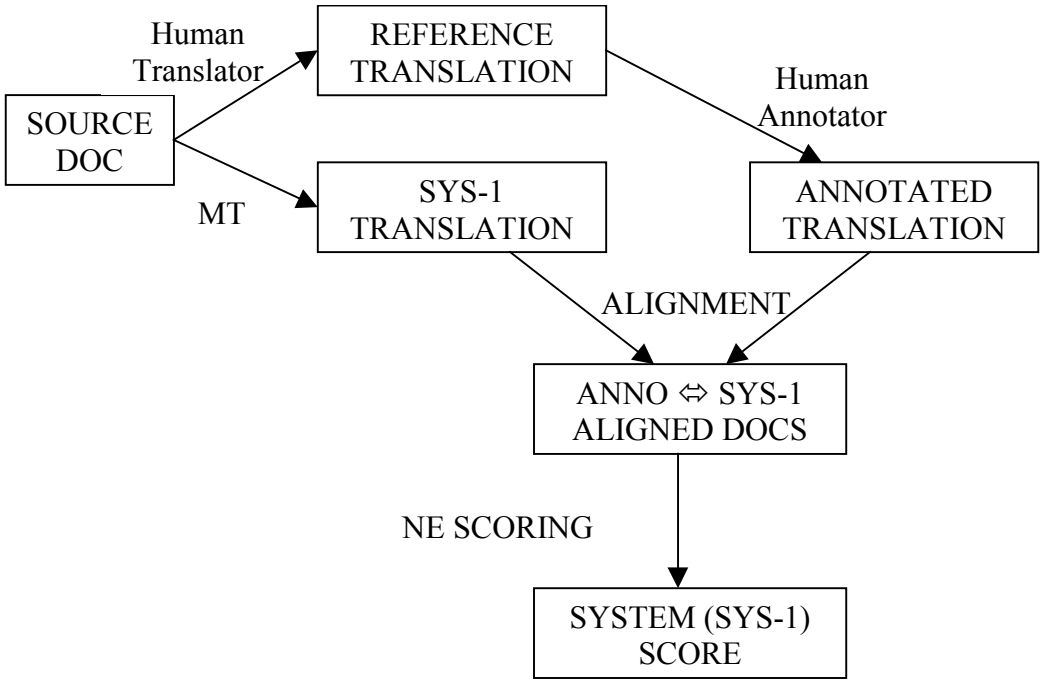

Figure 1. Scoring technique for the NEE metric.

The next stage is to align the ANNO translation text with the evaluation text (the output of the system SYS-1 for this example). To score the translation, for each article in the aligned pair, the tagged named entities are pulled from the ANNO and a list of unique names for the comparison unit (paragraph or article) is prepared. This is followed by normalization. At this time, the normalization steps applied are: (a) substitution of non-diacritic marked letters for the equivalent diacritic mark character for Romance languages (for instance **ã** becomes **a**); (b) down-casing; (c) the normalization of numeric quantities (particularly for numbers under 100) and (d) the removal of possessives. Other normalization steps may be needed, as well as the incorporation of partial match scoring (see Reeder et al., 2001). Once the named entity list and the SYS-1 tokens have been normalized, the search for named entities in the token lists is straightforward. Only exact matches given the normalization steps described are considered at this time and all results here reflect this.

2.2.4. Syntactic correctness (A4a)

The following describes a syntax metric based on the minimal number of corrections necessary to render an MT output sentence grammatical. Each evaluator must transform each sentence in the MT output into a grammatical sentence by making the minimum number of replacements, corrections, rearrangements, deletions, or additions possible. The syntax score for each sentence is then defined as the ratio of the number of changes for each sentence to the number of tokens in the sentence. For the purposes of this test, a token is defined as a whitespace-delimited string of letters or numbers. Additionally, individual punctuation marks, since they are subject to correction, are also counted as separate tokens. Each item of punctuation that occurs in pairs (e.g. brackets, braces, quotation marks, parenthesis) is counted as a separate token. Thus, in the following sentence, there are 24 tokens:

- *Mary, who had gone to see the fountain (in the center of town), said that it was turned off.*

It is important to remember that the final edited sentence need only be syntactically correct. That is, the final result may be semantically anomalous. Raters should endeavor to produce a syntactically correct sentence by making as few changes possible to the original MT output. Deletions, substitutions, additions, and rearrangements are counted by totaling the number of words deleted, substituted, added, or moved. In the event that there are combined operations, for example, moving a phrase consisting of four words, of which one has been deleted, the move is computed *after* the deletion is counted, thus the above-mentioned operation would result in one deletion and 3 moves. Finally, errors in inflectional morphology are not counted in the syntax metric. In applying this metric to test data, it was found that even when evaluators arrive at the same score for a given sentence (that is, they have the same total number of changes), they often choose a different combination of the four operations to arrive at their final grammatical sentence. The metric as it stands has not been automated, and would indeed be very difficult to automate; however, partial automation, such as automatic tracking and counting of necessary edit operations, would greatly assist in applying this metric in an efficient manner.

2.2.5. Automatic Ranking of MT Systems by X-Score (A4b)

Background: The X-Score metric aims to rank MT systems in the same order as would be given by a human evaluation of the Fluency of their outputs (Hartley & Rajman, 2001; Rajman & Hartley, 2002). The metric is especially adapted to rank machine translations relative to one another, rather than comparing human and machine translations. This metric was derived from experiments conducted on the French-English segment of the corpus used in the 1994 DARPA MT evaluation exercise. In that exercise, human evaluators scored translations of 100 source texts by 5 MT systems for their Fluency (among other attributes). To establish the present metric, the F-scores (Fluency scores) for individual texts were converted into rankings of systems using the aggregation technique of ranking by average ranks (average rank ranking or ARR). Using the same ARR technique, rankings were computed on the basis of the X-score for each document. The X-scores were found to represent a very good predictor of the ranking derived from the human evaluations (H-rankings). The distance between the H-ranking and the X-ranking is 1, corresponding to a similarity of 93.3%, a precision of 93,3% and a recall of 93.3%. If restricted to the most complete partial ranking, these values improve to a distance of 0.5, a similarity of 96.7%, a precision of 100% and a recall of 93.3%.

Computing the X-Score: The X-score is taken to measure the grammaticality of the translations. For any given document, the X-score is obtained as follows. First, the document is analyzed by the Xerox shallow parser XELDA in order to produce the syntactic dependencies for each sentence constituent. For example, for the sentence The Ministry of Foreign Affairs echoed this view, the following syntactic dependencies are produced: SUBJ (Ministry, echoed); DOBJ (echoed, view); NN (Foreign, Affairs); NNPREP (Ministry, of, Affairs).

On the corpus used in (Hartley & Rajman, 2001), XELDA produced 22 different syntactic dependencies, among which:

- RELSUBJ: for example, RELSUBJ(hearing, lasted) in “a hearing that lasted more than two hours”;
- RELSUBJPASS: for example, RELSUBJPASS(program, agreed) in “a public program that has already been agreed on ...”;
- PADJ: for example, PADJ(effects, possible) in “to examine the effects as possible”;
- ADVADJ: for example, ADVADJ(brightly, colored) in “brightly colored doors”.

After each document has been parsed, we compute its dependency profile (i.e. the number of occurrences of each of the 22 dependencies in the document). This profile is then used to derive the X-score using the following formula:

- *X-score = (#RELSUBJ + #RELSUBJPASS – #PADJ – #ADVADJ)*

Note that several formulae would have been possible for computing the X-scores. The above-mentioned one

was selected in such a way that, if applied to the average dependency profile, it correctly predicted the average rank ranking (ARR) derived from the F-scores. In this sense, one can say that the computation of the X-score was specifically tuned to the test data and so it was considered quite ad hoc in (Hartley & Rajman, 2001). However, this is not true of (Rajman & Hartley, 2002). This second experiment retained exactly the same formula for the X-scores, while completely changing the human evaluations – evaluators directly assigned rankings to series of translations instead of assigning individual scores to each of the translations. Moreover, a new MT system was added, not present at all in the data that was used for the tuning. Thus, there is no reason to believe the X-scores to be ad hoc, which strongly increases their chances of being highly portable to other experimental data.

Computing the Rankings: For each of the documents, the scores of the systems are first transformed into ranks and the average ranks obtained by the systems over all the documents are then used to produce the final ranking.

2.2.6. Dictionary update (A5a) and domain terminology (A5b)

Dictionary update (also known as *non-translated or untranslated words*) and *domain terminology* are two potentially automatable metrics. Although related, these two metrics are not identical, as can be seen from their descriptions below. There are many ways in which a dictionary update measure could be calculated, but it seems obvious to use two objective and easy to observe features of MT output:

- the number of words not translated;
- the number of domain-specific words that are correctly translated.

It is these two features that have been described in previous related work, including (Vanni & Miller, 2002), and that will be specified below.

2.2.7. Number of untranslated words (A5a)

This metric makes use only of the target text. It is based on the intuition that translation quality is linked to size of vocabulary. In its simplest form, the number of words left untranslated is counted. By untranslated, we mean simply that a word which should be translated is not, and is simply copied over untouched into the target text. (This reflects the behavior of many machine translation systems). There are, of course, words which should not be translated (most proper names are a good example): not translating these items is not counted as an error. A score is obtained by the following calculation:

- (number-of-untranslated-words) / (total-number-of-words-in-text) x 100 = percentage-of- untranslated-words… *high is bad*

One possible way to automate this metric would be to run a spelling checker over the target text and count the number of mistakes found. This would, of course, pick up any spelling mistakes in translated words which might exist, as well as finding words which were not legal words of the target language; however, this amount is probably low for translations programs, which generate words based on valid dictionaries. On the whole, this automatic measure might not invalidate the metric as an indicator of overall translation quality.

In discussing the automation of this measure, it is worth noting that some MT systems provide as ancillary output statistics concerning the numbers of untranslated words in the output. However, this is not the case for all systems. In these cases, other automated means must be developed for computing this measure. In cases of languages using a non-Roman script or containing characters outside the standard lower-ASCII range found in typical English text, one possible way of counting non-translated words (for systems that simply pass untranslated words through in the translation) would be to locate and count tokens containing these characters that do not appear in English text. However, even in the case of the Japanese-English systems, some systems did produce a romanization of the untranslated words, and did not leave them in the native script. The romanizations contained only characters found in the lower portion of ASCII.

Given that this metric is intended to compute the number of words that the MT system was unable to translate, another possibility would be to use a tool such as *ispell* in order to identify non-English strings within the output translation. Counting these strings and comparing with the output of a utility such as *wc* (Unix word count) could provide a ratio of untranslated words in the output text.

Two potential problems with this last approach could both lead to undercounting the number of untranslated words in a text. First, included in the untranslated word count for Japanese – English translation were Japanese particles and other bits of non-English material, which may or may not have been the result of romanization of text found in the source. Examples of this include *na*, *re*, *X*, and *inu*. Another Japanese particle, *no*, did not appear in this context in the translation, but had we relied on an automated spelling-based identification of untranslated words, words like *no*, which also happen to be valid English strings (although with a different meaning) would be left uncounted. Secondly, untranslated word scores would likewise be affected for languages that share a high number of cognates with English. For these languages, the string in the source and target language may be identical, and thus not counted as an untranslated word, regardless of whether the system actually translated the word or simply passed it through.

The application of this metric to translations produced by human translators is somewhat doubtful: human translators when faced by a gap in their lexical knowledge try to work round the problem, and do not, normally, simply transcribe the problematic word or leave a gap. It is possible though that the spelling mistake variation might be informative.

It is also worth noting that while untranslated words certainly have an impact on the usability of MT output, such output often contains sentences that are completely unintelligible, but in no way due to untranslated words. Thus, this test should clearly not be used in isolation to provide a picture of overall MT quality, whether quality is defined along the lines of clarity, fluency, adequacy, or coherence.

2.2.8. Translation of Domain Terminology (A5b)

The domain terminology score is calculated as the percentage of correctly translated pre-identified domain terms. The procedure for this test is as follows: First, a list of key term translations is extracted from the human translation. To accomplish this, raters individually select key terms from the human translation, and then the separate key term lists are reconciled before application of the test to the MT systems' output. This step is amenable to automation, but has not as yet been automated. During the test application, systems receive a point for each term for which the translation matches the human translation exactly, and no point otherwise. The final score is the percentage of exactly-matched translations of key terms.

There are two divergent directions in which this test could be developed in the future. First, it could be made more sensitive to acceptable variation in translation of key terms by application of the ACME Cloze test methodology as described for instance in Miller (2000). This methodology simulates basing lexical tests on multiple human translation, while sufficiently constraining the structure of the translation to enable automated comparison.

2.2.9. Evaluating syntactic correctness from the implementation of transfer rules (A6)

This metric proposal is the result of two previous studies. In the first former study, the authors chose to count the number of NPs (noun phrases) and VPs (verb phrases) in source text and target texts, a first indication being given by non parallel data (Mustafa El Hadi, Timimi, Dabbadie, 2001). Another study presented the results on the same corpus after terminological enrichment (Mustafa El Hadi, Timimi, Dabbadie, 2002).

Nevertheless, the use of finer grained criteria such as adjectives or prepositional phrases count could also be envisaged. Any overlap of this threshold might then be considered as an indication that MT system may have failed to analyze source syntactic structure and that therefore, the initial figures require further analysis. But this methodology is still imprecise and limited to a first indication of MT system's analysis failure, when a gap is observed on non parallel data. The use of this methodology also implies that the test is carried out on relatively syntactically isomorphic languages such as French and English. A methodology including a test tool that would implement source and target transfer rules might probably prove more accurate and also apply to non isomorphic languages.

We propose here the following steps for the application of the metrics:

1. Deduce a set of French / English transfer rules from the source text and the reference translation (this part involves manual processing).
2. Write a script (e.g., in Java or Perl) to implement these rules (if not, go to point n. 3)
3. Check that these rules apply through the various candidate translations from the test data (automatically with the script or manually).
4. Generate an output failure file (or else carry out a manual check) and work out syntactic correctness.

2.3. Human-based measures

2.3.1. Reading time (H1)

Reading time can be defined in one of two ways: oral reading time or closed reading time.

Oral reading time (Van Slype, 1979) tends to measure more closely with intelligibility and also tends to be more relevant to higher quality translations. Therefore, for each document, the evaluators should read out loud the first paragraph and time the length of time that it takes to read each sample. The number of words then can be used to calculate a words per minute (WPM) rate:

- *WPM = number-of-words / reading-time*

The closer the WPM rate is to the WPM of natural language (depending on the evaluator), the higher is the quality of the translation (on a scale to be defined by each participant).

Closed reading time relates to the amount of time that a user needs to read a document to a "sufficient" level of understanding. The sufficient level is often paired with other measurements such as comprehension score on a test. Still, the instructions can be given that the readers measure the amount of time necessary to arrive at an understanding they consider to be sufficient to answer basic questions about the text. Words-per-minute rate can be calculated in the same way.

2.3.2. Correction / post-editing time (H2)

This metric is based on the intuition that the time required to produce an acceptable translation from a raw translation (whether produced by a human or by a machine) is inversely proportional to the overall quality of the raw translation.

It can be measured fairly easily by noting when the person responsible for the revision/post-editing starts their task and when they finish it, normalizing the result by taking into account the size of the text measured in words, then multiplying by a fixed factor in order to obtain a number on a wider scale. For this exercise, the following calculation is suggested:

- (number-of-minutes-spent-in-correction) / (total-number-of-words-in-text) x 10 = correction-time… *high is bad*

Note that this metric can only sensibly be applied to a whole text: timing correction to smaller text elements is both annoying for the person doing the timing and difficult to do reliably.

A variation on this metric is to count not the overall time but the number of key strokes made by the corrector.

It should be noted that this metric is somewhat problematic both with respect to validity and reliability for a number of reasons:

- The amount of correction needed depends in part on the ultimate use to which the translation will be put: a text destined for publication will probably be treated with more care than a text intended for information assimilation, for example
- The errors corrected differ in their nature. There will be straightforward grammatical or lexical errors, as well as more complicated stylistic errors. This will affect the amount of time needed to carry out the correction. This would not matter

so much if those doing the correction always agreed on what corrections are needed. But, inevitably, where matters of style are concerned, no such agreement exists.
- There is considerable variety amongst correctors and the way they work. Some work quickly and decisively, others are more hesitant and sometimes change their minds.
- Correctors may be influenced by knowing whether they are dealing with a human produced translation or a machine produced translation. One anecdote tells of correctors correcting far more on machine produced translation but spending comparatively less time in doing so because they felt no need to take into account the computer's feelings.

Participants who choose to work with this metric are invited to reflect on these issues and on possible improvements to the simple metric defined here.

2.3.3. Cloze test (H3)

This metric is reported by Van Slype (1979) as a test of readability. It may however also be thought of as a test of fidelity or of intelligibility, since it is based on the ability of a reader to supply a missing word correctly, which intuitively relates both to readability and intelligibility when the target text alone is considered and to fidelity when the source text is taken into account.

The method is simple. Every *n*-th word in the translation is deleted (in the Van Slype Report (1979), $n = 8$, but other values appear also in the literature). The translation is then given to a group of readers, who are asked to supply the missing words. Two scores are normally computed, one based on the number of answers which comprise exactly the suppressed original word, the other based on the number of answers with a word close in meaning to the original word. The second score has to be interpreted partly in the light of the first score

- (number-of-exact-answers) / (number-of-deleted-items) x 100 = percentage-of-exact-items-supplied… *high is good*

- (number-of-close-answers) / (number-of-deleted-items – number-of-exact-items-supplied) x 100 = percentage-of-close-items-supplied… *high is good*

A possible weakness of this metric is that it potentially also tests the intelligence and wealth of vocabulary of the reader supplying the missing words. This weakness can be mitigated by controlling the size and type of the group of readers.

A second possible weakness appears if the translated text is technical in nature: the readers have to have sufficient knowledge of the subject matter to make it plausible that they should be able to supply the missing items.

Van Slype (1979) also points out that some texts are more redundant than others in the way they carry information, and that if translations of several texts are to be compared, it is important to take this factor into account. He suggests that this can be done by carrying out a Cloze test also on the original text.

2.3.4. Intelligibility / fluency (H4a)

Intelligibility is one of the most frequently used metrics of the quality of output. Numerous definitions (or protocols for measuring it) have been proposed for it, for instance in Van Slype's report or in the DARPA 1994 evaluations. We outline here the definition proposed by T.C. Halliday in (Van Slype, 1979, p. 70), which measures intelligibility on a 4-point scale (0 to 3).

Intelligibility or comprehensibility expresses how intelligible is the output of a translation device under different conditions (for instance, when the sentence fragments are translated while being entered, or after each sentence). Comprehensibility reflects the degree to which a complete translation can be understood. Intelligibility can be based on the general clarity of translation, or the output can be considered in its entirety or by segments out of context.

The following scale of intelligibility has been proposed, from 3 to 0, 3 being the most intelligible:

- 3 – Very intelligible: all the content of the message is comprehensible, even if there are errors of style and/or of spelling, and if certain words are missing, or are badly translated, but close to the target language.
- 2 – Fairly intelligible: the major part of the message passes.
- 1 – Barely intelligible: a part only of the content is understandable, representing less than 50% of the message.
- 0 – Unintelligible: nothing or almost nothing of the message is comprehensible

To apply the metric, the following steps are suggested:

1. Take the reference translation of a text (or the source if you are proficient in that language).
2. Separate and number the sentences.
3. Take a candidate translation and do the operation (2) on it. Match sentences with those in the reference/source translation.
4. Rate sentences from the candidate translation using the 0 to 3 scale described above.
5. Optional: to normalize scores, calculate intelligibility on a 0% to 100% scale, by averaging sentence ratings over the whole text.
6. Produce a final score for each translation

2.3.5. Clarity (H4b)

In work described in (Vanni & Miller, 2002) a metric called *clarity* is proposed that merges the ISLE categories of comprehensibility, readability, style, and clarity into a single evaluation feature. This measure ranges between 0 and 3. Raters are tasked with assigning a *clarity* score to each sentence according to the following criteria:

Score	Criterion
3	meaning of sentence is perfectly clear on first reading
2	meaning of sentence is clear only after some reflection
1	some, although not all, meaning is able to be gleaned from the sentence with some

effort

0 Meaning of sentence is not apparent, even after some reflection

Since the feature of interest is clarity and not fidelity, it is sufficient that some clear meaning is expressed by the sentence and not that that meaning reflect the meaning of the input text. Thus, no reference to the source text or reference translation is permitted. Likewise, for this measure, the sentence need neither make sense in the context of the rest of the text nor be grammatically well-formed, since these features of the text would be measured by tests proposed elsewhere, namely the *coherence* and *syntax* tests, respectively. Thus, the clarity score for a sentence is basically a snap judgement of the degree to which some discernible meaning is conveyed by that sentence.

2.3.6. Correctness / adequacy / fidelity (H5)

This evaluation metric reprises the DARPA 1994 *adequacy* test (Doyon, Taylor, and White, 1996). As with that test, the reference translation or "authority version" is placed next to each of the translations of the source text, to be used as a comparison against each one, human or machine. Before the test is performed, both the "authority version" as well as each of translations should be segmented, with each text separated into sentence fragments to appear next to the corresponding fragment in the translation.

Once each translation is lined up with its equivalent, evaluators grade each unit on a scale of one to five, where five represents a paragraph containing all of the meaning expressed in the corresponding text. The *Adequacy* scale is as follows:

- 5 – All meaning expressed in the source fragment appears in the translation fragment
- 4 – Most of the source fragment meaning is expressed in the translation fragment
- 3 – Much of the source fragment meaning is expressed in the translation fragment
- 2 – Little of the source fragment meaning is expressed in the translation fragment
- 1 – None of the meaning expressed in the source fragment is expressed in the translation fragment

2.3.7. Informativeness: comprehension task (H6)

There are two methods for testing comprehension. The most common of these is the reading comprehension exam (e.g., Somers & Prieto-Alvarez, 2000; DARPA-94; Tomita 1992). In this case, the evaluators design a set of questions, usually under 10, for the given texts. Sometimes, as in the case of Tomita, these tests are structured first and then applied to the translations. Tomita began with the Test of English as a Foreign Language (TOEFL) examinations which he then translated to Japanese and had students take. The theory being that the better scores on the exam will have resulted from the better translations. The big difficulty (Somers & Prieto-Alvarez, 2000) is that it is difficult to test only the reading without bringing a large amount of pre-existing world knowledge to the table. In addition, the design and structuring of such examinations is an art in and of itself.

The second method for a comprehension test takes instead the task of figuring out the kinds of questions that one might want to be able to answer from a translation and determining whether the translation can support answering said questions. For instance, one might want to know the people, places and organizations mentioned in an article. This is covered by the named entity metric. Yet, it is really only the first stage of measurement. The secondary measure would be to look to determine if the entity relationships are also preserved by the translation - that is, who belongs to what organization or who did what to whom. This is the question we began to study at MT Evaluation workshop organized at NAACL 2001, when we asked participants to fill in templates based on specific kinds of questions. The better systems would enable the successful template filling and scoring would follow Message Understanding (MUC) guidelines. It is this type of exercise you will be asked to do at this time. The previously identified named entities will be used here. You will fill out templates to answer specific details of events or relationships between parties.

Abstract

This section of the workbook describes the test data that is proposed to the participants. The data is part of a broader-scope corpus containing translations produced by students and corrected by their professors. Such a corpus will be used in automatic evaluation of MT systems. This section describes the structure of the corpus and provides some sample data. The full workshop data can be downloaded from: `http://www.issco.unige.ch/projects/isle/mteval-may02/`.

1. Introduction

Several automatic measures for MT evaluation have been proposed, and computational tools to carry them on effectively are now available. From Henry Thompson's (1992) proposal to IBM's BLEU, through Niessen et al.'s (2000) proposal and NIST's 2001 MT Evaluation, all of these measures make heavy use of large sets of reference data (or golden standard).

It is indeed acknowledged that, while a unique "correct translation" of a source is insufficient for evaluation (since another perfectly acceptable translation can differ substantially from the first one), the solution may reside in the use of a set of reference translations, which will hopefully encompass the range of possible variations among acceptable translations. Once such a set available, the quality of candidate translations can be judged with respect to it, by automatically computing a similarity distance between the candidate and the set. Evaluation is thus greatly accelerated.

However, producing such resources is quite expensive. A team of professional translators must be hired and asked to translate a number of reference texts. The quality of the reference translations thus produced would be high, but maybe some more simplistic formulations, acceptable from an MT system, would not be present in the corpus, thus biasing the results.

We propose here to build a corpus of translations using translations exams from the Ecole de Traduction et d'Interprétation (University of Geneva). These translations are encoded using markup, together with the corrections made by professors, and most important, with the *grade* that has been decided. We describe below this construction effort, than describe the data that will be used in the LREC 2002 MT Evaluation Workshop.

2. Description of the corpus

2.1. Structuring the data

One of the principles underlying the encoding of the data is to encode the most part of the information present on the paper version of the exam. This includes mainly the text produced by each student, the corrections added by the professors grading the exam, and the final grade.

We chose an XML-based annotation format, with one file per translation. Each file has a header containing useful data (except the name of the student, who is never typed in), and a <content> element with the translation. Instead of giving the DTD that was written, here is an example of exam file.

```
<?xml version="1.0"
      encoding="iso-8859-1"
      standalone="no" ?>
<!DOCTYPE exam SYSTEM "exam.dtd">
<exam>
  <header>
    <index>101</index>
    <author>101</author>
    <date>11/02/2002</date>
    <source-language>en</source-language>
    <target-language>fr</target-language>
    <level>2e cycle (years 3-4)</level>
    <exam-title>Traduct. FR/EN</exam-title>
    <comments>Exam graded by two
independent reviewers. This is a non-native
English speaker. Teacher's comments: "Your
style was confident, your English
idiomatic. Only minor mistakes appear in
the flow of your translation. Good work."
    </comments>
    <grade max="6.0" pass="4.0">5.0</grade>
  </header>
  <contents>
    <title-zone>
      <s>...</s>
    </title-zone>
    <p>
    <s>...</s>
    ...
    </p>
  </contents>
</exam>
```

Figure 1. Example of translation header.

Together with the DTD, we also use tools to validate each XML file, as well as a simple XSL file (stylesheet) that extracts the original text and discards the markup (this stylesheet is used to produce the workshop data described in the next section).

The innovative part of this corpus of "imperfect" translations is the encoding of the mistakes, together with their corrections. This requirement renders the typing of the data a bit more tedious, but increases the value of the resource, since the erroneous fragments of the texts can be discarded (or given a lower weight) when computing the distance between a candidate translation and the corpus.

Several conventions have been used to encode the mistakes and their correction: the <*m*> tag denotes a mistake, and the attributes encode its correction. The 't' attribute encodes the type, as noted by the professor ('–' means a fragment to be deleted), while the 'w' attribute encodes the replacement string. Missing parts are encoded as an empty <*m/*> element, with t="miss" and w="the missing string". A sample corrected paragraph is shown below.

```
<p>
   <s>Just like you, we feel convinced
   that the prevention of drug addiction
   <m t="-" w="none">s</m> starts at
   home, through <m t="-">the</m> <m
   t="miss" w="a good"/> <m t="w"
   w="relationship">relation</m> between
   adults and children, by strengthening
   self-esteem.</s>
   <s>The findings of recent studies
   clearly show that the earlier the
   prevention, the <m t="gr" w="more">
   most</m> efficient it is.</s>
</p>
<p>
   <s>You do not necessarily need to be a
   specialist in drug addiction <m t="-">
   s</m> to talk over this issue with
   your children.</s>
   <s> The most important thing <m t="-"
   w="is">lies in</m> dialog, <m t="-">
   in</m> attentive listening, <m t="-">
   in</m> reciprocal confidence.</s>
</p>
```

Figure 2. Translated paragraph and annotated mistakes.

2.2. Present state of the corpus

The corpus presented above is still under construction. As members of the Translation Faculty at the University of Geneva, we have been granted access to the written examinations of translations students (anonymized). We are focusing, for this corpus, on pure translations: the students are required to produce, in a limited amount of time and without dictionary, a translation of a piece of text – in general an excerpt from an article or essay, broadly speaking with a "general" vocabulary (through more specific exams, such as law translation, do exist).

Several language pairs are tested for at our faculty. The best represented ones, in terms of number of translations, are translations from English into French. However, given that a majority of researchers focuses on translation *into* English, we collect also French-to-English translations (less numerous).

The quality level of these translations is quite variable, as well as the difficulty of the source text. A considerable part of the corpus comes from entry-level examinations, but there are also translations from students that are close to graduation; in this case, the source texts are more "difficult" (a notion that must still be quantified).

The corrections are done on the paper version by two graders, teachers of the faculty. Their annotations are by no means standardized, but we attempt to grasp them in the most precise manner using the annotation format described above. The encoding principle is that *stripping a text from its XML annotation must yield exactly the text produced by the candidate.* The consistency and correction of the typed texts are checked by a second annotator, and the validity of the XML mark-up is checked against the DTD using a parser (Xalan-Java).

For the time being, a total of about 50 translations of two texts have been encoded. The public distribution of this data is still under consideration.

2.3. Possible uses of the corpus

The construction of this corpus is part of a long-term effort in MT evaluation at ISSCO/TIM/ETI, University of Geneva. The main use of the corpus is as a resource for automatic evaluation, where the cost of the resource lies in typing and encoding the data, rather than asking professional translators to translate a given source text. Given that this is a corpus of "imperfect" translations, we must encode also the corrections that were made by the graders (teachers). This increases the reliability of the corpus when used for automatic evaluation, since the erroneous fragments of the student translations can be discarded or given less confidence. The grades obtained by each translation can also be used to modulate the confidence attributed to each translation.

The corpus can also be used, of course, to extract statistics about the types of translations mistakes, and the correlation between the distribution of mistakes in a translation and the grade scored by that translation. Of course, the corpus could serve also to explore automatic techniques to grade human translations, which differ quite strongly from machine translations (translation quality, proximity to source structures, etc.).

3. Description of test data for the workshop

For the present workshop, the organizers provide test data consisting in two sets of translations extracted from the corpus, enriched with machine translations of the same text. The test data is available at the workshop's site: `http://www.issco.unige.ch/projects/isle/mteval-may02/`.

- The source texts (*10S.txt* and *20S.txt*) are excerpts from two longer essays, originally in French – the source is of course provided, as well as a reference translation for each text (*10A.txt* and *20A.txt*) constructed from the best student translations, using also the teacher's corrections. Of course, these aren't meant to be "the perfect translation", but only correct translations that are close enough to the source text to help evaluators that do not understand French

For each of the two source texts, we provide about a dozen translations in English, some of them by translation students and some by commercial systems available over the Internet. Translations are numbered *101.txt* through *113.txt* and *201.txt* through *213.txt* (three numbers are missing from the second list, for technical reasons). There is no particular order, and in particular *1XY.txt* vs. *2XY.txt* are not necessarily translated by the same translator (human or system).

The human translators were not instructed to use either of the particular varieties of English (British vs. American), hence some slight spelling variations. The systems were simply those made available over the Internet by various providers, as listed for instance on the following page, compiled by Laurie Gerber: `http://www.lim.nl/eamt/resources/`. We do not wish to disclose the names of the systems that produced the various translations, since the evaluations produced in this workshop do not claim commercial-level reliability.

A sample of the translations produced for the first text (including source and reference) is provided for visual comparison in the table below.

Subject to availability, and depending on decisions that will be made after the time of writing, extra data will be made available at the workshop's website (`http://www.issco.unige.ch/projects/isle/mteval-may02/`), and the participants will be informed as soon as possible about updates.

self-esteem. Recent studies have clearly shown that the earlier the prevention begins, the more efficient it is. It is not unavoidably necessary to be a specialist in drug addictions to talk about this subject with your children. What matters more is discussion, attentive listening and mutual trust.	of the regard of oneself. The results of the recent studies show it clearly: the more the prevention starts early, the more it is effective. It is not inevitably necessary to be a specialist in drug-addiction to tackle this subject with your children. Essence is elsewhere, in the dialogue, in listening, reciprocal confidence.
Translation 104 Like you, we are convinced that the prevention of dependences begins at home, through the relationship of parents with their children. This is done through the reinforcement of the child's self-esteem. As recent studies have clearly shown, the earlier prevention starts, the more efficient it will be. You do not necessarily need to be an expert in dependences to talk about this issue with your children. What really matters is talking together, listening to each other, and having confidence in one another.	*Translation 111* Like you, we are convinced that the prevention of drug-addiction starts in the family, in the relation between adults and children, through the reinforcement of the regard of oneself. The results of the recent studies show it clearly: the more the prevention starts early, the more it is effective. It is not inevitably necessary to be a specialist in drug-addiction to tackle this subject with your children. Essence is elsewhere, in the dialogue, in listening, reciprocal confidence.
Translation 105 Like you, we are convinced that prevention starts at home: the relationship between parents and children as well as the child's self-esteem are of great importance. Recent studies have shown very clearly that the earlier prevention starts, the more effective it will prove. You do not necessarily need to be an expert in addictions to talk about that issue with your children. Exchanging thoughts, listening to each other as well as mutual trust is much more important.	*Translation 112* As you, we are convinced of the prevention of the drug addictions beginning in the family, in the relationship between adults and children, through the reinforcement of the esteem of themselves. The results of recent studies demonstrate it clearly : the earlier the prevention begins, the more efficient it is. Him n ' is not inevitably necessary of to be a specialist of the drug addictions to approach this subject with your children. The essential is elsewhere, in the dialogue, in the listening, the reciprocal trust.
Translation 106 Like you, we are convinced that the prevention of drug addiction begins within the family, in the relationship between adults and children, through the reinforcement of self-confidence. Recent study results show this clearly: the earlier the prevention starts, the more efficient it is. It is not completely necessary to be a specialist on drug addiction to discuss this subject with your children. The importance is elsewhere: it is in the discussion, in the listening, in the mutual confidence.	*Translation 113* Like you, we are convinced that the prevention of drug-addiction starts in the family, in the relation between adults and children, through the reinforcement of the regard of oneself. The results of the recent studies show it clearly: the more the prevention starts early, the more it is effective. It is not inevitably necessary to be a specialist in drug-addiction to tackle this subject with your children. Essence is elsewhere, in the dialogue, in listening, reciprocal confidence.
Translation 107 As you, we are convinced that the prévention of the toxicomanies begin in the family, in the relation between adults and children, through the reinforcement of the esteem of oneself. The results of recent studies show it clearly: more the prévention begin early, more she is effective. It is not necessarily necessary be a specialist of the toxicomanies to approach this subject with your children. The essential is elsewhere, in the dialog, in the listen, reciprocal confidence.

Preface to the Workshop Proceedings

The ability to identify and analyse temporal information is important for a variety of natural language applications, such as information extraction, question answering, and multi-document summarisation. Nevertheless, this area of research has been relatively unexplored. It became evident during an ACL 2001 workshop on temporal and spatial information processing that that some research institutions have started to work on different aspects of temporal information, but no consensus has been achieved yet on what and how temporal information should be identified in text.

This workshop aims to provide a forum for researchers to present their work in this field and to discuss future developments such as building shared resources e.g. temporally annotated corpora. It is timely to coordinate the effort being undertaken in the community at this stage of research into temporal information.

We received 11 submissions and accepted 8 of them. The quality of the papers was very high and the topics diverse within the boundaries of the workshop theme. The selection process was therefore difficult. We would like to thank the members of the programme committe for their time and effort during the evaluation stage and for their valuable comments to the authors of the submitted papers.

The workshop will comprise presentation of each author and two talks by invited speakers. This will be followed by a panel discussion session at the end of the workshop. We would like to thank the invited speakers and the authors in advance for their participatation and we are looking forward to a hopefully enjoyable and enriching workshop which will contribute to this interesting and important emerging field within the natural language processing community.

Features required to distinguish between temporal uses of the preposition FOR

David S. Brée

Abstract

What are the features of a sentence that enable a reader to distinguish between the various different temporal uses of prepositions? To answer this question, we analyzed all the sentences in the million word Brown corpus containing a temporal use of FOR. The preposition FOR has been taken as a case study as it is both highly frequent and has several different uses. The results show that many different aspects of the FOR PP itself and of its matrix play a role. The most important are: the temporal nature of the noun in the PP as this indicates the temporal use, the definite v. indefinite nature of the determiner in the PP (in particular if there is no determiner, then the distinction between absence due to a proper noun v. a plural), the nature and aspect of the verb in the matrix of the PP, the position of the PP relative to other components of the matrix and finally the presence of certain qualifiers and post-modifiers in the PP which attach durations to the time axis. It is recommended that attention be paid to these features when tagging a text for temporal analysis.

1. Introduction

We use a dozen or so prepositions to convey temporal information. A few of do so in several different ways. How do listeners determine which of these ways the speaker intended? They use other features in the sentence, such as the aspect of the verb. Determining what these features are is the central concern of this talk.

We focus on just one of these prepositions: FOR. FOR is the most prolific of the temporal prepositions after IN, which I have already dealt with elsewhere (Brée, in press). And, like IN, but unlike the other high frequency temporal preposition AT, it is used in several different ways. The main distinction is between temporal durations (lengths of time not directly attached to the time line, e.g. FOR *five minutes*) and named temporal intervals, which are attached to the time line, e.g. FOR *1961*.

The most frequent temporal use of FOR is to indicate that a state given by the matrix in which the FOR Prepositional Phrase (PP) is embedded, holds for a length of time, i.e. FOR acts as a universal quantifier over a duration:

f32:084 She helped with teaching as well as office work FOR a few years . . .

During any sub duration of the duration *a few years*, the claim is being made that *she helped with teaching*. Indeed, the possibility or otherwise of adding a durational FOR phrase to a verb phrase is a well-known test of a state versus an event verb.

The duration may be attached to the time axis to indicate an interval, with one end or the other being the time of reference (`tor`) (Reichenbach, 1947):

n09:100b Tom had been laying for Aaron McBride FOR a long time . . .
p14:189 I won't be in town FOR a couple of days . . .

One of our tasks is to discover how to determine whether the duration indicated by the FOR prepositional phrase (PP) is attached to the `tor` or not.

FOR, unlike IN, cannot in general be used with a temporal interval, c.f.:

g14:001 There were fences IN/*FOR the old days when we were children.

So how is universal quantification over a temporal interval indicated? By using IN, even though with durations it is an existential quantifier, or, occasionally and for emphasis, *throughout*.

g32:061 Little enough joy was afforded Wright *in/*for/throughout* the spring of 1925 . . .

However, in certain circumstances FOR can be used with a temporal interval:

j66:011 "Evil, man, evil", he said, and that's all he said FOR *the rest of the night.*
b01:038 DeKalb's budget FOR *1961* is a record one . . .
h29:018b I look for TV sales and production to be approximately equal at 5.7 million sets FOR *the year* . . .

There are obviously restrictions on the use of FOR with an interval rather than a duration, and another of our tasks will be to determine what these restrictions are.

As with other temporal prepositions, FOR can be used not only to indicate a duration or an interval, but it also has special and idiomatic uses which will need to be recognized as such:

k19:060 Rector asked him to move it FOR the time being; . . . [*special*]
n23:015 And FOR the hundredth time that week, he was startled at her beauty. [*idiomatic*]

We will now look in more detail at these different ways in which FOR is used temporally before searching for the features of the context that may discriminate between these different uses. Then, by examining sentences with a temporal FOR PP in a corpus, we will develop a set of heuristic rules for actually making such discriminations using these features, and others if necessary.

The corpus that will be used is the Brown University corpus of a million words taken from 499 sample texts of American English (Kučera & Frances, 1967) selected randomly from 15 genres, labelled *a . . . r*. Sentences from the corpus are indicated by the use this letter, followed by a number to indicate the text, then a semi-colon and finally the sequential number of the sentence within its text. For example, n19:100b indicates the 100^{th} sentence in the 19^{th} text within the genre *n*. The final *b* indicates that the FOR being analyzed is its second occurrence in that sentence.

There is, in the Penn Tree Bank, a tagged version of the Brown corpus which was originally used. However, for the level of analysis that is to be undertaken here, the tagging proved to be insufficient. Since this analysis was made, a newly tagged and parsed version of the Brown corpus has been made available by the Language Data Consortium (Penn Tree version 3), but only 8 of the 15 genre have been parsed. This tagging includes an identification of the temporal use of prepositions. However, a check of the temporal uses of IN against a hand analysis showed that there were about 80% more instances tagged as the temporal use of IN (821) compared to those found by hand (483) in these same genres (Brée, in press). Consequently this new version of the Brown corpus is not suitable as a basis for the level of analysis that we are about to conduct.

2. Uses

2.1. Duration

We begin with cases in which FOR specifies a duration. It is usually indicated by an indefinite determiner in the FOR PP. In its simplest form the duration is unattached in any way to the time axis. Otherwise the duration is attached to the time axis at the `tor`, to indicate an interval either beginning or ending at the `tor`. Taken together these are the Duration uses.

The simplest Duration use is to specify a pure duration during which the matrix proposition holds, either just once or on a regular basis:

a24:035 One house was without power FOR about *half an hour* ...

k14:074 He worked FOR *two hours a day* with each model sent by the rabbi.

However, the duration may also be attached to the time axis just after or before the `tor`. The matrix state then lasts for the whole of the interval with the `tor` at one end and lasting the duration specified in the FOR phrase:

p14:189 I won't be in town FOR *a couple of days*, ...[tor+]

f34:092 Cereal grains have been used FOR *centuries* to prepare fermented beverages. [tor−]

Combinations with PPs introduced by other temporal prepositions give interesting possibilities here:

After: updates the `tor`, and the duration follows the `tor` (tor+):

n13:034 ...FOR a good minute *after* they rounded the bend ...Matilda could not speak at all.

Before: updates the `tor`, and the duration precedes the `tor` (tor−):

f13:080 ...usually you would do better to rent a place FOR a year or two *before* you buy.

Since: marks the beginning of the duration ending at the `tor` (tor−):

f20:073 FOR three years, *since* the liquor territorial conference, Torrio had ...tolerated O'Banion's impudent double-crossing.

Until: marks the end of the duration beginning at the `tor` (tor+):

d15:075 They went along the pass ...FOR a short while *until* they came to a river ...

Occasionally an indefinite duration will be found with a special use of FOR (see Section 2.3.):

p20:162 We went to the Louvre FOR *a* few hours ...

Note that the *going to the Louvre* did not last a few hours; it was the subsequent stay in the Louvre that lasted that time.

2.2. Interval

FOR phrases with intervals, usually indicated by a definite determiner, can be used in the same three ways as for IN phrases: attached to the VP, attached to an NP and as an interval over which a count in the matrix is to be taken. Taken together these are the Interval uses. We will look at each in turn.

2.2.1. Attached to the VP

As we have seen already, only certain intervals can be used in a FOR PP whose matrix is a VP. From the Brown corpus we find that there are just three types of interval that may be used.

The specification of the interval includes its duration. The interval in the FOR phrase is a duration but the duration is qualified or modified so that it becomes unique and definite:

- The duration is attached to the `tor` and made definite by using a suitable qualifier such as *past/last/next*:

  g08:010 But the South is, and has been FOR *the past* century, engaged in ...

  n19:053 FOR *the last* half hour Mary Jane had criss-crossed half the length of the Gardens ...

  l07:116 FOR *the next* hour he scrambled happily up and down the ladder, ...

- The duration is attached to some other time interval using a suitable post-modifier such as *following/ending/up to* ...:

  g54:071 ...FOR *the* weeks *following* it Tom did not know whether his return to Harvard could be arranged.

  a43:036 Operating revenues were ...up FOR *the* 12 months *ending* in March.

  g46:040 The plan is admirably fulfilled FOR *the* period *up to* 1832.

The interval is part of a larger definite interval. The part may be the beginning, the end or somewhere in the middle of the interval and is given either by an adjective or a complex NP:

- The beginning of a definite interval, using *the first*:

  f16:061 FOR *the first* three weeks, the ship skirted up the east coast of Great Britain, then turned westward.

- The end of a definite interval, using the qualifiers *the rest of/remainder of/remaining*:

  r08:022 FOR *the remainder of* the movie, Chancellor Neitzbohr proceeds to lash the piano stool ...

j79:009a Moreover, by ... always using the optimal Af-stage policy FOR *the remaining* stages, ...

- Some other part of a definite interval, using, e.g. *most/much/whole (duration)/all of*:

a18:027 FOR *most of* the 25 years the operation was under feminine direction.
a18:039 Col. Clifton Lisle ... headed the Troop Committee FOR *much of* its second and third decades ...
f15:021b ... it is possible to be exempt from the normal obligation of parenthood for a long time and even FOR *the whole duration of* married life ...

The `tor` is included in the interval using a noun phrase such as *now, the present, the moment*:

m03:016 "FOR *now*, it is clear that we were in the wrong.
g15:025 FOR *the present* it is enough to note that ...
l14:068 Try to forget motive FOR *the moment*.

In summary, the interval in a FOR phrase whose matrix is a VP must be either:

- a duration made definite by a qualifier or modifier linking it to the `tor` or another interval; or
- part of a larger interval; or
- an interval that includes the `tor` specifically, e.g. *now, the present, the moment*.

Note, in particular, that proper nouns indicating clock times and calendar dates, such as *7 p.m., May, 1996*, are not found.

2.2.2. FOR modifying a noun phrase

The matrix of FOR phrase may itself be a noun phrase referring to a regularly recurring event or object. The FOR phrase indicates a unique interval which serves to pick out a specific occurrence of this event or object. Here there is no restriction on the type of interval specified in the FOR PP:

- Regularly recurring events, e.g. plays

k05:140 The *play* FOR Saturday night was to be a benefit performance of The Octoroon.

- Regularly recurring financial objects, e.g. tax returns, budgets, costs, revenues etc.:

h24:009 Since ... your *return* FOR the calendar year 1961 will be timely filed.
b01:038 DeKalb's *budget* FOR 1961 is a record one ...
a28:013 FOR the year to date, *sales* ... still lag about 5 % behind 1960.

- Other regularly recurring objects, e.g. newspapers, journals, appointments, horoscopes, rates and even obligations:

g38:040 The final issue of the *Englishman*, No. 57 FOR February 15, ran to some length ...
j56:055 Eber L. Taylor of Manchester Depot recorded ... in his *diary* FOR 1906.
g49:003 ... having made a formal *engagement* by letter FOR the next week, ...
p21:082 I may settle on some makeshift *arrangements* FOR the summer.
r09:078 ... I'd say that your *horoscope* FOR this autumn is the reverse of rosy.
j07:030b ... to give reliable impact *rates* FOR the periods of exposure.
b17:009a Our only *obligation* FOR this day is to vote, ...

It could be argued that the use of a FOR phrase to qualify a noun is not essentially temporal. In many of the above examples the time in the FOR phrase could be replaced by an appropriate proper noun, e.g. FOR *IBM*, FOR *John*. The FOR phrase would then indicate possession or purpose, e.g. *the budget of IBM, the arrangements for John* (i.e. the special use of FOR, see Section 2.3.). We have included it here as we have chosen to include as temporal all uses of FOR that have a temporal noun in the PP.

2.2.3. There is a count over an interval given by the FOR PP

This is closely related to the above, but there is no NP which the FOR PP is modifying. Rather there is a count over an interval given by the FOR PP:

a43:038 FOR the year, the road earned 133 per cent of its interest costs ...

Normally IN is used for indicating the interval over which a count is taken, but when the interval is given by a duration made definite by the determiner *the*, then FOR is used.

The remaining examples of the use of a definite noun phrase with FOR are non-standard. These have been categorized as a special use (Section 2.3.) and an idiomatic use (Section 2.4.).

2.3. Special use

The special use is one in which the FOR phrase gives an interval but not one in which the matrix proposition holds. Rather it is an interval, later than the `tor`, in which some event, that is related to the matrix proposition in some way, will take place. The relationship may be a simple prediction, planning or purpose:

h29:008 I believe a further gain *is in prospect* FOR 1961. [*prediction*]
a10:045 The dinner is sponsored by organized labor and *is scheduled* FOR 7 p.m.. [*plan*]
l24:118 We *decided to* leave the third one intact FOR tomorrow. [*purpose*]

Note how in all these examples, the matrix proposition holds at the `tor` rather than in the interval given by the FOR PP. In:

h29:008 the *gain* is already *in prospect* at the `tor`; the actual gain will be realised later, in *1961*.

a10:045 the *dinner* is already *scheduled* by the `tor`; the actual dinner will take place later, at *7 p.m.*.

l24:118 the *third one* is *left intact* at the `tor`; the reason for this is so that it can serve some purpose *tomorrow*.

It is the matrix that is indicative of this special usage. It needs to indicate that an action has been undertaken that will lead to some event to take place or state to be the case at a future interval that is given by the FOR PP. How this is indicated is not simple. The matrix verb, plus particle if present, gives the indication: *be in prospect, be scheduled*,

decide to X. A list of verbs that were found in the corpus to indicate special use will be given in Section 4.2.

While the FOR PPs in the purposeful sentences such as l24:118 clearly have a temporal function, they are not only temporal. There is also a sense of purpose which is another use of FOR:

a01:060 Vandiver opened his race FOR governor in 1958 . . .

Should they be included as a temporal use of FOR? With prepositions with both temporal and spatial uses, such as AT or IN, the temporal use can be detected from the temporal nature of the noun in the PP (Brée & Pratt, 1997). If we wish to use this general heuristic to identify when a PP is being used temporally rather than spatially, we need to keep these as a special temporal use of FOR.

Note also that, as with NP attachment of the FOR interval, proper clock and calendar nouns can be used in the FOR PP when there is a special use.

2.4. Idiomatic

For the Nth time, where *Nth* is any ordinal, generally *first*, but including *last*, was classified as idiomatic use:

p22:041 It was weeks before we even kissed FOR *the first time*.

19:008 And FOR *the thousandth time*, I answered myself.

The reason for considering this an idiomatic use is that the noun *time* is here not being used in its temporal meaning but as an indication of position in a sequence. Confirmation of this difference is given by the different translations given in other languages. In Dutch, for instance, the normal word for time is *tijd*; but in the expression *for the Nth time*, it is *keer*.

This concludes the list of uses for temporal FOR phrases. We turn now to an examination of the components of the phrase in the expectation that they will distinguish between these different uses.

3. Components of the prepositional phrase

Our task now is to code features of the sentences which may indicate which of the temporal uses of the FOR PP was intended by the writer. The following information was coded for each sentence in the Brown corpus in which the preposition FOR was being used temporally. The features of the PP, being those specified in a standard grammar (Quirk et al., 1985), arranged in order of occurrence in the PP as in *Except for most of the first glorious year of his Presidency*, were:

- Any pre-modifier of FOR (16):[1] *not, except, only, save*.
- Any pre-determiner of the NP in the FOR PP (68): a fraction (*of*), a cardinal number *of, all, only, even, most of, much of, longer than, more than, about, approximately, nearly, almost, up to, at (the) least, over*.
- Any determiner of the NP: definite, indefinite, demonstrative, possessive, quantifier, none or zero. When there was no determiner a choice was made, by hand, whether to give a 'none' or a 'zero' entry. A 'none' entry was chosen if the noun was a noun, usually proper, which could not take any determiner, i.e. a particular year, month or date. Otherwise a 'zero' entry was chosen. The reason for this distinction is that the 'none' entries behave in the same way as definite determiners, whereas the 'zero' entries behave in the same way as indefinite determiners.[2]

  The distinction between 'definite' and 'indefinite' was important in distinguishing between Duration and Interval uses of FOR. The 'demonstrative' and 'possessive' entries all had the same effect as the 'definite' and 'none' determiners. We will refer to them as Definite determiners (302). The 'quantifiers' were the existentials *some* and *any*; they occurred in FOR phrases which were given a duration meaning. Therefore, they were grouped with 'indefinite' and 'zero'; this group will be referred to as Indefinite determiners (704).
- Any post-determiner of the NP (541): (*total of*) *N* [a cardinal number], *Ns of*, an ordinal number, *single, couple of, dozen, number of, few, several, (so) many, matter of, another, more, past, preceding, last, next, only*.
- Any qualifier of the head noun in the NP, e.g. *glorious*.
- The head noun in the NP, sub divided by type (Brée & Pratt, 1997):

  Measure of a temporal duration (865), e.g. *year*;

  Calendar interval (47), e.g. *1966, future*;

  Cyclical (22), e.g. *morning, spring*;

  Part of a longer event (10), e.g. *act, inning, movement, session, spell, stage*;

  Adverbials (25): *ever, long, now, once, tomorrow, tonight*;

  Life (2): *birthday, lifetime*;

  Complex, always with a post-modifier (2): *length, remainder*
- If there was a phrase post-modifying the NP, then the preposition or conjunction introducing this post-modifying expression (126): *of, when, in (advance), during*, any demonstrative, *ended, ending, up to, after(ward), since, following, commencing, starting, or, and, at, each, every, a(n), now, being, to (come), longer, forward, as (a whole), than.*

Certain properties of the verb in the matrix were also noted as these were required to make the distinction between different uses:

Tense (only coded when required): past, present, past/present participle, infinitive;

Aspect (174): perfect (146), progressive (2), perfect progressive (26);

[1] The numbers in parentheses give the number of occurrences in the total of all 1006 examples of temporal use of FOR in the Brown corpus.

[2] Two 'nouns', actually adverbials being used as nouns, never take a determiner, but the determiner was coded as 'Zero' rather than 'None' as they always occurred with Durations rather than Intervals: *long* (17), *ever* (1).

Modal (92): *will* (46), *shall* (5), *can* (30), *may* (6), *have to* (3).

Also with Interval uses, the position of the FOR PP relative to other components of the matrix, in particular its verb.

The categories that turned out to be of most help in discriminating between different uses of FOR were the determiner, the noun itself and the post-modifiers, which we now need to examine in some detail.

3.1. Post-modifiers

As we have seen, the noun in the FOR phrase is frequently post-modified (126). There are of several kinds of post-modifiers: adverbials, conjunctions, demonstratives and other temporal prepositions followed by a noun phrase. Each can be used for different functions depending on whether the determiner is Definite or Indefinite. We now will look in detail at which post-modifiers indicate which function. This section can be skipped without loss of continuity; a summary is given in Section 3.1.3..

3.1.1. With an Indefinite determiner

When the determiner was Indefinite (82), usually associated with one of the Duration uses (see Section 4.3.), the post-modifying phrase has one of the following functions:

- It can simply add information about the duration (22), usually just to say that a *period* is temporal (*period of time*, 7), but also to indicate more precisely its length (using *period of*, 4; *as long as*, 4) or even its nature (*of*, 5):

  j11:081 ... many have been made FOR a very short *period of time*.
  j08:054a All samplers were operated FOR a *period of* two hours ...
  j16:012b ... until used they were stored FOR *as long as* 2 weeks.
  f11:076 An average national figure FOR two to three years *of* treatment would be $ 650 to $ 1,000 .

- It can signal that the duration is generic (18), either directly (*at a time*, 2) or by giving the cyclical frequency (*a(n)*, 13; *every*, 3; *each*, 2):

  k14:074 He worked FOR two hours *a* day ...
  g37:010 ... the missionaries skipped FOR hours *at a time*.
  f04:117 Rugged outdoor exercise FOR an hour and a half *every* day

- It can link the duration to the `tor` (14), either as preceding it (*now*, 10) or following it (*to come*, 6; *longer*, 3; *forward*, 1)

  b08:066 She's been in and out of my house FOR a dozen years *now* ...
  b15:005b The demand for these lots can be met FOR some time *to come*.
  p07:005 Spencer was quiet FOR a moment *longer* ...
  h02:081a ... they must plan their own complex investment programs FOR at least 5 years *forward* ...

- It can link the duration to an interval other than the `tor` (20), either being in the interval (*in*, 6; *during*, 2; a demonstrative, 2) or beginning at the interval (*after(ward)*, 3; *since*, 1; *following*, 3; *starting*, 1; *commencing*, 1):

  a28:031 Except FOR a few months *in* late 1960 and early 1961 ...
  b23:087a A truth-revealing crisis erupted in Katanga FOR a couple of days *this* month ...
  k29:016 FOR many nights *afterward* ...
  j56:088a FOR a time *following* the abandonment of the local plant ...

- It can even alter the extent of the duration given by the head noun in the FOR PP (11), either by giving an alternative duration (using *or*, 5), by including another type of duration (*and*, 1) or by setting the given duration as a maximum (*as long as*, 4) or a minimum (*more ... than*, 1):

  f43:021 FOR a moment *or* two, both scenes are present simultaneously ,
  r06:063 ... her husband hasn't been home FOR two days *and* nights."
  j16:012b ... until used they were stored FOR *as long as* 2 weeks.

3.1.2. With a Definite determiner

When the determiner was Definite (44) the post-modifying phrase has one of the following functions:

- To specify the interval over which the count FOR *the* N^{th} *time* is to be taken (21), using *in* (14), a demonstrative (4) or *since* (3):

  l12:154 FOR the first time *in* his life ...
  n23:015 And FOR the hundredth time *that* week, he was startled at her beauty.
  r01:035 Then, FOR the first time *since* his arrest ...

- To specify the larger interval from which a part is selected by the head noun, using *of* (7):

  p03:078 FOR the first few months *of* their marriage ...
  r08:022 FOR the remainder *of* the movie ...

- When the head noun is a Measure noun, to specify the end of the duration thus selecting an interval and making the FOR NP Definite (5), using *ending/ed* (3), *up to* (1), *following* (1):

  h27:001 Sales and net income FOR the year *ended* December 31, 1960 ...
  h29:011 FOR the year as a whole, retail sales of TV sets ...

- To describe a further attribute of the interval which enables it to be identified uniquely (6), using *of* possessively (5), or *when* with a clause (1):

  a05:025b ... come up with recommendations for possible changes in time FOR the next session *of* the General Assembly.
  h15:081 A flashlight or electric lantern also should be available FOR those periods *when* a brighter light is needed.

- Other (5): relating an imprecise interval to the `tor` (*to date*, 1; *time being*, 1), giving a range (*to*, 1) or giving emphasis (*as a whole*, 2):

  a28:013 FOR the year *to date* ...

h13:008 ...total annual rail commutation dropped 124 million FOR 1947 *to* 1957.
h29:011 FOR the year *as a whole*, retail sales of

3.1.3. In summary

Most of the post-modifiers can be used with both a Definite and an Indefinite determiner:

- *of*:
  Indefinite: property of the duration,
  Definite: possessive, after a temporal part noun, to indicate which larger interval it is a part of;
- *in, during*: and the demonstratives *this, that*:
  Indefinite: linking the duration to an interval,
  Definite: to give the interval over which the count in *the N^{th} time* is to be taken;
- *ending, up to, after, since, following, commencing, starting*: after a Measure noun, indicating that the duration ends or begins at the interval in the post-modifier PP (the FOR PP may be either Definite or Indefinite);
- *or, and*: coordination of either a duration or an interval.

Certain post-modifiers only appear after an Indefinite determiner:

- *at a time, each, every, a(n)* indicate that the duration is generic (and give its frequency);
- *now, to come, longer, forward* attach a duration to the `tor`;
- *as long as, more ... than* affect the extent of a duration.

This concludes the description of the various features in a temporal FOR PP, and its matrix that are likely to indicate which of the different possible uses of temporal FOR was intended by a writer. Most attention has been given to the post-modifying phrase as this is the least well understood part of the FOR PP. While the post-modifier is important, it is by no means the only feature of significance. We will see that the determiner, the qualifier and the verbal aspect also influence the use.

4. Distinguishing uses

We turn now to the task of distinguishing between the different uses of temporal FOR phrases, using the features introduced in the previous section.

There are 9482 instances of FOR in 7710 sentences (out of a total of 52355 sentences) in the Brown corpus. If the noun following the FOR was one that is known to indicate temporal use (Brée & Pratt, 1997), then it was included in the sample. Correspondingly, if the noun clearly indicated another use, e.g. purpose, then it was discarded. For all the remaining instances, the complete sentence was inspected to determine whether or not there was a temporal use. All the temporal instances were classified by use. Finally, the features, as given in Section 3., were coded. The numbers of instances of each temporal use of FOR in the Brown corpus are shown in Table 4.

We begin with the two most distinctive uses, idiomatic and special. Then we will see how to distinguish Durations from Intervals. Finally we will look at the different types of Duration and Interval use.

Use	Instances	Sub-totals
pure duration	212	
`tor−`	168	
`tor+`	265	
All Durations		677
interval: Count	8	
interval: Identify	94	
interval: Universal	73	
All Intervals		175
Special		97
Idiomatic		57
Total		1006

Table 1: Temporal uses of FOR PPs in the Brown corpus

4.1. The idiomatic use

The idiomatic use of FOR (57) in which the noun *time* indicates a position in a sequence rather than the passage of time is readily detected. All occurrences of the singular noun *time* with a post-determiner were idiomatic use. The post-determiner was usually an ordinal number (54) but could also be *last* (2) or *only* (1):

j64:033 FOR *the only time* in the opera, words are not set according to their natural inflection ...

4.2. The special use

Detecting the special use of FOR (97) to give the interval in which a consequence of the matrix will take place, is not simple. Simple features turn out not to be useful. For example, usually (78/97) the determiner is Definite, but Definite determiners are more frequently used (167) for simple intervals.

It is the matrix verb that indicates the special use of FOR. These verbs all have some element of purpose, planning or prediction. Here are examples of such uses grouped by these features. Note that there is no hard and fast way to separate these verbs into these three categories.

planning i.e. carrying out an activity at the `tor` that sets up a later event or state in the interval given by the FOR PP (46), e.g. *be available, have, issue* something, *invite* somebody, *plan, schedule, set*:

a18:081 Their Majesties ... have jointly *issued* invitations FOR Shrove Tuesday evening at midnight.
a42:006 ...Mr. Kennedy *invited* Stevenson to Cape Cod FOR the weekend.
a43:051a Higher tolls are *planned* FOR July 1, 1961, ...
l12:101 Andy's performance was *scheduled* FOR eleven o'clock.
a18:048c A preview party for sponsors of the event and for the artists is *set* FOR April 8.

predicting from what is known at the `tor` that some event or state will occur at a later time given by the FOR PP (8): *auger well/badly, be in (prospect), be out, continue, leave, realize, suggest* something (once each):

b20:076 He has, moreover, another qualification which *augurs* well FOR the future.
b10:048 To me, Brandt looks as though he could *be in* FOR a fine year.
h29:008 I believe a further gain *is in prospect* FOR 1961.
a23:004 ...Multnomah, as of Aug. 22, had spent $ 58,918 out of its budgeted $ 66,000 in the category, *leaving* only $ 7,082 FOR the rest of the month.
j39:091b ...and to appraise the forecast that its interpretation *suggests* FOR the future of farm prices over the years immediately ahead.

purpose in which some activity is conducted at the `tor` in order to achieve some state in a time period given in the FOR PP (33), e.g. *be at, be out, bed down, develop* something, *go (back/to), live, prescribe, protect, shut up, stash (away)*:

p11:030 I made a lemon sponge, ..., so there *would be* something nice in the icebox FOR the weekend.
k12:002 Once, they *were at* Easthampton FOR the summer.
l02:107 ..., but when you ...know that you can't eat until he's *bedded down* FOR the night, ...
e28:104b Does your company have a program for selecting and *developing* sales and marketing management personnel FOR the longer term?
p20:162 We *went* to the Louvre FOR a few hours.
l11:082-4 "You *live* in the present?" "In the present', Felix proclaimed. "FOR the future. ..."
f34:027 The artist who paints in oil uses drying oils to carry the pigments and to *protect* his finished work FOR the ages.
k26:027 The women ...sounded like chickens *shut up* in a coop FOR the night.
l24:144 I've got a little *stashed* FOR a rainy day, and I guess this is rainy enough.

Clearly this list of verbs is incomplete. Nor is it obvious what test should be applied to verbs to decide whether or not they can indicate a special use of a temporal FOR phrase. They should admit of prediction, purpose or planning, but how to develop this insight into a test is not clear.

4.3. Duration versus Interval

Having distinguished idiomatic and special uses of temporal FOR, we turn to Duration and Interval uses (852). Both uses can be one-off or generic. Since distinguishing between one-off and generic sentences is a general problem whose solution does not depend on the FOR PP, we will not attempt to make the distinction here. Instead we now examine how to make the main distinction, that between Duration uses on the one hand and Interval uses on the other. In general this is easy: an Indefinite determiner indicates a Duration use (8/685), a Definite determiner indicates an Interval use (4/167). However, there are exceptions.

Very occasionally (8/685) an Indefinite determiner does not indicate a Duration use. This is when:

- There is the universal quantifier *all* as a pre-determiner (4):

j19:044 The managers stay the same, so that A[fj] is the same FOR *all* weeks.
f30:044 Probably a lawyer once said it best FOR *all* time in the Supreme Court of the United States.

These four sentences are the only ones in which *all* occurs as a pre-determiner. Hence it is a reliable if infrequent indicator of an interval use.

- A duration is made a particular interval by being directly attached to the `tor`, using the post-determiners *last, next* (2):

b06:083 South Viet Nam's rice surplus FOR *next* year ...may have been destroyed.
a27:024 A substantial rise in new orders and sales of durable goods was reported FOR *last* month.

This is similar to, but different from, the attachment of a duration to the `tor`, indicated by a perfect aspect or modal (see Sections 4.4. and 4.5.). The difference arises as the noun phrase itself is sufficient to detect that there is attachment to the `tor`. In fact, while there is no determiner in these examples, a definite determiner is acceptable: FOR *the next/last month*.

- A duration is made a particular interval by being directly attached to a point of time, using certain post-modifying expressions, such as *commencing, following* (4):

h07:095 ...they could levy taxes FOR an interim period of nine months, *commencing* with September 30 and ending with June 30.
a03:054 Full payment of nursing home bills FOR up to 180 days *following* discharge from a hospital.
d08:007 ...which succeeded in reuniting China and keeping it together FOR a longer period (*from* 202 B.C. *to* A.D. 220).
a23:002 FOR a second month *in a row*, Multnomah County may be short of general assistance money ...

This is somewhat different from the previous two cases, as here the determiner can't be definite. Moreover, several other gerundive post-modifiers would have this same effect, e.g. *beginning, starting, ending*.

- There is no determiner, but a definite determiner could have been used (2):

a26:086b ...estimated sales of domestic cars in the U.S. FOR first three months of 1961 were ...
j37:022a ...the rumors of election dates appeared once again, first FOR spring of 1958 and later for the summer.

In a26:086b it could be argued that a definite determiner should have been included. But j37:022a is quite acceptable as it stands. In fact, a definite determiner may be dropped with a season, and the season then acts as a proper noun.

Only 4 of the FOR PPs with a Definite determiner turned out to have a Duration rather than an Interval use, all but one with a superlative in the FOR PP.[3] Superlatives can be definite but still indicate a Duration use, here always `tor+`:

[3]The one exception was:

p25:068 Richard's dark eyes came up and seemed FOR *the tiniest moment* to reflect sharp light.

All the superlative qualifiers indicated tor+ use.

In summary, our simple rule for distinguishing between Durations and Intervals needs to be elaborated to:

- If the determiner is Indefinite, then there is a Duration use, unless:
  - there is the pre-determiner *all*;
  - *last* or *next* are qualifiers, indicating that the duration is attached to the tor;
  - there is a post-modifier that attaches the duration to some other time point, e.g.: *beginning, commencing, following, starting, ending*;
  - there is no determiner and the noun is a season;

  when there is an Interval use.
- If the determiner is Definite, then there is an Interval use, unless there is a superlative qualifier when there is a Duration use.

We now turn to distinguishing between the different Interval and Duration uses.

4.4. Distinguishing tor− from other Duration uses

The duration can be attached to the time axis to indicate an interval ending at the tor (tor−) (168). Can this tor− use be distinguished from other Durations? A likely indicator is the perfect aspect as it is used to place an event or state before the tor. While perfect aspect was an indicator of tor− use with IN PPs other features of the matrix, sometimes in conjunction with the perfect aspect, were better indicators: a negative, superlative or ordinal in the matrix (and sometimes if there was a cardinal number and perfect aspect), or if the IN PP was topicalized (Brée, in press). Turning to the data for FOR PPs we find, by contrast:

- The perfect aspect frequently (150/165) did indicate a tor− use:

  f31:080 They *have* not been friendly FOR years".
  n09:100b Tom *had* been laying for Aaron McBride FOR a long time ...

  However, 15 FOR PPs occurring in a matrix with a perfect aspect weren't tor− use. One reason is that a perfect aspect with a past tense is used to indicate a time earlier than the tor rather than the time just prior to the tor (10/15):[4]

  k28:165 After that they *had* sat FOR five minutes without saying a word.

  If the past perfect aspect is being used consistently, e.g. as it is in the text preceding k28:165:

  k28:161 "I'll give you ...", Miss Ada *had* said.

  then it is likely that the past perfect in the matrix is also setting the time of the event to before a past tor, rather than to the time immediately preceding the tor. The past perfect aspect occurs much more frequently with the tor− use than with the other Duration uses (65/10), so does not in itself provide an exclusion heuristic.

- The FOR PP was embedded in an *after* phrase (9), generally with a present participle (7):

  a17:001 *After being* closed FOR seven months, the Garden of the Gods Club will have its gala summer opening Saturday, June 3.
  f16:118 Once, *after* the Discovery lay FOR a week in rough weather ...

  Inserting a perfect aspect in these after phrases is quite possible, but clearly not necessary. All occurrences of an Indefinite FOR PP in a *after* phrase were tor− use.

- If the verb in the matrix was a past participle then there was usually (5/7) a tor− meaning:

  a12:074 Halfback Bud Priddy, *slowed* FOR almost a month by a slowly-mending sprained ankle, ...

  It is not possible to have a perfect aspect with a past participle:

  a12:074′ Halfback Bud Priddy, *had* slowed FOR almost a month by a slowly-mending sprained ankle, ...

  The 2 instances of a past participle in the matrix which were not tor− meaning were both generic durations. Distinguishing generic from episodic sentences is non trivial!

These rules explain 164 of the 168 instances of tor− use, but without any means for detecting that the past perfect had been established as the tense of story, they would also include 17 of the other 509 Duration uses (see Table 4.4.). So there is no hard and fast rule for distinguishing tor− use from other Duration uses, but the following heuristics would be most useful. The duration of FOR PP is likely to end at the tor if:

- there is a perfect aspect in the matrix (unless the perfect past has been established as the tense of use); or
- the matrix is an *after* phrase (generally one with a present participle rather than a full tense); or
- the tense verb in the matrix is a past participle.

Rule	When use is: tor−	all	Cumulative: OK	miss
Matrix is an *after* phrase	9	9	9	0
Perfect aspect in matrix	150	165	159	15
Matrix verb is past participle	5	7	164	17
Out of a maximum of:			168	509

Table 2: Evaluation of the heuristic rules for tor− use

j04:095 The temperature was maintained to within about A[fj] FOR *the* period of time required to make the measurement (usually about one hour).

[4] In all the remaining 5 examples it is a present tense perfect aspect that fails to indicate a tor− use. It seems unlikely that these examples could be excluded without resorting to domain knowledge.

4.5. Distinguishing tor+ from other Duration uses

Attachment of the duration to after the tor, the tor+ use, is also possible and indeed very frequent, occurring in almost half the Duration cases (297). With temporal IN PPs, the rules for distinguishing tor+ use from pure durations were heuristic, so the same is to be expected with FOR PPs. The indicators of the tor+ use with FOR PPs that were found are:

- Topicalization of the temporal PP, without a perfect aspect, always signalled tor+ use with IN (Hitzeman, 1997; Brée, in press). The tor+ use of IN is unusual in that the time of the matrix event is set to be at a time interval which is at the end of a duration, given by the IN PP, after the tor, rather than within an interval starting at the tor and lasting this duration, as one might expect. But even so topicalization without a perfect aspect also usually indicated tor+ use with FOR PPs (62/80):[5]

  l10:172 FOR exactly one week, she was able to continue in this manner.

  but not always (18):

  a19:034 FOR a number of years the board used a machine to keep a permanent record but abandoned the practice about two years ago.

- *Then* is a marker for the tor. When *then* is in the matrix (15) or begins the clause that follows the matrix (which may be the next sentence) (53) then tor+ is almost always (68/73) indicated:

  g67:080 *Then* he kept Blackman awake FOR more than an hour ...
  f31:098a She worked as a domestic, first in Newport FOR a year, and *then* in ...

- The vague noun *time*, without a qualifier or post-modifier, was an indicator of tor+ use with IN, as in the expression *in time*. With FOR, several nouns were found more frequently with a tor+ use than with a pure duration (177/203), e.g.: *instant* (10/11), *moment* (56/63), *second* (14/16), *minute* (50/63), *(a)while* (28/29), and *time* when there was no qualifier (19/21):

  n29:174 The kid showed FOR an *instant*, and his arm was cocked back.
  n07:110 Barton waited FOR a long *moment* ...
  n12:049 He studied the problem FOR a few *seconds* and thought of a means by which it might be solved.
  p20:079 She was silent FOR a *while* ...
  l14:048 Detective Pearson, Eighteenth Precinct, thought FOR *a time* he might be on to something.

  Why these nouns? *While*, like *time*, refers to only a vague duration, so is not useful for specifying the duration of an event unless the duration is attached to the tor. The other nouns (*instant, second, moment, minute*) refer to short or very short durations, almost too short for any ordinary event to take place within; so they are not often used for that purpose. When they are, it is usually in a generic context, where there is no explicit tor:

  k25:040 He looked at her out of himself, she thought, as he did only FOR *an instant at a time* ...
  k25:048a *Every* few minutes she would awaken FOR a *moment* to review things ...

  or there is a pre-modifier:

  g35:004 *Not* FOR a *moment* do we forget that our own fate is firmly fastened to that of these countries ...

- The post-determiner *another* (6) and the qualifier *additional* (1), always indicated tor+:

  f28:005b ...it would be best for all if the plantation were operated FOR *another* year.
  j27:054b ...the group felt a topic under study should not be dropped FOR an *additional* week ...

- Some post-modifiers, such as *to come* (6), *longer* (3), *afterward* (1), also always indicate tor+:

  h03:027 May the Divine Speaker in Heaven bless this country with Sam Rayburn's continued service here FOR years *to come*.
  l12:102 He stalled FOR a half-hour *longer* ...
  k29:016 FOR many nights *afterward*, the idea of ...would return

Rule	When use is: tor+	all	Cumulative: OK	miss
another, additional	7	7	7	0
to come, longer, afterward	10	10	17	0
Noun: *time* (not qualified)	19	21	35	2
Nouns: *instant, second*	52	56	85	5
then in matrix or following	68	73	135	10
Noun: *moment*	56	63	176	15
Noun: *minute*	50	63	210	25
FOR PP topicalized	62	80	219	42
Out of a maximum of:			297	212

Table 3: Evaluation of the heuristic rules for tor+ use

The affect of applying these rules together, rather than individually, is shown in Table 4.5.. The rules are applied in order of most effective first, starting with the post-determiners, qualifiers and post-modifiers that always indicate a tor+ use, then adding in those nouns that are most indicative, then the presence of *then*, then the remaining nouns and finally topicalization. The additional effect of each rule can be seen in the two rightmost columns. Note in particular that, although topicalization was a good indicator of tor+ use with IN PPs and that it frequently occurs with this use of FOR PPs, it detracts from the effectiveness of the rule set, adding only 9 tor+ uses but 17 pure duration uses; so topicalization, while a good heuristic in itself, is not a good heuristic in conjunction with the other rules in the set.

[5] The numbers in parentheses indicate the number of tor+ occurrences out of the total of tor+ plus pure duration occurrences. Occurrences with tor− are not included as tor− usage is almost always indicated by a perfect aspect or a matrix which is an NP.

To explain the remaining instances of tor+ use, further heuristics are necessary, for example the nature of the verb in the matrix. One of the heuristics useful for detecting tor+ use with IN PPs was the presence of one of the modals *will, shall* or *may*. However, this heuristic is not specific enough (25/ 51) to be useful with FOR.

We have selected the following heuristics (in addition to there being no perfect aspect, the matrix not being an *after* phrase and the adverbial *now* not being in the matrix, all of which indicate tor− use) as indicating tor+ rather than other Durative uses:

- there is a post-determiner or qualifier in the class of words such as *another*, or
- there is a post-modifier in the category of words such as *to come*.
- the noun in the FOR phrase is very short (*instant, second*) or vague (*while*, or
- the noun in the FOR phrase is *time*, unqualified, or
- *then* appears in the matrix or begins the following clause (which may be the next sentence), or
- the noun in the FOR phrase is shortish: *moment, minute*.

This concludes the rules for distinguishing between different Duration uses. The curious reader can check them for himself by taking any simple sentence in which there is a temporal FOR PP with a pure duration use and altering it in each of the above ways. They will find that the pure duration use switches to a tor+ use. The skeptical might like to put this hypothesis to a psychological test.

4.6. Distinguishing between different interval uses

We now turn to the distinguishing between the three different Interval uses. The main distinction to be made is whether the FOR PP is attached to a VP (73) or an NP (94). There are only a few (8) count uses.

Detecting NP attachment is a classic problem. In this context the noun to which a FOR PP is attached is usually a regularly recurring event or object, such as financial figures (see Section 2.2.2.). However, there are many such types of noun and it is not clear how to use this information to detect that a FOR PP is attached to an NP. It can sometimes (63/94) be detected by the following syntactic heuristics:

- Always whenever the FOR PP occurs after a noun but before the verb (41):

  h24:024 His return FOR the period January 1 to June 20, 1961, is due April 16, 1962.

- The FOR PP occurs not only after the verb but also after another PP (18):[6]

  b27:081 Sir Robert Watson-Watt wrote, *on* page 50 of SR Research FOR 4 March 1961: ...

- Whenever the FOR PP follows one of a sequence of nouns after the verb (4):

  h30:035 An alert dean will confer all through the year on personnel needs, plans FOR the future, qualifications of those on the job , and ...

There are various other clues, but there will remain about a third of the sentences, in which the FOR PP follows a single NP after the verb but which should be classified as NP attachment:

e28:098 Have you estimated your sales manpower needs FOR the future ...

Of course, if the verb in the matrix is an event, as in e28:098, then the FOR PP can't be given VP attachment. This would require classifying the verbs by Vendler's types (Vendler, 1957), a difficult but not impossible task. However, recall that attachment to the VP can only occur under rather restricted circumstances (Section 2.2.1.):

- The specification of the interval, signalled by a Definite determiner, includes its duration, attaching the duration to the tor using the post-determiners *past, last, next* (25/35):

  b16:038 My husband's hours away from home FOR the *past* years have been ...

- The FOR NP picks out a particular duration from part of a longer interval (24/31),[7] using:
  - the N^{th} interval of that duration, usually the *first* (11/16);
  - the end, using *rest of, remainder of* (6/ 7);
  - (almost) all, using *all, most, much, whole of* (8/ 9)

- The temporal noun is one that specifically includes the tor (13/13): *moment, present, now*:

  b02:067 ...this approach might be expected to head off Mr. Khrushchev FOR the *moment*.

These three heuristics pick out 70 of the 81 VP attachments, but also include 16 cases of NP attachment. This is more restrictive than the conditions for attachment to an NP, so it would be simpler to look for VP attachment rather than NP attachment. Fortunately, the heuristics for detecting NP attachment detect all but 6 of these 16 cases. So once it has been signalled that VP attachment is likely, a check should be made that after all it isn't NP attachment.

Finally, the occasional use (8) to indicate an interval over which a count is taken is easily spotted by there being a cardinal in the matrix giving the count. Clearly there can also be a cardinal in the matrix with VP attachment, but this happened not to be present in this FOR extract from the brown corpus.

An overview of the effect of each rule, starting with the rule for the count use, is shown in Table 4.6.. Note how adding the simple rule that a FOR PP before the verb must be NP attachment reduces considerably the misclassification as VP attachment. Adding the two additional rules for identifying miss classifications of NP attachment as VP

[6] There are 2 exceptions which are VP attachment:

n26:046 Blue Throat, who had ruled the town *with* his six-shooter FOR the last six months ...

a43:036 Operating revenues were off in the first three months of 1961, but up FOR the 12 months ending in March.

[7] The number after the forward slash gives the number of occurrences in all the interval readings taken together, here 31.

Use	Rule	When use is: this use	all	Cumulative: OK	miss
Count	Cardinal in matrix	8	8	8	0
VP attachment	Noun: *moment, present, now*	13	13	21	0
	Qualifier: *rest/remainder of*	6	7	27	0
	Pre-determiner: *all, much/most/whole of*	8	9	35	1
	Post-determiner: Nth	11	16	45	6
	Post-determiner: *past, last, next*:	25	35	70	16
Count and VP attachment		In total:		81	94
NP attachment	FOR PP before verb	41	41	111	9
	Sequence of nouns	4	4	115	8
	FOR PP after another PP	18	20	133	6
	NP attachment as default			164	6
All Interval uses		In total:		175	175

Table 4: Evaluation of the heuristic rules for Interval Uses

attachment helps only marginally. So the only rule that I propose for identifying NP attachment is the obvious one that the FOR PP is before the matrix verb. Then anything already identified as some Interval use but that isn't count use or VP attachment is, by default, NP attachment.

4.7. Summary

Bringing this all together we see that some uses of temporal FOR phrase can be readily distinguished:

- The expression *for the Nth time* indicates the idiomatic use;
- The special use is identified by the presence of predictive, planning or purposeful verbs in the matrix.
- *A Definite determiner indicates an Interval use:
  - provided that the adverbial 'nouns', such as *long, ever* are not classified as proper nouns, even though they can never take a determiner;
  - *unless there is a superlative qualifier.
- *An Indefinite determiner indicates one of the Duration uses, unless:
  - there is the pre-determiner *all*; or
  - *there is a qualifier that attaches the duration to the `tor`, e.g.: *last, next*; or
  - *there is a gerundive post-modifier that attaches the duration to some time point other than the `tor`, e.g.: *beginning, commencing, following, starting, ending*; or
  - there is no determiner and the noun is a season;

  in which cases there is an Interval use.

Other uses are difficult to distinguish, but the following heuristics would be of help. For distinguishing between the different Duration uses:

- Attachment of a duration to before the `tor` rather than pure duration is indicated by:
  - *a perfect aspect in the matrix, *unless the perfect aspect has been established as the tense of use; or
  - the matrix is an *after* phrase (generally with its verb in present participle form); or
  - the verb tense in the matrix is a past participle.
- Attachment of a duration to after the `tor` rather than pure duration is indicated by the following heuristics:
  - there is a post-determiner or qualifier in the class of words such as *another*; or
  - there is a post-modifier in the category of words such as *to come*; or
  - the noun in the FOR phrase is very short (*instant, second*) or vague (*while*); or
  - the noun in the FOR phrase is *time*, unqualified, or
  - *then* appears in the matrix or begins the following clause (which may be the next sentence); or
  - the noun in the FOR phrase is shortish: *moment, minute*.

To distinguish between the different Interval uses:

- Use of the FOR PP to specify an interval over which a count is to be made is indicated by there being a cardinal in the matrix.
- Attachment of an interval to the VP rather than an NP is indicated by:
  - the specification of the interval includes its duration which is attached to the `tor` using the post-determiners *past, last, next*; or
  - the FOR NP picks out a particular duration from part of a longer interval; or
  - the temporal noun is one that specifically includes the `tor`: *moment, present, now*;

  *unless the FOR PP occurs after a noun but before the verb, when NP attachment is signalled.
- *Otherwise there is attachment of the interval to an NP.

Those rules above that are marked with an asterisk (*) are also those used for distinguishing between the different

uses of IN in (Brée, in press). The rules for detecting the idiomatic and special uses are obviously going to be different between these two prepositions. The rules for discriminating Duration from Interval uses show a large overlap. There are some minor differences, most probably due to the size of the samples, that I believe could be avoided by the inclusion of exceptions under both prepositions. Discriminating the `tor−` use from other Duration uses is again largely the same. However, the heuristics for detecting the `tor+` use are very different. (With IN topicalization and modals were the main clues.) The `tor+` use with IN indicates that the matrix holds at a time after the `tor` by the duration indicated by the NP, rather than between the `tor` and this time, as is the case with FOR, so it is unlikely that a common set of heuristic rules will serve to detect the `tor+` use for both prepositions. For the Interval uses, the heuristics for detecting NP attachment and count use are very similar and could be generalised. (No heuristics were provided for detecting VP attachment for IN PPs.)

Clearly providing a common set of (heuristic) rules for discriminating between the different uses (except for `tor+`) for both FOR and IN is the next order of the day. There are also two further prepositions, both infrequent, that have both Duration and Interval uses and so should be examined with the same heuristics in mind: WITHIN, OVER.

5. Conclusions

For such a fine grained analysis as we have made here, a million word corpus is about the maximum size that can be managed by hand; but it is clearly not large enough to give testable results. A corpus of the order of 10 million words, such as the British National Corpus, is needed. To perform this type of analysis such a corpus would have first to be suitably coded. What features would be need to be coded to make the distinctions by the method we have developed?

Some features are easily coded:

- First and foremost the temporal use of FOR, and other prepositions, can be readily detected from the noun in their PP. A list of about 100 such nouns is already available (Brée & Pratt, 1997). Some nouns are marginally temporal, e.g. *in history*, but these are mercifully few. This should overcome the problem, in the latest Penn Tree version of the Brown corpus, of tagging as temporal many non-temporal uses of prepositions .
- The distinction between different types of temporal noun, as given in Section 3., would be useful, in particular, recognising seasons, short time periods, such as *now, present, instant, second, moment, minute* and that some nouns, such as *a while*, give vague times, would be useful.
- The idiomatic use of temporal prepositions needs to be recognised, here simply *for the N^{th} time*.
- The contrast between Definite and Indefinite determiners needs to be recognised. Mostly this is easy, but the distinction between a 'Zero' and a 'None' entry needs to be made on the basis of the nature of the noun. Perhaps this is best left to the user, but then a provision has to be made for recognising proper nouns.
- The presence of a superlative in the PP as, while this is Definite, it is not a signal for an Interval use, but for a Duration use.
- The aspect of the verb in the matrix.
- The distinction between pre-determiners, determiners and post-determiners needs to be made along the lines in (Quirk et al., 1985).
- The position of the FOR PP relative to other components in its matrix, in particular the verb.

Other features are more difficult to code:

- To recognise the special use of FOR, the verb in the matrix must be coded as one of prediction, planning or purpose.
- Recognising those qualifiers, such as *past, last, next*, which attach a duration to the `tor`.
- Recognising those post-modifiers, such as *beginning, commencing, following*, which attach a duration to the `tor`.
- Distinguishing the temporal use of *then* to signal the `tor` from other uses, such as inferential.
- It would also assist the analysis if the entire matrix could be categorised as a state, process or event, or something similar to Vendler's types, although this feature has not been explicitly used here.

This is some wish list. But most features would be useful not only for distinguishing between the different temporal uses of FOR but for all the other temporal prepositions.

A Language-Neutral Representation of Temporal Information

Abstract

We propose a framework for representing semantic tense that is language-neutral, in the sense that it represents what is expressed by different tenses in different languages in a shared formal vocabulary. The proposed framework allows the representation to retain surface distinctions for particular languages, while allowing fully semantic representations, such as a representation of event sequence, to be derived from it. The proposed framework also supports the incorporation of semantic tense information that does not derive from grammatical tense, but derives instead from other expressions such as time adverbials. The framework is currently implemented in NLPWin, a multi-lingual, multi-application natural language understanding system currently under development at Microsoft Research, but the representational framework is in principle independent of any particular system.

1. Introduction[1]

Multilingual applications face (at least) two problems in the domain of semantic tense: First, there is the problem that grammatical, or morphological, tenses in different languages do not mean the same thing. In English, for example, grammatical past tense situates an event prior to the utterance ("speech time" in Reichenbach's (1947) terminology), and grammatical present tense situates an event simultaneous with the utterance. In contrast Japanese past tense situates an event prior to some reference time, and present tense situates an event simultaneous with some reference time, where the reference time may or may not be the utterance time. Neither language has a tense that expresses exactly what is expressed by past or present in the other. This poses a problem for applications such as machine translation (MT), since a given grammatical tense in one language does not automatically translate into the same surface tense in another language:

(1) 彼女は病気だと言った。
kanozyo-wa [byooki **da**] to itta
she -Top sick be-**Pres** that say-Past
'she said [she **was** sick]'

In (1), for example, the grammatical present tense in the embedded clause (indicated by brackets) translates into English as grammatical past tense, both of which allow the interpretation that the event described in the embedded clause is simultaneous with that described in the main clause.

Another problem is that what is expressed as grammatical tense in one language is sometimes only expressible as an adverbial construction in another language. For example, Chinese has no grammatical tense per se (see Section 3.3 for more details); consequently a single form can in principle express past, present or future; this is illustrated in the following examples:

(2) 昨天他来看我
zuotian ta lai kan wo
yesterday he come see me
'Yesterday he came to see me.'

(3) 明天他来看我
mingtian ta lai kan wo
tomorrow he come see me
'Tomorrow he will come to see me.'

In (2) and (3), the adverbials *zuotian* 'yesterday' and *mingtian* 'tomorrow' are all that indicate that these sentences are set in the past and future, respectively.

In this paper, we propose a framework for representing semantic tense, by which we mean information about the sequence of events. Our framework is *language-neutral*, in the sense that it represents surface tense marking of various languages using a shared formal vocabulary. Our framework also allows the incorporation of semantic tense information that is not expressed as grammatical tense, for example, that (2) is about a past time. Also, since a large part of what is expressed by tenses concerns the sequence of events and states, one aspect of our framework is enabling an explicit representation of temporal sequence. The analyses reported here are currently implemented in the NLPWin system under development at Microsoft Research (Heidorn, 2000).

Most (if not all) other proposals for a language-neutral representation of tense, such as Van Eynde (1997), are explicit attempts to represent the semantics of tense directly. However, the kind of semantic representation of tense may vary considerably depending on application. For example, some applications may require tense to be represented in first-order predicate calculus, perhaps incorporating Davisonian event arguments (Davidson, 1980), while others might require only an explicit sequence of events, as in Filatova and Hovy (2001).

The novelty of our approach lies in the fact that it does not attempt to be a particular semantic representation. Our goal is to preserve syntactic information about semantic tense so that various semantic representations of

[1] We would like to thank three anonymous reviewers and our colleagues in the Natural Language Processing group at MSR for their helpful comments and discussion, especially Michael Gamon, Marisa Jimenez, Jessie Pinkham and Hisami Suzuki.

tense can be constructed if necessary for a particular application. For example, our representation is compatible with both the referential theory of tense (e.g. Enç, 1987) and the quantificational theory of tense (e.g. Ogihara, 1995). Also, although it does not express sequence of events directly, a representation of such a sequence can be derived from our representation.

Our framework owes much to Reichenbach (1947); but while a strictly Reichenbachian approach to tense may work well for European languages, such an approach becomes unwieldy when faced with a set of languages with more typologically diverse tense systems, including Japanese and Chinese, aspects of which are discussed below. We therefore do not rely on the Reichenbachian notions of reference and event times, as does e.g. Van Eynde (1997), but adapt what we take to be Reichenbach's essential insights to a wider range of tense systems.[2]

Before proceeding, it is necessary to say something about the terms *tense* and *aspect*, and to lay out what the scope of the paper is. By *semantic tense*, we mean information about how events or situations are sequenced; this includes some of what in some traditions is called aspect, such as the interpretation of the English perfect, etc. It also includes information that may not be recorded by grammatical tense, as shown in (2) and (3). By *aspect*, we mean temporal information that goes beyond temporal sequence, such as (im)perfectivity, progressive, stative, habitual, and the like. In this paper, we are concerned with semantic tense, not primarily with aspect, though some aspectual features are considered in Section 3.3.2, below.

The paper is organized as follows: In Section 2 we outline the general framework of Language-Neutral Syntax (LNS) (Campbell, 2002; Campbell & Suzuki, 2002), within which we situate the current proposal; in Section 3, we lay out our proposal for the representation of semantic tense; in Section 4, we compare our system to other proposals for representing semantic tense; Section 5 offers a conclusion.

2. Language-neutral syntax

In this section we describe the basic properties and motivation for LNS. For more detailed descriptions, the reader is referred to Campbell (2002) and Campbell & Suzuki (2002).

LNS is a level of representation that is more abstract than a surface-syntactic analysis, yet not as abstract as a fully-articulated semantic analysis; rather, it is intermediate between the two. The basic design principle of LNS is that it be close enough to the surface syntax of individual languages to allow reconstruction of the surface structure of a given sentence (i.e., LNS can serve as the input to a language-particular generation function), yet abstract and language-independent enough to allow derivation of deeper semantic representations, where necessary, by a language-independent function. The role of LNS is illustrated schematically in Figure 1.

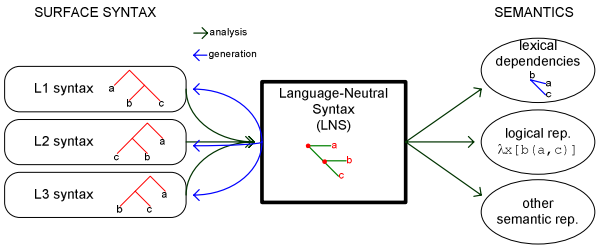

Figure 1: Language-Neutral Syntax

The primary motivation for such an intermediate representation is to mediate between languages in multi-lingual applications, given that fully articulated semantic representations are typically not needed in most such applications. For example, the Adjective + Noun combinations *black cat* and *legal problem* have identical surface structures, but very different semantics: the first is interpreted as λx[black(x) & cat(x)], i.e., as describing anything that is both a cat and black; the second, however, does not have the parallel interpretation as a description of something which is both a problem and legal: rather, it typically describes a problem having to do with the law. To accurately analyze this distinction would require extensive and detailed lexical annotation for adjective senses and, most likely, for lexicalized meanings of particular Adj + Noun combinations; such extensive annotation, if it is even possible, would make a system that depends on it very brittle. For most applications, however, this semantic difference is immaterial, and the extensive and brittle annotation unnecessary: for example, all that we need to know to translate these phrases into French *chat noir* lit. 'cat black' and *probléme legal* lit. 'problem legal' is that the adjective modifies the noun in some way. LNS is a representation in which *black cat* and *legal problem* have the same structure, despite their deep semantic difference, and in which *black cat* and *chat noir* have the same structure, despite their superficial syntactic difference.

An LNS representation is an annotated tree, in which constituents are unordered, and linked to their parent by labeled arcs, the labels corresponding to semantically motivated grammatical functions such as semantic head, logical subject, time, etc. The LNS tree is annotated with semantically motivated features and relations expressing long-distance dependencies (such as binding and control) and discourse-oriented functions (such as topic and focus). An example (somewhat simplified, and with tense not represented for the time being) is given below; this figure represents the LNS for this noun phrase before the implementation of the framework for tense representation presented below.

(4) the cat that was seen yesterday

```
NOMINAL1 (+Def +Sing)
|_SemHeads--cat1
|_L_Attrib--FORMULA1 (+Pass +Proposition)
                |_SemHeads--see1
                |_L_Sub---_X1
                |_L_Obj---NOMINAL2
                          |_SemHeads--that1
                          |_Cntrlr: cat1
                |_L_Time-- yesterday1
```

[2] However, we do use the terms "reference time" and "event time" informally below.

The root node (NOMINAL1) is in the upper left; the daughters of a given node are indicated by labeled arcs such as *SemHeads* (semantic head), *L_Attrib* (logical attributive modifier), *L_Obj* (logical object), and the like. In addition to these attributes indicating deep grammatical relatons, there are other attributes which express additional relations among nodes in the tree. For example, the relative pronoun NOMINAL2 has a *Cntrlr* attribute, whose value is *cat1*, and indicates that *cat1* is the antecedent of the relative pronoun. The Cntrlr attribute is not part of the LNS tree per se; that is, the value of Cntrlr must be part of the LNS tree independently of the Cntrlr relation (in this case, as the semantic head of NOMINAL1). We refer to attributes such as Cntrlr as *non-tree* attributes. For display purposes only in this paper, we display non-tree attributes as labeled arcs, even though they are not part of the LNS tree per se; they will be displayed slightly differently, however, in that the value of the attribute is introduced by a colon, instead of by a dashed line.

In this example we see also that passives are normalized in terms of their argument structure, but the fact that the relative clause is passive is recorded in the feature +Pass on FORMULA1. This reflects a basic design principle of LNS: The basic structure is normalized for variation both within and among languages, but surface distinctions (such as the active/passive distinction) are retained as much as possible.

Thus an LNS representation needs to be close enough to the surface syntax to indicate meaningful distinctions, yet abstract enough to normalize meaningless cross-linguistic variation.

3. Framework for semantic tense

The LNS representation of semantic tense must therefore satisfy the following design criteria:

(5) *Design criteria for LNS representation of tense*:
a. Each individual grammatical tense in each language is recoverable from LNS.
b. The explicit sequence of events entailed by a sentence is recoverable from LNS by a language-independent function.

Criterion (5)(a) says that we must be able to reconstruct, by a distinct generation function for each language, how the semantic tense was expressed in the surface form of that language; this criterion will be satisfied if the LNS representation is different for each tense in a particular language. Criterion (5)(b) says that we must be able to derive an explicit representation of the sequence of events from an LNS representation by means of a language-independent function. This criterion will be satisfied if the representation of each tense in each language is truly language-neutral. In this section we detail a framework for semantic tense that meets the design criteria in (5). We begin by giving the details of the basic formalism (which we will add to in subsequent subsections), followed by a discussion of the motivation and function of its various aspects.

3.1. Basic framework: simple tenses

3.1.1. Tense features and relations

In our proposal each tensed clause contains a distinct Tense node, which is in the *L_Tense* ("logical tense") relation with the clause, and which is specified with semantic tense features, representing the meaning of each particular tense, and attributes indicating its relation to other nodes (including other Tense nodes) in the LNS tree. Semantic tense features can be either *global* or *anchorable*.[3]

The basic tense features, along with their interpretations, are given in the following tables; Table I shows the global features, and Table II the anchorable ones ('U' stands for the utterance time: 'speech time' in Reichenbachian terms):[4]

Feature	Meaning
G_Past	before U[5]
G_NonPast	not before U
G_Future	after U

Table I: Global tense features

Feature	Meaning
Befor	before Anchr if there is one; otherwise before U
NonBefor	not before Anchr if there is one; otherwise not before U
Aftr	after Anchr if there is one; otherwise after U
NonAftr	not after Anchr if there is one; otherwise not after U

Table II: Anchorable tense features

The tense features of a given Tense node are determined on a language-particular basis according to the interpretation of individual grammatical tenses. For example, the simple past tense in English is [+G_Past], the simple present is [+G_NonPast +NonBefor], etc.

Additional features may turn out, on further analysis, to be necessary; for example, many languages make a grammatical distinction between immediate future and general future, or between recent past and remote or

[3] The distinction between global and anchorable tense features is very similar to Comrie's (1985) distinction between 'absolute' and 'relative' tenses. We have adopted the different terminology to emphasize that the global/anchorable distinction is for features, not for tenses per se, as in Comrie's taxonomy.

[4] Note that, given their meanings, some pairs of Tense features are semantically incompatible with each other, and cannot occur on the same node. For example, a given Tense cannot be [+G_Past +G_NonPast].

[5] Strictly speaking the meaning of the global tense features is to express a relation between a given time t and a globally specified reference time, G. Conceivably, the value of G could vary, depending on various factors including genre, discourse context, etc. However, we currently have no theory as to how G might be set to any value other than U, so we will assume throughout that the global referene time is always the same as the utterance time.

general past. We have nothing to say about these specific contrasts, however, other than to note that the framework we propose is flexible enough to accommodate new tense features, if necessary.

A Tense node T will also under certain conditions have a non-tree attribute called *Anchr*, which indicates a relation that T bears to some other Tense node (the value of the Anchr attribute must be another Tense node). Like other non-tree attributes such as Cntrlr, Anchr should be thought of as an annotation on the basic tree, not as part of the tree itself; that is, the value of the Anchr attribute must fit into the LNS tree in some independent way. A Tense node has an Anchr attribute if (a) it has anchorable tense features; and (b) meets certain structural conditions. For simple tenses, the structural condition that it must meet to have an Anchr is that the clause containing it is an argument (i.e., logical subject or object) of another clause; in this case the value of Anchr is the Tense node in the governing clause. In the discussion of compound tenses below we will augment the set of sufficient structural conditions for having an Anchr.[6]

3.1.2. Past tense in English and Japanese

As indicated in Table II, if a Tense node with anchorable features has no Anchr, then it is interpreted as if anchored to the utterance time U. This means that, for example, a [+G_Past] Tense and an unanchored [+Befor] Tense have the same interpretation, all else being equal. Consider the following English and Japanese sentences, with the relevant parts of their LNS structure shown:[7]

(6) She was sick.
FORMULA1
|_SemHeads----sick1
|_L_Tense----_Tense1 (**+G_Past**)

(7) 彼女は病気だった。
kanozyo-wa byooki datta
she -Top sick be-Past
'She was sick.'
FORMULA1
|_SemHeads----病気1 (sick)
|_L_Tense--_Tense1 (**+Befor**)

The English and Japanese past tenses are represented differently because they are semantically different, though in these simple examples that difference is neutralized. The English simple past tense is [+G_Past], indicating that it denotes a time that is before U. The Japanese simple past tense on the other hand is [+Befor], indicating that it denotes a time that is before its Anchr. However, in this simple root sentence, there is no Anchr, so it is interpreted as if anchored to U; hence the interpretation is before U. Thus the design criterion (5)(b) is met, at least for these simple cases: a simple language-independent function would yield the correct sequence *be_sick* < *U* for both these examples.

The semantic difference between the English and Japanese past tenses comes into play when the Anchr attribute is present, which for simple tenses is in clauses that are arguments of a higher clause. Consider the following English and Japanese examples, in which the tense in question (in boldface) is in an embedded sentence (indirect speech), represented in LNS as the logical object (L_Obj) of the matrix clause:

(8) She said she was sick.
FORMULA1
|_SemHeads--say1
|_L_Tense--_Tense1 (+G_Past)
|_L_Obj--FORMULA2
|_SemHeads--sick1
|_L_Tense--**_Tense2** (+G_Past)

(9) 彼女は病気だったと言った。
kanozyo-wa byooki datta to itta
she -Top sick be-Past that say-Past
'she said she was sick'
FORMULA1
|_SemHeads--言う1 (say)
|_L_Tense--_Tense1 (+Befor)
|_L_Obj--FORMULA2
|_SemHeads--病気1 (sick)
|_L_Tense--**_Tense2** (+Befor)
|_Anchr: _Tense1

Since the embedded tense in (8) is +G_Past, its interpretation is before U; left unspecified is whether the situation described by the embedded clause (FORMULA2) is reported to have occurred before, or simultaneous with, the situation described by the matrix clause. In fact, both interpretations are possible in this case: her reported sickness may be simultaneous with her saying that she was sick (i.e., she said "I am sick"), or it may have preceded it (i.e., she said "I was sick").[8] The structure we assign to it captures that underspecification succinctly.

In (9), on the other hand, the embedded tense, *_Tense2*, is +Befor; since it has an anchorable feature, and its clause is the logical object of another clause, it must be anchored to the tense of that matrix clause, i.e., to *_Tense1*. Consequently, it denotes a time that is before the time denoted by *_Tense1* (which, like *_Tense1* in (7), denotes a time before U). So the only interpretation (9) has is that her reported sickness is prior to her saying that she was sick; i.e., it can only mean 'she said "I was sick"'; it cannot mean 'she said "I am sick"'. This construction illustrates the essential difference between the English and Japanese past tense forms: the former directly expresses a

[6] We have not ruled out the possibility of language-particular anchoring conditions, but so far have not encountered any need for them.

[7] In this paper we show only the parts of the LNS necessary to illustrate the treatment of tense; for example, we leave out logical subject, etc., unless otherwise necessary. Note also that the copula is regularly omitted from the LNS (see Campbell, 2002).

[8] A third logical possibility, consistent with the interpretation of G_Past, is that her sickness was in the past (i.e., before U), but after her saying that she was sick; i.e., she said "I will be sick". But this kind of interpretation seems to be universally disallowed without some kind of irrealis marking on the clause (such as a modal), and therefore does not need to be separately indicated.

relation to U, while the latter directly expresses a relation to some "reference" time, which may or may not be U.

Examples such as (8) and (9) illustrate precisely why the English and Japanese grammatical past tenses have different representations in the current framework. Suppose for example that the Japanese past tense were [+G_Past] (like the English past), instead of [+Befor]; then Japanese (9) should have the same range of interpretations as English (8), in particular it should be able to serve as a description of an event in which she said "I am sick"—i.e., where the time of her being sick coincides with the time that she said she was sick. As noted, however, this interpretation is not available for (9), as it is for (8).

Our analysis of the English and Japanese past tenses differs from the approach taken by e.g. Ogihara (1995), who claims that English and Japanese past tenses mean the same thing, and that differences such as that between (8) and (9) below are due to the optional application in English of a rule that deletes the embedded past tense from the logical form component. Our analysis gives a uniform description to both the English and Japanese grammatical past tenses.

It is important to note that there is only one sense of the feature Befor (the same holds true for all the anchorable features in Table II), and hence only one meaning for Japanese past tense, in our system. This is a crucial point which is easily overlooked: phrased in strictly Reichenbachian terms, we may appear to be saying that the Japanese past tense means *either* E<R (if it is anchored) *or* E<S (if not anchored). But this appearance of bi-vocalism is due, we believe, to an overly rigid adherence to Reichenbach's notation; our own notation is more flexible, allowing us to characterize the Japanese past tense as univocal, while still retaining what we regard as Reichenbach's essential insights, namely that some tenses relate to U and others to a structurally determined "reference" time.

3.1.3. Present tense in English and Japanese

Another good illustration of the differences between global and anchorable tense features is provided by the English and Japanese present tenses. As in the case of past tense, the two tenses receive the same interpretation in simple sentences:

(10) She is sick.
FORMULA1
|_SemHeads—sick1
|_L_Tense--_Tense1 (**+G_NonPast** +NonBefor)

(11) 彼女は病気だ。
kanozyo-wa byooki da
she-Top sick be-Pres
'She is sick'
FORMULA1
|_SemHeads—病気1 (sick)
|_L_Tense--_Tense1 (**+NonBefor**)

Since the English present tense in (10) is [+G_NonPast] (as well as [+NonBefor]; see below), it must denote a time that is not before U. The Japanese present tense is just [+NonBefor], so it denotes a time that is not before its Anchr; since it lacks an Anchr, in this case, it must denote a time that is not before U. Consequently (10) and (11) receive the same interpretation.

Note that nothing in these representations directly expresses anything about the "present": G_NonPast is interpreted as "not before" U, but does not have to be simultaneous with U. This is by design: the English grammatical present tense allows a future interpretation as well as a "present" one, as in *We speak tomorrow* (see Section 4, below). Our assumption is that present-time reference is the default denotation for any Tense whose features and relations to other time expressions are consistent with that interpretation. Similar comments hold for the Japanese present tense, which is [+NonBefor] in our analysis. As in English, the Japanese present tense also allows a future-time construal (see Section 3.3.3, below).

As in the case of the past tenses, the difference between the English and Japanese present tenses shows up when there is an Anchr:

(12) She said she is sick.
FORMULA1
|_SemHeads--say1
|_L_Tense--_Tense1 (+G_Past)
|_L_Obj--FORMULA2
|_SemHeads--sick1
|_L_Tense--**_Tense2 (+G_NonPast +NonBefor)**
|_ Anchr: _Tense1

(13) 彼女は病気だと言った。
kanozyo-wa byooki da to itta
she -Top sick be-Pres that say-Past
'she said she was sick'
FORMULA1
|_SemHeads--言う1 (say)
|_L_Tense--_Tense1 (+Befor)
|_L_Obj--FORMULA2
|_SemHeads--病気1 (sick)
|_L_Tense--**_Tense2 (+NonBefor)**
|_ Anchr: _Tense1

In this case, both embedded tenses are anchored, since both have the anchorable feature [+NonBefor]. The English present tense is [+G_NonPast], however, so *_Tense2* denotes a time that is not before U; it is also [+NonBefor], so it also denotes a time that is not before the (past) time denoted by *_Tense1*. Consequently, the period of her sickness must overlap both the time of her saying that she was sick and the utterance time U (see also Note 8); in fact, as Enç (1987) notes, this construction has exactly that meaning. This example also illustrates the fact that a given tense may have any collection of mutually-compatible tense features, including both global and anchorable ones.

In contrast, the Japanese example (13) (the same as (1)) does not imply that the period of her sickness includes the utterance time; instead, the possibility that she is still sick at the present moment is left open, unlike (12). In our framework, this is because the Japanese present lacks a global tense feature. *_Tense2* is [+NonBefor] and not [+G_NonPast] like (12), so its only requirement is that it denote a time that is not before the time denoted by its Anchr, *_Tense1*. As indicated in the gloss, the best English translation of (13) is with the past tense. Examples like (12) and (13) illustrate precisely why the

English and Japanese present tenses are to be represented differently.

3.2. Compound tenses

One of the great insights of Reichenbach's (1947) analysis of tense is his treatment of compound tenses, such as the English present- and past-perfect. In this subsection, we outline our representation of compound tenses, which, despite notational differences, is essentially Reichenbachian.

We begin by making a formal distinction between *primary* and *secondary* tenses, the latter being tenses, such as English *have* + past participle, which require an Anchr within the same clause, the former being all others. Thus each language-particular tense must be specified as to its features, and whether it is primary or secondary. Consider the following example of the past perfect in English:

(14) He had arrived.
FORMULA1
|_SemHeads—arrive1
|_L_Tense--_Tense1 (+G_Past)
--_Tense2 (**+Befor**)
|_ **Anchr: _Tense1**

We treat English perfect constructions as consisting of two tenses: a secondary tense that is [+Befor], anchored to a primary tense, in this case simple past (hence [+G_Past]). There is no principled upper limit to the number of Tense nodes in a given clause (though particular grammars presumably impose de facto limits), though the following conditions must be met for well-formedness: (1) each clause has one and only one Tense that is not anchored within the clause (though it may be anchored outside the clause); this is the Tense that designates the "reference" time; and (2) each clause has one and only one Tense which is not the Anchr of another Tense in the same clause (though it may be the Anchr of another Tense in another clause); this is the Tense that designates the "event" time. In (14), the first condition is satisfied by *_Tense1*, and the second condition is satisfied by *_Tense2*. In the simple tense examples discussed in Section 3.1, both conditions are satisfied by the same Tense node.

The advantages of treating the perfect construction as a compound tense, instead of as a simple tense, are two-fold: (1) it allows us to distinguish English present perfect and simple past without additional features (thus helping to satisfy the design criterion (5)(a)); and (2) it captures the fact that the perfect construction co-occurs with every simple tense in English, with the same interpretation.

3.3. Survey of tenses across languages

The framework described above is not a theory of tense, in that it does not uniquely determine a representation for each grammatical tense in each language, but provides a language-neutral vocabulary for expressing differences among grammatical tenses across typologically diverse languages. To implement the framework in an NLP system, then, we need to have actual analyses of specific tenses. In this section we provide such analyses for several tenses in several languages.

3.3.1. English

The discussion above gives examples of the past, present and perfect tenses in English and their combinations. Here we give two more examples of English grammtical tenses: the future with *will*[9] and the past with *used to*.

Future: Though an argument might be made that the future with *will* is actually a compound tense, we take the simpler route here and analyze it as a distinct primary tense with the feature [+G_Future], as in the following example:

(15) You will be sick.
FORMULA1
|_SemHeads—sick1
|_L_Tense--_Tense1 (+G_Future)

Past with used to: The past tense formed with *used to*, as in *he used to work here*, like the simple past tense is [+G_Past], but differs from the simple past not only in aspectual properties (not treated here), but also in that it has the anchorable feature [+Befor]. Consider the following example:

(16) He said he used to work here.
FORMULA1
|_SemHeads—say1
|_L_Tense--_Tense1 (+G_Past)
|_L_Obj—FORMULA2
|_SemHeads—work1
|_L_Tense--_Tense2 (**+G_Past +Befor**)
|_ **Anchr: _Tense1**

Since the embedded *_Tense2* is [+Befor], it denotes a time that is not only before U, but also before the (past) time denoted by *_Tense1*. This reflects the fact that in (16), the time that he worked here must be before the time that he said he used to work here (compare to (8), above); that is, it can only mean that he said "I used to work here", and cannot mean that he said "I work here".

3.3.2. Other European languages

Apart from aspectual differences, the tense systems of Western European languages such as French, German and Spanish are very similar to that of English. The aspectual differences are of course important, and must be represented in LNS. Although a complete discussion of aspect goes beyond the scope of the present paper, we include a brief discussion of some diferences between English and Spanish here.

One notable difference between Spanish and English is that Spanish has two distinct grammatical past tenses, the perfective, or preterite, and the imperfective. The

[9] Needless to say, this is not the only way to express future-time reference in English. The simple present can sometimes be used, and there are at least two other constructions that are future only: *be going to* + infinitive, and *be about to* + infinitive. The latter construction has a different meaning from the others (immediate future), and should be distinguished, perhaps with a feature. The difference between *will* and *be going to* is hard to detect, if it exists at all, but in keeping with design criterion (5)(a) they should be distinguished in some way.

difference is entirely aspectual, and does not appear to affect the interpretation of sequence of events per se. Another notable difference between English and these other languages is that most of them use the simple grammatical present tense to refer to an event ongoing at the utterance time, as in the following Spanish example:

(17) Llueve.
rain-Pres
'It's raining.'

The simple present in English, however, cannot be used this way; English *it rains* has only a generic or habitual sense.

For both of these distinctions, a feature indicating the aspectual difference is used; in our system, the relevant features are *Discrete* and *NonDiscrete*; the former indicating that events are viewed in their entirety, the latter that events are subdivided into arbitrarily small subintervals. Thus the Spanish preterite is [+Discrete], while the imperfect is unmarked for either of these features. Also, the simple present in English is [+Discrete], while the simple present in e.g. Spanish is umarked for this feature.

Aside from such aspectual differences, the most notable tense difference between Spanish and English is that the Spanish present progressive, in contrast to the simple present, is incompatible with future time reference:

(18) Vuelvo mañana.
return-1sg tomorrow
'I return/am returning tomorrow'

(19) Estoy volviendo (*mañana).
be-1sg returning tomorrow
'I am returning tomorrow.'

This is handled by assigning the present progressive the features [+G_NonPast +NonBefor +NonAftr] (in addition to aspectual features), which differs from the simple present in being [+NonAftr]. In (19) there is no Anchr, so the [+NonAftr] feature dictates that the time referred to is not after U; i.e, is not in the future; this accounts for this tense's incompatibility with a future time adverbial.

3.3.3. Japanese

The discussion above gives some examples of the simple past and present in Japanese, analyzed in our framework as [+Befor] and [+NonBefor], respectively. Since there is no separate future tense in Japanese, future time reference is normally achieved with the simple present tense, as in the following example:

(20) 明日雨が降る。
ashita ame-ga furu
tomorrow rain-Nom fall-Pres
'Tomorrow, it will rain.'
FORMULA1
|_SemHeads—降る1 (fall)
|_L_Time—明日1 (tomorrow) (+G_Future)
|_L_Tense--_Tense1 (+NonBefor)

The feature [+NonBefor] on *_Tense1* is compatible with future time reference, as discussed in Section 3.1.3, above. The future, as opposed to present, reading of (20) comes from the presence of the adverbial *ashita* 'tomorrow'. In Section 4, we discuss how semantic tense information from adverbials is incorporated into our framework.

3.3.4. Chinese

Unlike the other languages discussed above, Chinese has no grammatical tense. As noted in the introduction vis-a-vis examples (2) and (3), semantic tense, when expressed, is often expressed via adverbials, and not with grammatical tense; this is discussed in more detail in Section 4, below. However, Chinese does have a limited number of particles, traditionally referred to as aspect markers, which, besides indicating aspect, also indicate semantic tense information. The aspectual meaning of these particles is beyond the scope of this paper, but we will discuss a few examples to show how they express semantic tense, and how that information is represented in our framework.

We discuss here the particles *le*, *guo* and *jiang*, as in the following examples:

(21) 他说他买**了**书
ta shuo ta mai **le** shu
he say he buy Aspect book
'He says/said that he has/had bought books.'
FORMULA1
|_SemHeads--说1 (say)
|_L_Tense--_Tense1
|_L_Obj—FORMULA2
|_SemHeads--买1 (buy)
|_L_Tense--**_Tense2 (+Befor)**
|_Anchr: _Tense1

(22) 他说他买 **过**书
ta shuo ta mai **guo** shu
he say he buy Aspect book
'He says/said that he has/had (once) bought books.'
FORMULA1
|_SemHeads--说1 (say)
|_L_Tense--_Tense1
|_L_Obj—FORMULA2
|_SemHeads--买1 (buy)
|_L_Tense--**_Tense2 (+Befor)**
|_Anchr: _Tense1

(23) 他说他**将**到美国去
ta shuo ta **jiang** dao meiguo qu
he say heAspect to US go
'He says/said that he will/would go to the US.'
FORMULA1
|_SemHeads--说1 (say)
|_L_Tense--_Tense1
|_L_Obj—FORMULA2
|_SemHeads--买1 (buy)
|_L_Tense--**_Tense2 (+Aftr)**
|_Anchr: _Tense1

In all these examples, the tense of the main clause (*_Tense1*) has no features; we take this to be the default case in Chinese, in which an unmarked clause can be interpreted as past, present or future (see the discussion of examples (2) and (3) in the Introduction, and Section 4,

below). However, aspectual particles such as *le*, *guo* and *jiang* can also contribute semantic tense information, which we represent as if it were grammatical tense.

The particles *le* and *guo* are both [+Befor] (their difference is aspectual, not represented here); in (21) and (22), the embedded clause Tense is anchored to the matrix, indicating that the buying of books took place before his saying. In contrast, *jiang* in (23) is [+Aftr], so this example means that the going to the US takes place after his saying.

4. Deriving semantic tense from syntactic context

It is often the case that semantic tense information is not represented as grammatical tense per se, but can come, at least in part, from adverbials or other features of the syntactic environment. We have seen that this is one of the main sources of semantic tense information in Chinese; an example from English is *We speak tomorrow*, which is grammatically present tense (hence [+G_NonPast +NonBefor], but semantically is unambiguously about the future. To deal with this situation, we propose to augment the framework outlined in Section 3 with an additional non-tree attribute *Spcfrs*, which indicates, for a given Tense node, any other temporal expressions in the clause that contributes to the semantic tense of that clause. Like Anchr, Spcfrs is not part of the LNS tree per se, but is an annotation on the tree. The representation is given below:

(24) We speak tomorrow.
FORMULA1
|_SemHeads—speak1
|_L_Time—tomorrow1 (+G_Future)
|_L_Tense--_Tense1 (+G_NonPast +NonBefor)
|_ Spcfrs: tomorrow1

_Tense1 has only the features of any present tense, so the representation satisfies the first design criterion (5)(a); but its Spcfrs is the adverb *tomorrow1*, which itself has the feature [+G_Future], since tomorrow is unambiguously in the future. This relation indicates to the language-independent function that derives the explicit sequential representation that the temporal reference of the clause is to a time that is after U, thus satisfying the second design criterion (5)(b).

Note that design criterion (5)(a) is satisfied in another way, as well: the structure of (24) is different from the structure of a sentence with a future tense, which presumably makes use of the feature [+G_Future] (see below); thus the distinction between the "scheduled" future (Comrie, 1985) in (24) and the more basic future of *We will speak tomorrow* is preserved.

The need for the Spcfrs relation is much more prevalent in languages that make little or no use of grammatical tense, such as Chinese. Consider the following examples:

(25) 昨天他来看我
zuotian ta lai kan wo
yesterday he come see me
'Yesterday he came to see me.'
FORMULA1
|_SemHeads--来1 (come)
|_L_Time--昨天1 (yesterday) (+G_Past)
|_L_Tense--_Tense1
|_Spcfrs: 昨天1

(26) 明天他来看我
mingtian ta lai kan wo
tomorrow he come see me
'Tomorrow he will come to see me.'
FORMULA1
|_SemHeads--来1 (come)
|_L_Time--明天1 (tomorrow) (+G_Future)
|_L_Tense--_Tense1
|_Spcfrs: 明天1

The Spcfrs relation thus permits specification of semantic tense features that are not expressed as grammatical tense.

5. Comparison to other frameworks

Our proposal is for a system of representation of semantic tense that is language-neutral; i.e., that represents the tense distinctions of different languages in a formal vocabulary that has the same meaning in all languages. As such, our proposal is very different from proposals to represent the semantics of tense in a particular language such as English, both in the obvious respect that we consider other languages, and in the less obvious respect that our proposal is not a semantic one in any deep sense, but rather a syntactic representation that is language-neutral, as sketched in Section 2 (Campbell & Suzuki, 2002).

As such, the nearest thing to a comparable proposal that we have encountered in the computational literature is Van Eynde (1997), which explicitly provides a Reichenbachian semantic framework for multiple languages, and incorporates information from temporal adverbs in addition to grammatical tense. Unlike our proposal, however, Van Eynde's framework is explicitly Reichenbachian, characterizing tenses in terms of three possible values for sTENSE, expressing the relation between the reference and speech times, and six values for sASPECT, expressing the relation between the event and reference times. Although our framework encodes the same essential insight, it does so without rigidly adhering to the reference time/event time distinction, which leads to a simpler representation in our view.

6. Application

Having a language-neutral representation of semantic tense has clear implications for multi-lingual applications such as MT. Consider again the Japanese example (13), in which an embedded present tense is to be translated into past tense in English. A simple transfer of the language-particular present tense yields the wrong result, since *She said she is sick* (=(12)) means something very different from (13). Instead, what needs to be transferred is the whole temporal structure of *_Tense2*, including its features and its Anchr, since this is the information that

determines that it denotes a time that is before U. Such context-sensitive transfers are possible in an MT system such as that described by Richardson, *et al*. (2001).

Similarly, consider the Chinese example (25), in which there is no grammatical tense specified. A Chinese-English MT system must transfer not the grammatical tense (which yields no information whatsoever), but rather the whole temporal structure, which in this case includes its Spcfrs, in order to give the English generation system the information it needs to generate past tense.

7. Conclusion

We have presented and exemplified a framework for representing semantic tense in a language-neutral fashion, which meets the competing design criteria in (5): that each language-particular tense be reconstructible by a generation function, and that an explicit representation of temporal sequence be derivable by means of a language-independent function.

The framework we have proposed allows us to get semantic tense information from grammatical tense, or from adverbial modifiers, and represents this information in a semantically motivated, language-neutral fashion.

Abstract

In this paper, we propose a representational scheme for temporal and causal information processing which is based on the exploitation of linguistic elements of narrative texts having a temporal and/or causal interest. We show that the framework of generalized intervals provides an adequate representational device for temporal information as it is conveyed from descriptions in natural language. The linguistic elements which are used in order to determine the temporal structure of the text are: temporal adverbials, verbs, derived nouns, temporal and/or causal connectives. Reasoning over the resulting temporal constraint network allows the disambiguation of ambiguous temporal relations and provides answers to questions concerning the temporal order of events in the text, their relative positioning and their causal interpretation.

1. Introduction

The extraction and processing of temporal information from natural language texts requires an effective representational scheme which facilitates the answer to questions such as: «What happened»?, «Why?», «Did event A take place before event B?», etc. In this paper, we propose such a scheme and we focus on its theoretical justification.

We show that the framework of generalized intervals (Ligozat 1991; Ligozat 1997; Bestougeff and Ligozat 1992) which extends Allen's interval framework (Allen 1983; Allen 1984) provides an adequate representational device for temporal information as it is conveyed from descriptions in natural language. The formalism of generalized intervals allows a direct representation of qualitative temporal relations possessing an internal structure. Therefore, it is suitable for the representation of events which are classified according to the tripartite ontology of events (Moens 1987; Moens and Steedman 1988). This representation allows reference to their internal structure and proves to be well adapted to the representation of temporal information

In our approach, the linguistic elements which are used in order to determine the temporal structure of the text are: temporal adverbials, verbs, derived nouns, temporal and/or causal connectives. The above mentioned elements contribute to determining the order of events in the text, their relative position, their degree of completion and their duration.

Reasoning over the temporal constraint network which reflects the temporal structure of the text allows the disambiguation of ambiguous temporal relations and provides answers to questions concerning the temporal order of events in the text, their relative positioning and their causal interpretation.

The structure of the paper is as follows: In section 2 the theoretical assumptions of the approach are presented. Section 3 is concerned with the representational scheme while in section 4 the final conclusions are presented.

2. Theoretical assumptions

Our choice of a representation language is motivated by the complexity and richness of the linguistic information required for the processing of temporal and causal phenomena. Indeed, most of the well known formalisms such as the interval-based framework proposed by Allen (1983; 1984) prove to be inadequate for the representation of complex linguistic information. In the following we briefly present the formalism of generalized intervals as proposed by Ligozat (1991; 1996; 1997) and Bestougeff and Ligozat (1992).

2.1. The generalized interval framework

In this approach, the main temporal object is a a poly-typed string (henceforth PTS) which consists of a generalized interval, i.e. an increasing sequence of typed boundaries (time points) corresponding to an event, and its associated linguistic information. The typing of the boundaries (opening, closing, undefined) allows to reason over the degree of completion of an action and therefore proves to be adequate for the representation of the grammatical aspect. A sequence of n typed boundaries is called an n-string and it defines a partitioning of time into 2n+1 zones numbered from 0 to 2n. Odd numbers correspond to boundaries and even numbers correspond to open intervals defined by these boundaries. Using this numbering we are able to define all the combinatorial possibilities of relations between two n-strings: Consider a p-string X and a q-string Y. The relations between X and Y is determined by specifying for each boundary of X which zone of Y it belongs to. We thus obtain a non-decreasing sequence of p integers between 0 and 2q.

A sequence of polytyped strings reflecting a consistent piece of discourse is called a temporal site. This temporal site is represented by a temporal constraint network, that is, a graph where the edges correspond to typed strings and the arcs to relations between them.

2.2. Events in the generalized interval framework

The processing of temporal and causal information as it is conveyed by natural language requires an ontology which is constituted on the cognitive basis of relations such as causation and enablement (grouped under the more general notion of consequentiality) between events and states rather than on purely temporal primitives. An ontology which satisfies the above requirements and is also able to capture most of the relevant linguistic phenomena is the tripartite ontology of events (Moens 1987; Moens and Steedman 1988). The basic element of this ontology is an «event nucleus» which is composed by a preparatory process, leading to a culmination point followed by a consequent state. In this way, we can explain the fact that the same event (for example, the construction of a bridge) can be used by referring to its preparatory process (drawing the plans), to its culmination point (the bridge was inaugurated) or to its consequent state (traffic problems were solved). Temporal and aspectual categories as conveyed by natural language utterances are classified into states and events. Following (Parsons 1990) we will use the term *eventuality* in order to describe an event or a state. Events are further classified into culminated processes, processes, culminations and points (punctual events which are not associated to a preparatory process or consequent state). Reference to the appropriate part of the nucleus determines the exact nature of the event or state at hand.

3.2.3. Representing temporal knowledge

In the generalized interval framework, different types of processes are associated to typical schemata in terms of sequences of typed boundaries.

In the following we sketch the representation of temporal knowledge in the generalized interval framework (Galiotou 1999; Galiotou and Ligozat 1997).

A culminated process (the nucleus) situated in the past will be represented by a sequence of typed boundaries numbered by odd numbers from 1 to 7.

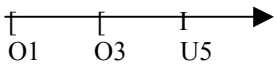
Preparatory process: (1 3), Culmination point: 3, Consequent state: (3 5), Speech time: 7, Aspect: Perfect, Tense: Past

The boundaries take their values among the following: **[** (**O**pening boundary), **]** (**C**losing boundary), **U** (**U**ndefined boundary)

A culmination situated in the past will be represented by a sequence of three boundaries as in the following:

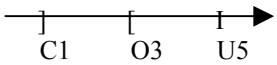
Culmination point: 1, Consequent state: (1 3), Speech time: 5, Aspect: Perfective, Tense:Past

A process situated in the past will represented as:



Process: (1 3), Speech time: 5 , Aspect: Imperfective, Tense: Past

A state will represented as:



State: (1 3), Speech time: 5, Aspect: Imperfective, Tense: Past

A punctual event will be represented as:

Point: 1, Speech time: 3, Aspect: Perfective, Tense: Past

3.2.3. Building the temporal site

Using this schematic representation we try to express the corresponding temporal relations (see also Galiotou 1999, Galiotou and Ligozat 1997). In the following, we give an example of a temporal relation expressed by means of relations between typed boundaries:

Suppose that we consider two 4-intervals X and Y each referring to an event nucleus. X is defined by the sequence of boundaries x_1, x_2, x_3, x_4 and Y is defined by the the sequence of boundaries y_1, y_2, y_3, y_4. The variables x_i and y_i , $i \in \{1,3,5,7\}$ have a type among the following: {O(pening), C(losing), U(ndefined)}. The open intervals defined by the boundaries will be numbered by even numbers. So, the representation of the two 4-intervals will be:

The relation of temporal precedence will be represented by the following:

([0,2], [0,2], [0,6], 7)

The culmination point of X (x_3) is related to the culmination point of Y (y_3) by a relation of temporal precedence while the position of x_5 is not completely determined.

Based on this representation, we build a temporal constraint network reflecting the temporal structure of a text. Actually, the arcs of the network correspond to two types of relations: on the one hand, purely temporal relations, and on the other hand discourse relations reflecting the hierarchical structure of the text and having a temporal or causal significance (Asher 1993): narration, elaboration, explanation, background, and result. We also take into account the discourse relation of contrast which has a rather non-temporal character but proves to be useful in establishing contextual constraints for the processing of causal information.

At this point of the representation we can anticipate different ways of processing (Bestougeff and Ligozat 1992):

- Restrict *a priori* the number of possible relations between two n-intervals in a natural language utterance.
- In case of an incomplete graph, calculate the possible relations between two generalized intervals using the formula of composition of relations between two generalized intervals (Ligozat 1991). An application of this procedure can be found in (Galiotou 1999).
- Verify that the set of temporal relations in the temporal constraint network is consistent.
- Verify that updating the network does not introduce any inconsistency.

Every time a new set of constraints between two generalized intervals is introduced in the temporal constraint network, the set of relations is updated. For the propagation of constraints in the graph we use a variant of Allen's constraint propagation algorithm (Allen 1983; Allen 1984) suitably adapted for the generalized interval framework (Ligozat 1991; Galiotou 1999).

3. A proposal for a representational scheme

Before proceeding with the definition of the scheme, we have to specify the linguistic elements of the text which contribute to determining the temporal relations.

3.1. Linguistic elements in the text

In our experimentation we have used a corpus of short newspaper articles in Modern Greek describing car accidents. The study of temporal and causal phenomena in such a corpus had two goals:

- extract the events which have led to an accident as well as its consequences;
- provide all plausible explanations of the causes of the accident.

In general, the causes of the accident are explicitly mentioned in the text using causal connectives and/or causal expressions. This explicit causal information contributes to the determination of the temporal order and the relative positioning of events in conjunction with the «Causes precede Effects» rule.

Our corpus consists of narrative texts composed of simple clauses containing temporal adverbials, subordinates introduced by temporal and/or causal connectives, verb phrases, derived nouns and adjectives. In this type of narration, events are situated in the past so, verbal forms of the future do not appear in the text. The most frequent verbal forms are those of the preterite, while the present tense is used in order to describe consequent states. As far as grammatical aspect is concerned, all possible values for Greek are present, i.e. imperfective, perfective and perfect (Mackridge 1985). The lexical aspect follows the tripartite ontology of events as already stated in section 2.

Temporal adverbials are classified (Tzevelekou 1995) into:

- those which require a different starting point from the starting point of the narration: kat' ar`xin[1] (at first), sti si`nexia (afterwards) etc.
- those which establish their reference either from the starting point of the narration or form another starting point: ta ksime`romata tis kiriakis (on Sunday morning), `liγo prin ta me`sanixta tis paraske`vis (short before Friday midnight) etc.
- deictic adverbs which establish their reference uniquely from the starting point of the narration: xθes (yesterday), pro`xθes (the day before yesterday), etc.

Temporal clauses are introduced by temporal connectives which on the one hand provide information on the temporal order of events and on the other hand help determine implicit causal relations (i.e. causal relations which are not expressed by causal markers in the text). Consider the case of the temporal connective `otan (when). Its use in the corpus is in accordance with the observation that its basic meaning is not temporal in the first place (Moens and Steedman 1988). Indeed, `otan (when) establishes a consequentiality relation between the main clause event and the subordinate clause event provided that the eventualities in the text follow the organizational scheme of the tripartite ontology of events. Therefore, it is a candidate for expressing causality in the text. Take for example, the case of the construction

Q(Past-perfective) `otan P(Pat-Perfective)

In this case the processes Q and P are related with a consequentiality relation as in the following example:

tris `nei `exasan ti zo`i tus otan to afto`kinito tus ana`trapike
Three young men lost their lives when their car overturned.

Explicit causal information in the text is expressed by causal connectives such as *epi`δi (because)* of causal expressions such as *me apo`telesma (with result*) or *`loγo (because of).*

It is also expressed by noun phrases which are introduced in simple sentences such as:

e`pisimi e`tia tu δisti`ximatos ine i olisθi`rotita tu `δromu
The official cause of the accident is the slipperiness of the road.

or, verbal phrases with a causal sense such as:

to δi`stixima o`filete stin ipervoli`ki ta`xitita tu aftoki`nitu
The accident is due to the excessive speed of the car.

The combination of a causal expression with a derived noun phrases such as *i olisθi`rotita tu `δromu (the slipperiness of the road), i api`ria tu oδi`γu (the inexperience of the driver), I aprose`ksia ton pe`zon (the inattention of the pedestrians)* etc is used in order to

[1] Greek words are transcribed according to the characters of the International Phonetic Alphabet. When necessary, stress is indicated with symbol « ` » before any stressed syllable.

establish discourse relations and to build the temporal structure of the text. For example:

to δi`stixima o`filete stin apì`ria tu oδi`γu a`la ke stin aprose`ksia ton pe`zon

The accident is due to the inexperience of the driver but also, to the inattention of the pedestrians.

Here, a relation of explanation holds between the propositions and therefore, a relation of consequentiality between the corresponding eventualities. The derived nominal represents a state. So, the consequentiality relation is specified as an enablement relation between the state represented by the derived nominal and the main clause event which in this case is the accident. Thus we obtain an overlap relation between the related temporal intervals.

3.2. The representational scheme

The theoretical assumptions described in section 2 lead to the definition of a representational scheme taking into account the linguistic elements of the text which are described in the previous subsection. As already stated, our treatment of temporal information in the text is based solely on the exploitation of linguistic knowledge.

Therefore, we propose a single-dimensional scheme consisting of a list of labels relative to the temporal and/or causal knowledge as it is expressed by the linguistic elements of the text.

Note that, since the starting point of our research was the study of temporal and causal phenomena in Modern Greek, we had to take into account the particularities of the temporal and aspectual system of the language in elaborating a suitable tag set. Yet, in our opinion, this does not constitute a major problem since the set of values is easily extendable in order to capture particularities of other languages provided that the general guidelines are kept.

The text segments to be annotated are taken at the clause level.

3.2.3. The tag set

The proposed tag set takes into account the following classes:

BOUNDARY_LIST : The generalized interval expressed in terms of a list of typed boundaries for example,

<U1, 03, U5>

TENSE: Values are limited to

<past>, <non_past>

since in Modern Greek future is considered as modal.

ASPECT: <imperfective>, <perfective>, <perfect>

LEXASP: The values follow the tripartite ontology of event and they are limited to:

<state>, <culm_process>, <process>, <culmination>, <point>.

The number of categories could easily be modified provided that the principles of the ontology are respected.

CONNECTIVE: We take into account causal and/ or temporal connectives therefore, the proposed tags are:

<cn_causal>, <cn_temp>, <cn_ct>

TEMPADV: Temporal adverbials play a crucial role in our processing of temporal and causal information but there was no need for a more fine-grained characterization. So, the only possible tag is:

<tempadv>

In the current state of the scheme we have decided to encode dates under the <tempadv> tag.

CUE_PHRASE: Cue_phrases contribute to the determination of temporal and explicitly causal information, so they enter our scheme with the tag:

<cue_phrase>

3.2.3. The decision rules

Following (Klein, 1999) we provide a decision tree aiming at giving an overview of all possible tags and how they are related to each other. We also provide rules that help to mutually constraint the tags between categories and ensure the coherence of the annotation:

In figure 1, we give an example of the decision rules :

if the segment is tagged with <culmination> and <past >
then label with <U1 O3 U5>
….
if the segment is tagged with <past> and <perfect>
then label with <culm_process>
…
if the segment is tagged with <past> and <imperfective>
then label with <state>
…

Figure 1. Example of decision rules

3.2.3. Examples and evaluation

In table 1 we give an example of the application of the scheme to a fragment of a text describing a car accidents (in Modern Greek).

A quick overview this application has shown that as far as the temporal entities are concerned there was an approximately even distribution of culminated processes and culminations. and to a lesser extent states and processes. The fifth category of temporal entities, namely that of punctual events, did not appear in any text.

As for the verbal forms, there was no occurrence of the future tense. The most frequent forms were those of the preterite, while the present tense was used in order to describe the consequent states of events and conclusions.

The distribution of temporal and causal connectives indicated that the most frequent appearance is that of the *`otan (when)* connective used both as a temporal and as a causal one.

We must also report an extensive use of cue_phrases for the expression of causal knowledge in the text. Contrary to what one may have expected in a corpus of short newspaper articles describing car accidents, causal connectives were not the most frequent elements used in order to express causality. Explicit causal information was mostly put forward using cue phrases in simple sentences.

The scheme proved to be quite easy to apply by the human annotator. Yet, the tagging procedure, as far the boundary list was concerned proved to be more difficult to implement. This has led us to the conclusion that the annotation procedure should be automated at least as far as the boundary_list category is concerned.

ORIGINAL TEXT	ANNOTATED TEXT
tris `nei `exasan ti zo`i tus otan to afto`kinito tus ana`trapike (Three young men lost their lives when their car overturned).	<U1 O3 U5> <culm> tris `nei <past><imperfective>`exasan </past></imperfective> ti zo`i tus </culm> </U1 O3 U5> <O1 U3 O5 U7> <culm_process> <cn_temp>otan </cn_temp> to afto`kinito tus <past><perfective>ana`trapike</past></perfective> </culm_process></O1 U3 O5 U7>

Table 1: Application of the scheme to a fragment of a text

4. Conclusions

In this paper, we proposed a representational scheme which provides the background for the processing of temporal and causal information.

We have insisted on the theoretical assumptions of the scheme concerning:

- the temporal positioning of events;
- the appropriate temporal ontology;
- the interaction of temporal and causal information in texts;
- the causal interpretation of events.

We also discussed the nature of the linguistic elements of a text which can be used to determine the temporal structure of the text.

We then briefly described a representational scheme based on the theoretical assumptions mentioned above.

This representational scheme was applied to a corpus of short newspaper articles describing car accidents in Modern Greek. These articles were selected with respect to their informational interest and the temporal and causal relations they contained. Therefore, the particularities of the temporal and aspectual system of the Greek language were taken into account in the proposed tag set. Nevertheless, this tag set could easily be modified to take into account the particularities of other languages provided that the general approach is followed.

The scheme has proved to be quite reliable in its application to the particular corpus. Yet, the task of the human annotator would be greatly facilitated if at least certain procedures such as the tagging with the boundaries_list notation were automated.

Toward an Ontology of Time for the Semantic Web

Jerry R. Hobbs

Artificial Intelligence Center
SRI International
Menlo Park, California 94025
USA
hobbs@ai.sri.com

Abstract

In connection with the DAML project for bringing about the Semantic Web, an ontology of time is being developed for describing the temporal content of Web pages and the temporal properties of Web services. The bulk of information on the Web is in natural language, and this information will be easier to encode for the Semantic Web insofar as community-wide annotation and automatic tagging schemes and the DAML time ontology are compatible with each other.

1. Introduction

The DARPA Agent Markup Language (DAML) project is an effort aimed at bringing into reality the Semantic Web, in which Web users and automatic agents will be able to access information on the Web via descriptions of the content and capabilities of Web resources rather than via key words. An important part of this effort is the development of representative ontologies of the most commonly used domains. We are beginning to develop such an ontology of temporal concepts, for describing the temporal content of Web pages and the temporal properties of Web services. This effort is being informed by temporal ontologies developed at a number of sites and is intended to capture the essential features of all of them and make them easily available to a large group of Web developers and users.

The bulk of information on the Web is in natural language, and this information will be easier to encode for the Semantic Web insofar as community-wide annotation and automatic tagging schemes and the DAML time ontology are compatible with each other.

In this paper I outline the temporal ontology as it has been developed so far, in order to initiate a dialog between the two communities. Five categories of temporal concepts are considered, and for each the principal predicates and their associated properties are described.

A note on notation: Conjunction ($\wedge$) takes precedence over implication($\supset$) and equivalence ($\equiv$). Formulas are assumed to be universally quantified on the variables appearing in the antecedent of the highest-level implication. Thus,

$$p_1(x) \wedge p_2(y) \supset q_1(x,y) \wedge q_2(y)$$

is to be interpreted as

$$(\forall x,y)[[p_1(x) \wedge p_2(y)] \supset [q_1(x,y) \wedge q_2(y)]]$$

2. Topological Temporal Relations

2.1. Instants and Intervals

There are two subclasses of temporal-entity: $instant$ and $interval$.

$$instant(t) \supset temporal\text{-}entity(t)$$
$$interval(T) \supset temporal\text{-}entity(T)$$

(In what follows, lower case t is used for instants, upper case T for intervals and for temporal-entities unspecified as to subtype. This is strictly for the reader's convenience, and has no formal significance.)

$start\text{-}of$ and $end\text{-}of$ are functions from temporal entities to instants.

$$temporal\text{-}entity(T) \supset instant(start\text{-}of(T))$$
$$temporal\text{-}entity(T) \supset instant(end\text{-}of(T))$$

For convenience, we can say that the start and end of an instant is itself.

$$instant(t) \supset start\text{-}of(t) = t$$
$$instant(t) \supset end\text{-}of(t) = t$$

$inside$ is a relation between an instant and an interval.

$$inside(t,T) \supset instant(t) \wedge interval(T)$$

This concept of $inside$ is not intended to include starts and ends of intervals, as will be seen below.

Infinite and half-infinite intervals can be handled by positing time instants at positive and negative infinity, and using them as start and end points.

It will be useful in characterizing clock and calendar terms to have a relation between instants and intervals that says that the instant is inside or the start of the interval.

$$in\text{-}interval(t,T) \equiv [start\text{-}of(T) = t \vee inside(t,T)]$$

$interval\text{-}between$ is a relation among a temporal entity and two instants.

$$interval\text{-}between(T,t_1,t_2) \supset temporal\text{-}entity(T) \wedge instant(t_1) \wedge instant(t_2)$$

The two instants are the start and end points of the temporal entity.

$$interval\text{-}between(T,t_1,t_2) \equiv start\text{-}of(T) = t_1 \wedge end\text{-}of(T) = t_2$$

The ontology is silent about whether the interval from t to t, if it exists, is identical to the instant t.

The ontology is silent about whether intervals *consist of* instants.

The ontology is silent about whether intervals are uniquely determined by their starts and ends.

We can define a proper interval as one whose start and end are not identical.

$$\begin{array}{l}\mathit{proper\text{-}interval}(t) \equiv \\ \quad \mathit{interval}(t) \wedge \mathit{start\text{-}of}(t) \neq \mathit{end\text{-}of}(t)\end{array}$$

The ontology is silent about whether there are any intervals that are not proper-intervals.

2.2. Before

There is a $before$ relation on temporal entities, which gives directionality to time. If temporal entity T_1 is before temporal entity T_2, then the end of T_1 is before the start of T_2. Thus, before can be considered to be basic to instants and derived for intervals.

$$\begin{array}{l}before(T_1, T_2) \\ \quad \equiv before(\mathit{end\text{-}of}(T_1), \mathit{start\text{-}of}(T_2))\end{array}$$

The end of an interval is not before the start of the interval.

$$\begin{array}{l}\mathit{interval}(T) \\ \quad \supset \ before(\mathit{end\text{-}of}(T), \mathit{start\text{-}of}(T))\end{array}$$

The start of a proper interval is before the end of the interval.

$$\begin{array}{l}\mathit{proper\text{-}interval}(T) \\ \quad \supset before(\mathit{start\text{-}of}(T), \mathit{end\text{-}of}(T))\end{array}$$

If one instant is before another, there is an interval between them.

$$\begin{array}{l}\mathit{instant}(t_1) \wedge \mathit{instant}(t_2) \wedge before(t_1, t_2) \\ \quad \supset (\exists T)\mathit{interval\text{-}between}(T, t_1, t_2)\end{array}$$

The ontology is silent about whether there is an interval from t to t.

If an instant is inside a proper interval, then the start of the interval is before the instant, which is before the end of the interval. The converse is true as well.

$$\begin{array}{l}\mathit{instant}(t) \wedge \mathit{proper\text{-}interval}(T) \\ \quad \supset [\mathit{inside}(t, T) \\ \quad\quad \equiv before(\mathit{start\text{-}of}(T), t) \\ \quad\quad\quad \wedge before(t, \mathit{end\text{-}of}(T))]\end{array}$$

Intervals are contiguous with respect to the $before$ relation, in that an instant between two other instants inside an interval is inside the interval.

$$\begin{array}{l}before(t_1, t_2) \wedge before(t_2, t_3) \\ \quad\quad \wedge \mathit{inside}(t_1, T) \wedge \mathit{inside}(t_3, T) \\ \quad \supset \mathit{inside}(t_2, T)\end{array}$$

The $before$ relation is anti-symmetric and transitive.

$$\begin{array}{l}before(T_1, T_2) \supset \neg before(T_2, T_1) \\ before(T_1, T_2) \wedge before(T_2, T_3) \\ \quad \supset before(T_1, T_3)\end{array}$$

The relation $after$ is defined in terms of $before$.

$$after(T_1, T_2) \equiv before(T_2, T_1)$$

The ontology is silent about whether time is linearly ordered.

2.3. Interval Relations

The relations between intervals defined in Allen's temporal interval calculus (Allen and Kautz, 1985) can be defined in a straightforward fashion in terms of $before$ and identity on the start and end points.

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}equals}(T_1, T_2) \\ \quad\quad \equiv \mathit{start\text{-}of}(T_1) = \mathit{start\text{-}of}(T_2) \\ \quad\quad\quad \wedge \mathit{end\text{-}of}(T_1) = \mathit{end\text{-}of}(T_2)]\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}before}(T_1, T_2) \equiv before(T_1, T_2)\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}after}(T_1, T_2) \equiv after(T_1, T_2)\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}meets}(T_1, T_2) \\ \quad\quad \equiv \mathit{end\text{-}of}(T_1) = \mathit{start\text{-}of}(T_2)\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}met\text{-}by}(T_1, T_2) \\ \quad\quad \equiv \mathit{int\text{-}meets}(T_2, T_1)]\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}overlaps}(T_1, T_2) \\ \quad\quad \equiv before(\mathit{start\text{-}of}(T_1), \mathit{start\text{-}of}(T_2)) \\ \quad\quad\quad \wedge before(\mathit{start\text{-}of}(T_2), \mathit{end\text{-}of}(T_1)) \\ \quad\quad\quad \wedge before(\mathit{end\text{-}of}(T_1), \mathit{end\text{-}of}(T_2))]\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}overlapped\text{-}by}(T_1, T_2) \\ \quad\quad \equiv \mathit{int\text{-}overlaps}(T_2, T_1)]\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}starts}(T_1, T_2) \\ \quad\quad \equiv \mathit{start\text{-}of}(T_1) = \mathit{start\text{-}of}(T_2) \\ \quad\quad\quad \wedge before(\mathit{end\text{-}of}(T_1), \mathit{end\text{-}of}(T_2)]\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}started\text{-}by}(T_1, T_2) \\ \quad\quad \equiv \mathit{int\text{-}starts}(T_2, T_1)]\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}during}(T_1, T_2) \\ \quad\quad \equiv (before(\mathit{start\text{-}of}(T_2), \mathit{start\text{-}of}(T_1)) \\ \quad\quad\quad \wedge before(\mathit{end\text{-}of}(T_1), \mathit{end\text{-}of}(T_2))]\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}contains}(T_1, T_2) \\ \quad\quad \equiv \mathit{int\text{-}during}(T_2, T_1)]\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}finishes}(T_1, T_2) \\ \quad\quad \equiv before(\mathit{start\text{-}of}(T_2), \mathit{start\text{-}of}(T_1)) \\ \quad\quad\quad \wedge \mathit{end\text{-}of}(T_1) = \mathit{end\text{-}of}(T_2)]\end{array}$$

$$\begin{array}{l}\mathit{interval}(T_1) \wedge \mathit{interval}(T_2) \\ \quad \supset [\mathit{int\text{-}finished\text{-}by}(T_1, T_2) \\ \quad\quad \equiv \mathit{int\text{-}finishes}(T_2, T_1)]\end{array}$$

In addition, it will be useful below to have a single predicate for "starts or is during". This is called $\mathit{int\text{-}in}$.

$$\begin{array}{l}\mathit{int\text{-}in}(T_1, T_2) \\ \quad \equiv [\mathit{int\text{-}starts}(T_1, T_2) \vee \mathit{int\text{-}during}(T_1, T_2)]\end{array}$$

It will also be useful to have a single predicate for intervals intersecting in at most an instant.

$$\begin{aligned}&\textit{int-disjoint}(T_1, T_2)\\ &\quad \equiv [\textit{int-before}(T_1, T_2) \vee \textit{int-after}(T_1, T_2)\\ &\qquad \vee \textit{int-meets}(T_1, T_2)\\ &\qquad \vee \textit{int-met-by}(T_1, T_2)]\end{aligned}$$

So far, the concepts and axioms in the ontology of time would be appropriate for scalar phenomena in general.

2.4. Linking Time and Events

The time ontology links to other things in the world through four predicates—*at-time*, *during*, *holds*, and *time-span-of*. We assume that another ontology provides for the description of events—either a general ontology of event structure abstractly conceived, or specific, domain-dependent ontologies for specific domains.

The term "eventuality" will be used to cover events, states, processes, propositions, states of affairs, and anything else that can be located with respect to time. The possible natures of eventualities would be spelled out in the event ontologies.

The predicate *at-time* relates an eventuality to an instant, and is intended to say that the eventuality holds, obtains, or is taking place at that time.

$$\textit{at-time}(e, t) \supset \textit{eventuality}(e) \wedge \textit{instant}(t)$$

The predicate *during* relates an eventuality to an interval, and is intended to say that the eventuality holds, obtains, or is taking place during that interval.

$$\textit{during}(e, T) \supset \textit{eventuality}(e) \wedge \textit{interval}(T)$$

If an eventuality obtains during an interval, it obtains at every instant inside the interval.

$$\textit{during}(e, T) \wedge \textit{inside}(t, T) \supset \textit{at-time}(e, t)$$

Whether a particular process is viewed as instantaneous or as occuring over an interval is a granularity decision that may vary according to the context of use, and is assumed to be provided by the event ontology.

Often the eventualities in the event ontology are best thought of as propositions, and the relation between these and times is most naturally called *holds*. *holds* can be defined in terms of *at-time* and *during*:

$$\begin{aligned}&\textit{holds}(e, t) \wedge \textit{instant}(t) \equiv \textit{at-time}(e, t)\\ &\textit{holds}(e, T) \wedge \textit{interval}(T) \equiv \textit{during}(e, T)\end{aligned}$$

The event ontology may provide other ways of linking events with times, for example, by including a time parameter in predications.

$$p(x, t)$$

This time ontology provides ways of reasoning about the t's; their use as arguments of predicates from another domain would be a feature of the ontology of the other domain.

The predicate *time-span-of* relates eventualities to instants or intervals. For contiguous states and processes, it tells the entire instant or interval for which the state or process obtains or takes place.

$$\begin{aligned}&\textit{time-span-of}(T, e)\\ &\quad \supset \textit{temporal-entity}(T) \wedge \textit{eventuality}(e)\\ &\textit{time-span-of}(T, e) \wedge \textit{interval}(T)\\ &\quad \supset \textit{during}(e, T)\\ &\textit{time-span-of}(t, e) \wedge \textit{instant}(t)\\ &\quad \supset \textit{at-time}(e, t)\end{aligned}$$

$$\begin{aligned}&\textit{time-span-of}(T, e) \wedge \textit{interval}(T)\\ &\qquad \wedge \neg \textit{inside}(t_1, T) \wedge \neg \textit{start-of}(t_1, T)\\ &\qquad \wedge \neg \textit{end-of}(t_1, T)\\ &\quad \supset \neg \textit{at-time}(e, t_1)\\ &\textit{time-span-of}(t, e) \wedge \textit{instant}(t) \wedge t_1 \neq t\\ &\quad \supset \neg \textit{at-time}(e, t_1)\end{aligned}$$

time-span-of is a predicate rather than a function because until the time ontology is extended to aggregates of temporal entities, the function would not be defined for non-contiguous eventualities. Whether the eventuality obtains at the start and end points of its time span is a matter for the event ontology to specify. The silence here on this issue is the reason *time-span-of* is not defined in terms of necessary and sufficient conditions.

The event ontology could extend temporal functions and predicates to apply to events in the obvious way, e.g.,

$$\begin{aligned}&\textit{ev-start-of}(e) = t\\ &\quad \equiv \textit{time-span-of}(T, e) \wedge \textit{start-of}(T) = t\end{aligned}$$

This would not be part of the time ontology, but would be consistent with it.

Different communities have different ways of representing the times and durations of states and events (processes). In one approach, states and events can both have durations, and at least events can be instantaneous. In another approach, events can only be instantaneous and only states can have durations. In the latter approach, events that one might consider as having duration (e.g., heating water) are modeled as a state of the system that is initiated and terminated by instantaneous events. That is, there is the instantaneous event of the start of the heating at the start of an interval, that transitions the system into a state in which the water is heating. The state continues until another instantaneous event occurs—the stopping of the heating at the end of the interval. These two perspectives on events are straightforwardly interdefinable in terms of the ontology we have provided. This is a matter for the event ontology to specify. This time ontology is neutral with respect to the choice.

3. Measuring Durations

3.1. Temporal Units

This development assumes ordinary arithmetic is available.

There are at least two approaches that can be taken toward measuring intervals. The first is to consider units of time as functions from Intervals to Reals, e.g.,

$$\begin{aligned}&\textit{minutes}\text{: Intervals} \rightarrow \text{Reals}\\ &\textit{minutes}([5:14, 5:17]) = 3\end{aligned}$$

The other approach is to consider temporal units to constitute a set of entities—call it TemporalUnits—and have a

single function *duration* mapping Intervals × TemporalUnits into the Reals.

$$duration([5:14, 5:17], *Minute*) = 3$$

The two approaches are interdefinable:

$$seconds(T) = duration(T, *Second*)$$
$$minutes(T) = duration(T, *Minute*)$$
$$hours(T) = duration(T, *Hour*)$$
$$days(T) = duration(T, *Day*)$$
$$weeks(T) = duration(T, *Week*)$$
$$months(T) = duration(T, *Month*)$$
$$years(T) = duration(T, *Year*)$$

Ordinarily, the first is more convenient for stating specific facts about particular units. The second is more convenient for stating general facts about all units.

The aritmetic relations among the various units are as follows:

$$seconds(T) = 60 * minutes(T)$$
$$minutes(T) = 60 * hours(T)$$
$$hours(T) = 24 * days(T)$$
$$days(T) = 7 * weeks(T)$$
$$months(T) = 12 * years(T)$$

The relation between days and months (and, to a lesser extent, years) will be specified as part of the ontology of clock and calendar below. On their own, however, month and year are legitimate temporal units.

In this development durations are treated as functions on intervals and units, and not as first class entities on their own, as in some approaches. In the latter approach, durations are essentially equivalence classes of intervals of the same length, and the length of the duration is the length of the members of the class. The relation between an approach of this sort (indicated by prefix *D-*) and the one presented here is straightforward.

$$(\forall T, u, n)[duration(T, u) = n$$
$$\equiv (\exists d)[D\text{-}duration\text{-}of(T) = d$$
$$\wedge D\text{-}duration(d, u) = n]]$$

At the present level of development of the temporal ontology, this extra layer of representation seems superfluous. It may be more compelling, however, when the ontology is extended to deal with the combined durations of noncontiguous aggregates of intervals.

3.2. $Hath$

The multiplicative relations above don't tell the whole story of the relations among temporal units. Temporal units are *composed of* smaller temporal units. The basic predicate used here for expressing the composition of larger intervals out of smaller clock and calendar intervals is $Hath$, from statements like "30 days hath September" and "60 minutes hath an hour." Its structure is

$$Hath(S, N, u, x)$$

meaning "A set S of N calendar intervals of type u hath the calendar interval x." That is, if $Hath(S, N, u, x)$ holds, then x is composed of the disjoint union of N intervals of type u; S is the set of those intervals. For example, if x is some month of September and S is the set of the successive days of that September, then $Hath(S, 30, *Day*, x)$ would be true.

The principal properties of $Hath$ are as follows:

The type constraints on its arguments: S is a set, N is an integer, u is a temporal unit, and x is an interval:

$$Hath(S, N, u, x)$$
$$\supset set(S) \wedge integer(N)$$
$$\wedge temporal\text{-}unit(u) \wedge interval(x)$$

The elements of S are intervals of duration u:

$$Hath(S, N, u, x)$$
$$\supset (\forall y)[member(y, S)$$
$$\supset interval(y) \wedge duration(y, u) = 1]$$

S has N elements:

$$Hath(S, N, u, x) \supset card(S) = N$$

The elements of S are disjoint:

$$Hath(S, N, u, x)$$
$$\supset (\forall y_1, y_2)[member(y_1, S)$$
$$\wedge member(y_2, S) \wedge y_1 \neq y_2$$
$$\supset int\text{-}disjoint(y_1, y_2)]$$

There are elements in S that start and finish x:

$$Hath(S, N, u, x)$$
$$\supset (\exists y_1)[member(y_1, S)$$
$$\wedge int\text{-}starts(y_1, x)]$$

$$Hath(S, N, u, x)$$
$$\supset (\exists y_2)[member(y_2, S)$$
$$\wedge int\text{-}finishes(y_2, x)]$$

Except for the first and last elements of S, every element of S has an element that precedes and follows it:

$$Hath(S, N, u, x)$$
$$\supset (\forall y_1)[member(y_1, S)$$
$$\supset [int\text{-}finishes(y_1, x)$$
$$\vee (\exists y_2)[member(y_2, x)$$
$$\wedge int\text{-}meets(y_1, y_2)]]]$$

$$Hath(S, N, u, x)$$
$$\supset (\forall y_2)[member(y_2, S)$$
$$\supset [int\text{-}starts(y_2, x)$$
$$\vee (\exists y_1)[member(y_1, x)$$
$$\wedge int\text{-}meets(y_1, y_2)]]]$$

If time is linearly ordered, the existential quantifier $\exists$ in the last four axioms can be replaced by $\exists !$.

Finally, we would like to say that the set S covers x. A simple way to say this is as follows:

$$Hath(S, N, u, x)$$
$$\supset (\forall t)[inside(t, x)$$
$$\supset (\exists y)[member(y, S)$$
$$\wedge in\text{-}interval(t, y)]]$$

That is, if an instant t is inside x, there is a smaller unit y that t is inside or the start of.

However, this is a good place to introduce notions of granularity. In describing the temporal properties of some class of events, it may make sense to specify their time with respect to some temporal unit but not with respect to a smaller temporal unit. For example, one might want to talk about an election as a point-like event being at some instant, and specifying the day that instant is in, but not specifying the hour or minute.

To accomodate this, the above axiom can be loosened by applying it only when the instant t is located in *some interval* of size u. The axiom above would be modified as follows:

$$\begin{array}{l} Hath(S, N, u, x) \\ \quad \supset (\forall t, y_1)[inside(t, x) \wedge inside(t, y_1) \\ \qquad \wedge duration(y_1, u) \\ \qquad \supset (\exists y)[member(y, S) \\ \qquad \wedge in\text{-}interval(t, y)]] \end{array}$$

Essentially, the conjuncts $inside(t, y_1) \wedge duration(y_1, u)$ specify that t can be viewed at a granularity of u.

This treatment of $Hath$ could be extended to measurable quantities in general.

3.3. The Structure of Temporal Units

We now define predicates true of intervals that are one temporal unit long. For example, $week$ is a predicate true of intervals whose duration is one week.

$$\begin{array}{l} second(T) \equiv seconds(T) = 1 \\ minute(T) \equiv minutes(T) = 1 \\ hour(T) \equiv hours(T) = 1 \\ day(T) \equiv days(T) = 1 \\ week(T) \equiv weeks(T) = 1 \\ month(T) \equiv months(T) = 1 \\ year(T) \equiv years(T) = 1 \end{array}$$

We are now in a position to state the relations between successive temporal units.

$$\begin{array}{l} minute(T) \supset (\exists S) Hath(S, 60, *Second*, T) \\ hour(T) \supset (\exists S) Hath(S, 60, *Minute*, T) \\ day(T) \supset (\exists S) Hath(S, 24, *Hour*, T) \\ week(T) \supset (\exists S) Hath(S, 7, *Day*, T) \\ year(T) \supset (\exists S) Hath(S, 12, *Month*, T) \end{array}$$

The relations between months and days are dealt with in Section 4.4.

4. Clock and Calendar

4.1. Time Zones

What hour of the day an instant is in is relative to the time zone. This is also true of minutes, since there are regions in the world, e.g., central Australia, where the hours are not aligned with GMT hours, but are, e.g., offset half an hour. Probably seconds are not relative to the time zone.

Days, weeks, months and years are also relative to the time zone, since, e.g., 2002 began in the Eastern Standard time zone three hours before it began in the Pacific Standard time zone. Thus, predications about all clock and calendar intervals except seconds are relative to a time zone.

This can be carried to what seems like a ridiculous extreme, but turns out to yield a very concise treatment. The Common Era (C.E. or A.D.) is also relative to a time zone, since 2002 years ago, it began three hours earlier in what is now the Eastern Standard time zone than in what is now the Pacific Standard time zone. What we think of as the Common Era is in fact 24 (or more) slightly displaced half-infinite intervals. (We leave B.C.E. to specialized ontologies.)

The principal functions and predicates will specify a clock or calendar unit interval to be the nth such unit in a larger interval. The time zone need not be specified in this predication if it is already built into the nature of the larger interval. That means that the time zone only needs to be specified in the largest interval, that is, the Common Era; that time zone will be inherited by all smaller intervals. Thus, the Common Era can be considered as a function from time zones to intervals.

$$CE(z) = T$$

Fortunately, this counterintuitive conceptualization will usually be invisible and, for example, will not be evident in the most useful expressions for time, in Section 4.5 below. In fact, the CE predication functions as a good place to hide considerations of time zone when they are not relevant.

Time zones should not be thought of as geographical regions. Most places change their time zone twice a year, and a state or county might decide to change its time zone, e.g., from Central Standard to Eastern Standard. Rather it is better to have a separate ontology articulate the relation between geographical regions X times and time zones. For example, it would state that on a certain day and time a particular region changes its time zone from Eastern Standard to Eastern Daylight.

Moreover, time zones that seem equivalent, like Eastern Standard and Central Daylight, should be thought of as separate entities. Whereas they function the same in the time ontology, they do not function the same in the ontology that articulates time and geography. For example, parts of Indiana are always on Eastern Standard Time, and it would be false to say that they shift in April from that to Central Daylight time.

In this treatment it will be assumed there is a set of entities called time zones. Some relations among time zones are discussed in Section 4.5.

4.2. Clock and Calendar Units

The aim of this section is to explicate the various standard clock and calendar intervals. A day as a calender interval begins at and includes midnight and goes until but does not include the next midnight. By contrast, a day as a duration is any interval that is 24 hours in length. The day as a duration was dealt with in Section 3. This section deals with the day as a calendar interval.

It is useful to have three ways of saying the same thing: the clock or calendar interval y is the nth clock or calendar

interval of type u in a larger interval x in time zone z. This can be expressed as follows for minutes:

$$min(y, n, x)$$

Because y is uniquely determined by n and x, it can also be expressed as follows:

$$minFn(n, x) = y$$

For stating general properties about clock intervals, it is useful also to have the following way to express the same thing:

$$clock\text{-}int(y, n, u, x)$$

This expression says that y is the nth clock interval of type u in x. For example, the proposition $clock\text{-}int(10:03, 3, *Minute*, [10:00, 11:00])$ holds.

Here u is a member of the set of clock units, that is, one of *Second*, *Minute*, or *Hour*.

In addition, there is a calendar unit function with similar structure:

$$cal\text{-}int(y, n, u, x)$$

This says that y is the nth calendar interval of type u in x. For example, the proposition $cal\text{-}int(12Mar2002, 12, *Day*, Mar2002)$ holds. Here u is one of the calendar units *Day*, *Week*, *Month*, and *Year*.

The unit *DayOfWeek* will be introduced below in Section 4.3.

The relations among these modes of expression are as follows:

$$\begin{aligned}
&sec(y, n, x) \equiv secFn(n, x) = y \\
&\quad \equiv clock\text{-}int(y, n, *sec*, x) \\
&min(y, n, x) \equiv minFn(n, x) = y \\
&\quad \equiv clock\text{-}int(y, n, *min*, x) \\
&hr(y, n, x) \equiv hrFn(n, x) = y \\
&\quad \equiv clock\text{-}int(y, n, *hr*, x) \\
&da(y, n, x) \equiv daFn(n, x) = y \\
&\quad \equiv cal\text{-}int(y, n, *da*, x) \\
&mon(y, n, x) \equiv monFn(n, x) = y \\
&\quad \equiv cal\text{-}int(y, n, *mon*, x) \\
&yr(y, n, x) \equiv yrFn(n, x) = y \\
&\quad \equiv cal\text{-}int(y, n, *yr*, x)
\end{aligned}$$

Weeks and months are dealt with separately below.

The am/pm designation of hours is represented by the function $hr12$.

$$\begin{aligned}
&hr12(y, n, *am*, x) \equiv hr(y, n, x) \\
&hr12(y, n, *pm*, x) \equiv hr(y, n + 12, x)
\end{aligned}$$

Each of the calendar intervals is that unit long; a calendar year is a year long.

$$\begin{aligned}
&sec(y, n, x) \supset second(y) \\
&min(y, n, x) \supset minute(y) \\
&hr(y, n, x) \supset hour(y) \\
&da(y, n, x) \supset day(y) \\
&mon(y, n, x) \supset month(y) \\
&yr(y, n, x) \supset year(y)
\end{aligned}$$

A distinction is made above between clocks and calendars because they differ in how they number their unit intervals. The first minute of an hour is labelled with 0; for example, the first minute of the hour [10:00,11:00] is 10:00. The first day of a month is labelled with 1; the first day of March is March 1. We number minutes for the number just completed; we number days for the day we are working on. Thus, if the larger unit has N smaller units, the argument n in clock−int runs from 0 to $N - 1$, whereas in $cal\text{-}int$ n runs from 1 to N. To state properties true of both clock and calendar intervals, we can use the predicate $cal\text{-}int$ and relate the two notions with the axiom

$$cal\text{-}int(y, n, u, x) \equiv clock\text{-}int(y, n - 1, u, x)$$

The type constraints on the arguments of $cal\text{-}int$ are as follows:

$$\begin{aligned}
&cal\text{-}int(y, n, u, x) \\
&\quad \supset interval(y) \wedge integer(n) \\
&\quad \wedge temporal\text{-}unit(u) \wedge interval(x)
\end{aligned}$$

There are properties relating to the labelling of clock and calendar intervals. If N u's hath x and y is the nth u in x, then n is between 1 and N.

$$\begin{aligned}
&cal\text{-}int(y, n, u, x) \wedge Hath(S, N, u, x) \\
&\quad \wedge member(y, S) \\
&\quad \supset 0 < n <= N
\end{aligned}$$

There is a 1st small interval, and it starts the large interval.

$$\begin{aligned}
&Hath(S, N, u, x) \\
&\quad \supset (\exists y)[member(y, S) \wedge cal\text{-}int(y, 1, u, x)] \\
&Hath(S, N, u, x) \wedge cal\text{-}int(y, 1, u, x) \\
&\quad \supset int\text{-}starts(y, x)
\end{aligned}$$

There is an nth small interval, and it finishes the large interval.

$$\begin{aligned}
&Hath(S, N, u, x) \\
&\quad \supset (\exists y)[member(y, S) \\
&\quad \wedge cal\text{-}int(y, N, u, x)] \\
&Hath(S, N, u, x) \wedge cal\text{-}int(y, N, u, x) \\
&\quad \supset int\text{-}finishes(y, x)
\end{aligned}$$

All but the last small interval have a small interval that succeeds and is met by it.

$$\begin{aligned}
&cal\text{-}int(y1, n, u, x) \wedge Hath(S, N, u, x) \\
&\quad \wedge member(y_1, S) \wedge n < N \\
&\quad \supset (\exists y_2)[cal\text{-}int(y_2, n + 1, u, x) \\
&\quad \wedge int\text{-}meets(y_1, y_2)]
\end{aligned}$$

All but the first small interval have a small interval that precedes and meets it.

$$\begin{aligned}
&cal\text{-}int(y_2, n, u, x \wedge Hath(S, N, u, x) \\
&\quad \wedge member(y_2, S) \wedge 1 < n \\
&\quad \supset (\exists y_1)[cal\text{-}int(y_1, n - 1, u, x) \\
&\quad \wedge int\text{-}meets(y_1, y_2)]
\end{aligned}$$

If time is linearly ordered, the existential quantifier $\exists$ can be replaced by $\exists !$ in the above axioms.

4.3. Weeks

A calendar week starts at midnight, Saturday night, and goes to the next midnight, Saturday night. It is independent of months and years. However, we can still talk about the nth week in some larger period of time, e.g., the third week of the month or the fifth week of the semester. So the same three modes of representation are appropriate for weeks as well.

$$\begin{aligned} &wk(y,n,x) \equiv wkFn(n,x) = y \\ &\quad \equiv cal\text{-}int(y,n,*Week*,x) \end{aligned}$$

As it happens, the n and x arguments will often be irrelevant.

A calendar week is one week long.

$$wk(y,n,x) \supset week(y)$$

The day of the week is a temporal unit (*DayOfWeek*) in a larger interval, so the three modes of representation are appropriate here as well.

$$\begin{aligned} &dayofweek(y,n,x) \\ &\quad \equiv dayofweekFn(n,x) = y \\ &\quad \equiv cal\text{-}int(y,n,*DayOfWeek*,x) \end{aligned}$$

Whereas it makes sense to talk about the nth day in a year or the nth minute in a day or the nth day in a week, it does not really make sense to talk about the nth day-of-the-week in anything other than a week. Thus we can restrict the x argument to be a calendar week.

$$dayofweek(y,n,x) \supset (\exists n_1, x_1) wk(x,n_1,x_1)$$

The days of the week have special names in English.

$$\begin{aligned} &dayofweek(y,1,x) \equiv Sunday(y,x) \\ &dayofweek(y,2,x) \equiv Monday(y,x) \\ &dayofweek(y,3,x) \equiv Tuesday(y,x) \\ &dayofweek(y,4,x) \equiv Wednesday(y,x) \\ &dayofweek(y,5,x) \equiv Thursday(y,x) \\ &dayofweek(y,6,x) \equiv Friday(y,x) \\ &dayofweek(y,7,x) \equiv Saturday(y,x) \end{aligned}$$

For example, $Sunday(y,x)$ says that y is the Sunday of week x.

A day of the week is also a day of the month (and vice versa), and thus a day long.

$$\begin{aligned} &(\forall y)[[(\exists n,x) dayofweek(y,n,x)] \\ &\quad \equiv [(\exists n_1,x_1) da(y,n_1,x_1)]] \end{aligned}$$

One correspondance will anchor the cycle of weeks to the rest of the calendar, for example, saying that January 1, 2002 was the Tuesday of some week x.

$$\begin{aligned} &(\forall z)(\exists x) Tuesday(dayFn(1, monFn(1, \\ &\qquad yrFn(2002, CE(z)))), x) \end{aligned}$$

We can define weekdays and weekend days as follows:

$$\begin{aligned} &weekday(y,x) \\ &\quad \equiv [Monday(y,x) \vee Tuesday(y,x) \\ &\quad \vee Wednesday(y,x) \vee Thursday(y,x) \\ &\quad \vee Friday(y,x)] \\ &weekendday(y,x) \\ &\quad \equiv [Saturday(y,x) \vee Sunday(y,x)] \end{aligned}$$

4.4. Months and Years

The months have special names in English.

$$\begin{aligned} &mon(y,1,x) \equiv January(y,x) \\ &mon(y,2,x) \equiv February(y,x) \\ &mon(y,3,x) \equiv March(y,x) \\ &mon(y,4,x) \equiv April(y,x) \\ &mon(y,5,x) \equiv May(y,x) \\ &mon(y,6,x) \equiv June(y,x) \\ &mon(y,7,x) \equiv July(y,x) \\ &mon(y,8,x) \equiv August(y,x) \\ &mon(y,9,x) \equiv September(y,x) \\ &mon(y,10,x) \equiv October(y,x) \\ &mon(y,11,x) \equiv November(y,x) \\ &mon(y,12,x) \equiv December(y,x) \end{aligned}$$

The number of days in a month have to be spelled out for individual months.

$$\begin{aligned} &January(m,y) \\ &\quad \supset (\exists S) Hath(S,31,*Day*,m) \\ &March(m,y) \supset (\exists S) Hath(S,31,*Day*,m) \\ &April(m,y) \supset (\exists S) Hath(S,30,*Day*,m) \\ &May(m,y) \supset (\exists S) Hath(S,31,*Day*,m) \\ &June(m,y) \supset (\exists S) Hath(S,30,*Day*,m) \\ &July(m,y) \supset (\exists S) Hath(S,31,*Day*,m) \\ &August(m,y) \\ &\quad \supset (\exists S) Hath(S,31,*Day*,m) \\ &September(m,y) \\ &\quad \supset (\exists S) Hath(S,30,*Day*,m) \\ &October(m,y) \\ &\quad \supset (\exists S) Hath(S,31,*Day*,m) \\ &November(m,y) \\ &\quad \supset (\exists S) Hath(S,30,*Day*,m) \\ &December(m,y) \\ &\quad \supset (\exists S) Hath(S,31,*Day*,m) \end{aligned}$$

The definition of a leap year is as follows:

$$\begin{aligned} &(\forall z)[leap\text{-}year(y) \\ &\quad \equiv (\exists n,x)[year(y,n,(CE(z)) \\ &\qquad \wedge [divides(400,n) \\ &\qquad\quad \vee [divides(4,n) \wedge \neg divides(100,n)]]] \end{aligned}$$

We leave leap seconds to specialized ontologies.

Now the number of days in February can be specified.

$$\begin{aligned} &February(m,y) \wedge leap\text{-}year(y) \\ &\quad \supset (\exists S) Hath(S,29,*Day*,m) \\ &February(m,y) \wedge \neg leap\text{-}year(y) \\ &\quad \supset (\exists S) Hath(S,28,*Day*,m) \end{aligned}$$

A reasonable approach to defining month as a unit of temporal measure would be to specify that the start and end points have to be on the same days of successive months.

$$\begin{aligned} &month(T) \\ &\quad \equiv (\exists d_1,d_2,n,x,m) \\ &\qquad [in\text{-}interval(start\text{-}of(T),d_1) \\ &\qquad \wedge in\text{-}interval(end\text{-}of(T),d_2) \\ &\qquad \wedge da(d_1,n,monFn(m,x)) \\ &\qquad \wedge da(d_2,n,monFn(mod+(m,1,12),x))] \end{aligned}$$

Here $mod+$ is modulo addition to take care of months spaning December and January. So the month as a measure of duration would be related to days as a measure of duration only indirectly, mediated by the calendar.

To say that July 4 is a holiday in the United States one could write

$$(\forall\, d, m, y)[da(d, 4, m) \wedge July(m, y) \supset holiday(d, USA)]$$

4.5. Time Stamps

Standard notation for times list the year, month, day, hour, minute, and second. It is useful to define a predication for this.

$$time\text{-}of(t, y, m, d, h, n, s, z) \equiv in\text{-}interval(t, secFn(s, minFn(n, hrFn(h, daFn(d, monFn(m, yrFn(y, CE(z)))))))))$$

For example, an instant t has the time

5:14:35pm PST, Wednesday, February 6, 2002

if the following properties hold for t:

$$time\text{-}of(t, 2002, 2, 6, 17, 14, 35, *PST*)$$
$$(\exists\, w, x)[in\text{-}interval(t, w) \wedge Wednesday(w, x)]$$

The second line says that t is in the Wednesday w of some week x.

The relations among time zones can be expressed in terms of the time−of predicate. Two examples are as follows:

$$h < 8 \supset [time\text{-}of(t, y, m, d, h, n, s, *GMT*) \equiv time\text{-}of(t, y, m, d-1, h+16, n, s, *PST*)]$$
$$h \geq 8 \supset [time\text{-}of(t, y, m, d, h, n, s, *GMT*) \equiv time\text{-}of(t, y, m, d, h-8, n, s, *PST*)]$$
$$time\text{-}of(t, y, m, d, h, n, s, *EST*) \equiv time\text{-}of(t, y, m, d, h, n, s, *CDT*)$$

5. Deictic Time

Deictic temporal concepts, such as "now", "today", "tomorrow night", and "last year", are more common in natural language texts than they will be in descriptions of Web resources, and for that reason we are postponing a development of this domain until the first three are in place. But since most of the content on the Web is in natural language, ultimately it will be necessary for this ontology to be developed. It should, as well, mesh well with the annotation standards used in automatic tagging of text.

We expect that the key concept in this area will be a relation *now* between an instant and an utterance or document.

$$now(t, d)$$

The concept of "today" would also be relative to a document, and would be defined as follows:

$$today(T, d) \equiv (\exists\, t, n, x)[now(t, d) \wedge in\text{-}interval(t, T) \wedge da(T, n, x)]$$

That is, T is today with respect to document d if and only if there is an instant t in T that is now with respect to the document and T is a calendar day (and thus the nth calendar day in some interval x).

Present, past and future can be defined in the obvious way in terms of now and before.

Another feature of a treatment of deictic time would be an axiomatization of the concepts of "last", "this", and "next" on anchored sequences of temporal entities.

6. Aggregates of Temporal Entities

A number of common expressions and commonly used properties are properties of sequences of temporal entities. These properties may be properties of all the elements in the sequence, as in "every Wednesday", or they may be properties of parts of the sequence, as in "three times a week" or "an average of once a year". We are also postponing development of this domain until the first three domains are well in hand.

This may be the proper locus of a duration arithmetic, since we may want to know the total time an intermittant process is in operation.

7. Vague Temporal Concepts

In natural language a very important class of temporal expressions are inherently vague. Included in this category are such terms as "soon", "recently", "late", and "a little while". These require an underlying theory of vagueness, and in any case are probably not immediately critical for the Semantic Web. This area will be postponed for a little while.

Acknowledgments

I have profited from discussions with James Allen, George Ferguson, Pat Hayes, Adam Pease, and Stephen Reed, among others, none of whom however would necessarily agree entirely with the way I have characterized the effort. The research was funded by the Defense Advanced Research Projects Agency under Air Force Research Laboratory contract F30602-00-C-0168 and by the Advanced Research and Development Agency.

Abstract

This paper suggests that video indexing is an interesting and important natural language application for which it is crucial to identify temporal information in collateral text that articulates the semantic content of moving images. Recently a rich source of information about the content of films and television programmes has become available in the form of audio description scripts. The analysis of the expression of temporal information in a corpus of audio description scripts leads to a discussion of some consequences for schemes to annotate such information in a video indexing application.

1. Introduction

The further development of digital libraries to retrieve, manipulate, browse and generate complex multimedia artefacts depends upon the machine-based representation of those artefacts, and in particular their 'semantic content'. An image can be understood at different levels of meaning: an image sequence, like a movie, can also tell a story by depicting a sequence of events. A crucial part of a film's semantic content is the narrative that it relates. As the story unfolds, the viewer constructs their understanding of the story guided by the director's careful sequencing of scenes and editing of shots. A machine-level representation of a film should maintain its rich structure and detail the entities, events and themes depicted; but how can a representation be instantiated for a given film?

One general approach to video indexing is based on the association of moving images and *collateral text* so that keywords, and potentially richer representations, are extracted from text fragments. Consider, for example, the speech of news and documentary presenters, sports commentaries and even newspaper film reviews. The challenge is to explicate the relationship between the moving image and the text. This involves dealing with temporal information in various ways; for example it is necessary to associate text fragments with the video intervals for which they are true; temporal relationships between the events depicted in the moving image must be extracted from the text; and, the time at which the action takes place must be ascertained.

A newspaper film review gives an incomplete and temporally re-ordered account of the events in a film. The speech of a newsreader is temporally aligned with the moving image but does not always refer to the visual information directly – much of a news broadcast comprises head and shoulders shots of newsreaders or stock video footage used to illustrate a story, thus keywords are more likely to be indicative of general story content than refer directly to what can be seen. By contrast, an audio description is a kind of 'narrative monologue' that gives a detailed account of what can be seen on screen in which the text order tends to follow the order of events in a programme or film. Audio description enhances the enjoyment of most kinds of films and television programmes for visually impaired viewers. In the gaps between existing speech the audio description gives key information about scenes, people's appearances and on-screen actions so that in effect the story conveyed by the moving image is retold in words.

We are interested in applying information extraction technology to generate machine-level representations of video content from audio description. It is hoped that the enhanced representation of video content could facilitate more complex querying ("find all clips showing X happening" – where X is a detailed description of events) and perhaps also contribute further to systems for video generation and maybe even question answering about what happened in a movie and why. As a first step towards information extraction we are considering the annotation of a corpus of audio description scripts to explicate what and how information is conveyed. At the moment priority is being given to temporal information because it seems to be crucial for the proper integration of moving images and collateral text.

Audio description is scripted before it is recorded. An audio description script is thus a text which is 'written to be spoken' and includes time-codes to indicate when each utterance is to be spoken. The task of processing audio description scripts is constrained because audio describers follow guidelines that restrict the language they use, i.e. normally the present tense, simple sentences and few pronominal references. This restricted language, the presence of time-codes and the relatively straightforward chronological order of the texts make audio description scripts a good starting point for extracting information for video indexing.

Though it is straightforward to associate a time-coded text fragment approximately with a video interval, a more precise association requires consideration of tense and aspect. For example, consider how the following fragments relate to intervals in the moving image: they are from audio description for *The English Patient* – time codes are in the format [minute:second][1].

[1] This sample is reproduced from *The English Patient*. Please note that further examples in the paper are fictitious but based closely on actual audio description and maintain grammatical structure (i.e. only names and events have been changed).

[11:43] Hanna passes Jan some banknotes – a near instantaneous event in the present tense, so the fragment relates to a short video interval at the time of speaking;

[11:55] Laughing, Jan falls back into her seat – the present participle indicates that 'laughing' is ongoing and so relates to a longer video interval that includes the instantaneous 'falls back';

[12:01] An explosion on the road ahead – use of nominalisation to refer to an event;

[12:08] The jeep has hit a mine – the present perfect indicates that the event is completed and the video interval that the text relates to must have start and end points before the time-code of the text fragment (general knowledge tells us that this event occurred before the explosion and was its cause).

Once text fragments have been associated with video intervals the events depicted in the steady flow of the moving image must be related to each other according to a different time-line – that of the diegetic world depicted by the movie. For example the 'hit mine' event happens immediately before the 'explosion' described above and it might be appropriate to label the relationship with causality. There are also examples of simultaneous and included events, such as – *he prevents her from leaving, holding her firmly*. Events in a movie are grouped in scenes where each scene has a (normally) unique combination of time and location. In audio description an explicit time reference might be used to introduce a new scene, e.g. *October 1944*; *later* is also used to introduce scenes and indicate story progression.

This paper suggests that video indexing is an interesting and important natural language application for which it is crucial to identify and analyse temporal information in collateral texts that articulate the semantic content of moving images. A review of video retrieval systems shows that the use of collateral text is important, but in order to extend the approach to more kinds of video material and collateral text it will be essential to process temporal information. The conceptualisation of time and events with respect to semantic content in digital video systems is outlined, particularly for films (Section 2).

We attempt to formalise the challenge of integrating video data and collateral text by describing three tasks that would contribute to the use of collateral text for video indexing. These tasks guided the analysis of an audio description script corpus (70,856 words): prominent expressions of temporal information are quantified and exemplified (Section 3). The results begin to give a basis for discussing what would be required of a scheme to annotate temporal information in this scenario: existing annotation schemes are reviewed and some tentative extensions are proposed (Section 4). The paper closes by considering further directions for this work (Section 5).

2. Digital Video Systems

Video data can be indexed with visual features based on the distribution of pixels, e.g. colour, texture, shape and motion: however a 'semantic gap' appears between video databases and users who often conceive their information needs in terms of the relationships between entities, events and themes to be depicted in the video sequence of interest. Indexing could be achieved by attaching keywords and other descriptors manually to either whole video data files or intervals and regions within them. A cheaper alternative is to use language technology to process 'collateral text'; Srihari introduced this term to refer to textual information associated with visual information, specifically photo captions (1995). Video data sometimes includes an *integral* textual component in the form of speech and closed-captions. Other *external* textual information arises in the production and distribution of video material, e.g. scripts and production notes, and now audio description (legislation in a number of countries makes the provision of audio description mandatory for an increasing amount of digital TV and film output).

In news broadcasts and documentary programmes much of the information content is carried by the spoken words of the presenters, and the subjects on which they are speaking will reflect, albeit to varying degrees, the entities, events and themes shown in the accompanying moving images. The *Informedia* system indexes news broadcasts and documentary programs by keywords that are extracted from speech and closed captions: since the speech is time-aligned with the moving images the keywords can be associated with specific video intervals (Wactlar et al., 1999). This approach has been extended into a multi-lingual context in the Pop-Eye and Olive projects, and to deal with sports footage in the current MUMIS project (de Jong et al., 2000). Other researchers have applied text segmentation techniques to the speech stream of video data in order to segment video sequences (Mani et al., 1997; Takeshita, Inoue and Tanaka, 1997). The transcribed speech of news presenters has been exploited in a system for browsing through news broadcasts by following hypertext links between terms and viewing associated video sequences (Shahraray, 1999). Research and systems focused on accessing broadcast news, including further tasks like multi-stream segmentation, combined name/face recognition and multimedia summarisation are collected in Maybury (2000).

There are moving images that do not contain 'integral' text, but that can be indexed with text that was produced specifically to elucidate the video's content. The *WebSEEK* system, which has indexed hundreds of thousands of images and videos on the WWW, selects keywords from the text of hyperlinks to images and videos on WWW-pages (Smith and Chang, 1997); note that this system only indexes whole videos rather than intervals. Another system, developed at the Japan Broadcasting Corporation, parses the notes kept in the production of wildlife documentary programs that describe the entities and events in the recorded footage and are time-coded. Queries for video intervals can be made in terms of the relationships between entities and actions (Kim and Shibata, 1996).

More recently there have been developments to combine visual and textual features for the classification of video sequences. For example, visual features may indicate the location of a scene (indoors/outdoors) and whether there is one or many people in the shot, and textual features may indicate the nature of the spoken words (a news report / a political speech): taken together these features suggest whether a video sequence depicts a political rally, an outside news broadcast, or a political party's conference (Satoh, Nakamura and Kanade, 1999).

Textual information from TV sit-com scripts has been combined with visual features, through a process involving user interaction, so a system can locate scenes containing a particular character (Wachman and Picard, 2001).

Collateral text could potentially be used for extracting information about other kinds of video, including those with rich semantic content like films and dance sequences. In specialist domains, like dance, there is an extensive range of collateral texts available (dance programmes, newspaper reviews, textbooks, choreographer's notes, biographies, etc.) and spoken commentaries can be elicited from experts asked to 'describe' and to 'interpret' sequences. The KAB system was developed to index fixed-length intervals of dance videos with keywords from such commentaries: this work also specified requirements for a general system to process diverse collateral texts (Salway and Ahmad, 1998; Salway, 1999). A key requirement is a video data model and representation scheme that captures semantic video content, including temporal organisation, at an appropriate level of detail to facilitate complex queries, browsing and even video generation; the link with collateral text also needs to be modelled.

In the video database literature semantic content is usually treated as comprising the objects and events depicted by a moving image and the spatio-temporal relationships that hold between them; for a survey see Chen, Kashyap and Ghafoor (2000). Descriptions of objects and events (as keywords and propositions, for example) are associated with intervals of video data which can be modelled either as a hierarchy of discrete intervals (Weiss, Duda and Gifford, 1995) or as multi-layered overlapping intervals (Davenport, Aguierre Smith and Pincever, 1991).

Allen's (1983) temporal logic has been applied widely in video data models to facilitate reasoning about video content and more complex queries: the number of the 13 possible interval relationships that are used varies between applications. A hierarchical model is appropriate for dealing with film in terms of scenes and shots (see Corridoni et al., 1996). However, to capture more detail about the events within a shot it might be necessary to allow for overlapping video intervals and more description of the relationships between events.

Knowledge representation schemes aim to provide unambiguous representations of meaning and to facilitate inferencing: a number of proposals have been made to use such schemes for semantic video content. Regarding the composition of events/sub-events in moving images, particularly in stereotypical situations, a framework was developed based on Schank and Abelson's scripts (1977), see (Parkes, 1989; Nack and Parkes, 1997). Semantic networks have been used in a video browsing system to elaborate the description of events, for example to specify participants and causal relationships between events (Roth, 1999). The use of conceptual dependency graphs and story grammars has also been discussed (Tanaka, Ariki and Uehara, 1999). Independent to this, but sharing some similar goals, researchers in computer vision have proposed levels to deal with complex visual information at stages from raw visual input to final representation, e.g. 'change – event – verb – history' (Nagel, 1988), and specifically for human motion 'movement – activity – action' (Bobick, 1997).

3. Temporal Information in Collateral Text

This section characterises the expression of temporal information in a corpus of audio description scripts with respect to three tasks we consider important for video indexing with collateral text. First though, in order to extend the use of collateral text to index films it is necessary to explicate how a linear text relates to a film with multi-faceted content. The discussion here is limited to film content that is conveyed visually, and hence accessible through audio description - we are not currently considering dialogue and sound effects. The focus is on films and accompanying audio description but much of what is discussed could be relevant to other kinds of video and other collateral text types.

3.1. Integrating Moving Images and Text

In order to integrate audio description text with film at a semantic level it is necessary to deal with film in terms of the shots and scenes by which it is structured. It is also important to recognise two timelines: (i) film time, i.e. the time it takes to watch the film; and, (ii) story time, i.e. the time in which the events depicted take place. Figure 1 shows how a film (stored as a video data file) can be modelled in terms of shots which are defined as continuous pieces of filming, and scenes which are characterised by each having a unique combination of location and time. The story timeline is shown in parallel with layers of events taking place. Of course the relative position of events may differ between the two timelines, e.g. the film may depict events in a different order than they happen in the story, and events that are happening at the same time but in different locations will be depicted in different scenes. For video retrieval purposes it is important to maintain temporal relationships between events; different sub-sets of Allen's relationships will be required for different applications.

The structure of film provides some useful constraints when dealing with temporal information. It is reasonable to assume that all events depicted within a scene take place close together in the story timeline, and are likely to form larger events (information about scene boundaries may be available from sources like film scripts and automatic video analysis). When considering how events are depicted at the shot level it is important to note film-making techniques that are used to convey that an event is taking place, or has taken place, without showing it in its entirety; a director may choose to portray only the end result of an event and allow the viewer to infer that the event took place.

The collateral text is shown as a series of time points that indicate the time at which the speaker starts the utterance (assuming a temporally aligned collateral text, like an audio description). The three tasks outlined next relate to the extraction of temporal information from collateral text to: (i) associate an utterance with the video interval for which it is true, be it a shot, scene or some other interval; (ii) specify event-event relationships – here we only consider relationships holding within a scene (in film time); (iii) establish the time at which scene is set (in story time).

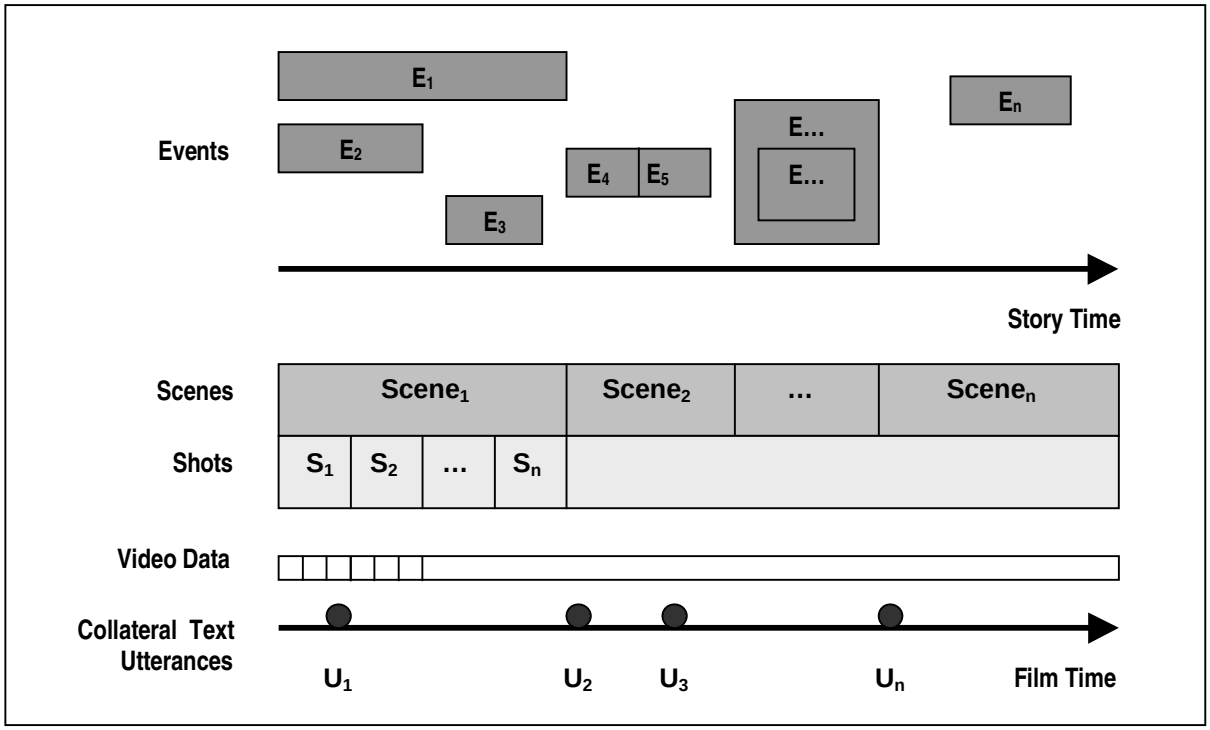

Figure 1. The organisation of a film's content in terms of shots and scenes (which relate to film time) and the events that comprise the semantic video content (which relate to story time). Collateral text such as audio description is temporally aligned with the video data in film time.

3.1.1. Task 1: Associate an audio description fragment with the interval in film time for which it is true.

Given a time coded text fragment it is relatively straightforward to associate it approximately with the video interval for which it is true, i.e. the interval in which the event it refers to is taking place; the time-code plus and minus an arbitrary number of seconds works as a crude approximation of start and end times. However, it is desirable to be more precise about at least one of: start time, end time or duration. (A greater challenge, not addressed here, is to ascertain whether the event is depicted on-screen throughout the duration). As well as events, it is also appropriate to deal with states if they change significantly during the movie, e.g. to indicate scenes in which a character is a child or grown-up.

The problem can be gauged to some extent by considering an earlier feasibility study for indexing moving images with audio description (Turner, 1998). A small sample of video material with accompanying audio description was analysed (including a film and various kinds of television programme). Results showed that overall about 50% of shots were described but only about 40% of the audio description referred directly to the shot on-screen at the time of speaking.

To ascertain appropriate video intervals it may help to consider some of the aspectual features of events classified by Comrie (1976). Whether an event has internal structure (*punctual* / *durative*) gives some information about its duration; this may be an inherent characteristic of a verb but may be modified grammatically, e.g. with the progressive. Knowing about an event's end result, if it has one (*telic* / *atelic*), gives information about its completion (and in audio description may be all that is referred to).

3.1.2. Task 2: Event-event relationships in story time (within the same scene).

Moving images can depict many events at the same time, and in the case of film the temporal organisation of events and relationships such as event / sub-event and causality are crucial to a viewer's understanding. As discussed previously some or all of Allen's 13 temporal relationships might be needed, though whether they can all be extracted from collateral text remains to be seen. In a narrative dialogue by default events are mentioned in the order in which they occur – however, events may occur simultaneously, or there may be stylistic reasons to mention them out of order.

Ascertaining basic temporal relationships, like before / after / overlapping, may be possible just from the collateral text. However, to construct rich representations of composite events within scenes perhaps relies more on prior 'world knowledge' than it does on information immediately available in a narrative monologue (cf. the use of Schank's scripts to deal with semantic video content); the problem becomes harder still when event-event relationships across different scenes are considered. A lexical resource, like WordNet, might help as a first step to relate events, in light of the entailment relations for verbs described by Fellbaum (1998). When considering temporal inclusion some sets of verbs are *co-extensive*, e.g. 'march and walk', 'whisper and talk'; whereas other share a relationship of *proper inclusion*, e.g. 'sleep and snore'. Having access to these relationships may help to

associate descriptions of the same event and to establish sub-event relationships. Other relationships allow events to be associated according to *backward presupposition*, e.g. 'forget and know', and on the basis of *causality*, e.g. 'show and see'.

3.1.3. Task 3: Establish the time a scene takes place (in story time).

A viewer's appreciation of a film requires knowing when it is set, and if it is set over a long time period then the time of each scene must be known – thus information needs to be extracted to give each scene a time. Unless a film is based upon true-life events then it is normally set within a time period without specific dates being implied. Similarly, within the course of a day in story time exact times are usually less important than whether the viewer knows it is morning, afternoon, evening or night (of course exact times will be crucial for some plots). Unless otherwise indicated the assumption is that scenes are ordered sequentially according to the story timeline, but for some movies the use of flashback will have to be dealt with.

3.2. Temporal Information in Collateral Text: a case study with audio description scripts

The intention of this case study is to quantify and exemplify prominent expressions of temporal information in audio description scripts: the analysis is organised around the three tasks for video indexing described in the previous section. The corpus comprises audio description scripts for 12 movies, covering a range of movie genres, and written by six different describers. It currently totals 70,856 words – this will be expanded to around 500,000 words in coming months.

When carrying out the analysis we considered the variety of ways temporal information can be expressed in English as outlined by Quirk et al. (1985), i.e. by using tense, aspect, adverbials, prepositional phrases, subordinate clauses, nouns and proper nouns. Of course in narrative monologues text order is highly informative about the order in which events take place. Our 'conceptualisation of time' is guided by approaches to video data modelling, i.e. the association of event and state descriptions with video intervals, the specification of interval relationships following Allen (1983), and the organisation of complex events using knowledge representation schemes. Theoretical perspectives on events, such as Comrie's classification of aspect (1976) and Fellbaum's entailment relations (1998) were also considered.

Based on the 50 most frequent verbs in the corpus it appears that the majority of events are material processes (84%), with some mental processes (10%), a few relational processes (4%) and a few behavioural processes (2%), following Halliday (1994).

3.2.1. Information to Associate Text Fragments with Video Intervals

The present tense proliferates in the audio description corpus. It is even used to describe events that are about to happen, for example to describe speech acts which cannot be described at the time they occur – *the doctor questions Tom*. The occasional use of the present perfect is important to describe events after they happened (possibly because there was not an opportunity to describe them at the time they occurred, or because only the end result is depicted on screen) – *the cake has been eaten*. Past events are also sometimes referred to in relative clauses used to identify unnamed characters – *the woman who visited Paul is walking down the street*. In order to be more precise about the start, end or durations of events it seems that a variety of aspectual information is important, especially aspectual verbs and the inherent aspect of verbs.

In the audio description corpus the verbs *start, stop, begin* and *finish* occur relatively far more frequently than they do in the general language British National Corpus (BNC), Table 1 shows just 3rd person singular forms. These verbs almost always appeared in the present tense to refer to another event so it would be straightforward to use them to compute their arguments' start and end times.

Verb	Abs. Freq	Ratio with BNC
stops	105	65.79
starts	60	25.13
begins	19	4.67
finishes	3	25.65

Table 1: Showing prominent aspectual verbs in Surrey's audio description corpus (only for 3rd person singular). The third column is calculated by dividing relative frequency in the audio description corpus with relative frequency in the British National Corpus (BNC)

Regarding the duration of events the adverb *still* is frequently used with durative events that have not finished at the time of speaking (85 occurrences of *still* in the corpus; 62 of these are in the time sense). There was little sign of time expressions giving information about exact durations but relatively short periods were frequently indicated with *for a moment* (29 occurrences). Other frequent, adverbs like *slowly* (111 occurrences) and *quickly* (20) might make a small contribution to understanding the duration of an event.

The grammatical marking of progressive aspect does not appear to be significant for the task of associating text fragments with video intervals. In a narrative monologue we learn nothing about the duration of the event from the distinction between 'he runs' and 'he is running'; the simple present and the progressive are used interchangeably in the corpus. In fact it is probably an event's inherent aspect that is most important to determine, at least approximately, its duration in film time. In general language this will be problematic given that the many senses of common verbs often have different aspectual characteristics, however in specialist domains it may be possible to store default durations for events, like dance movements.

3.2.2. Information to Specify Event-Event Relationships in Film Time

The most frequent conjunction to indicate events happening at the same time in the audio description corpus was *as* (350 occurrences in the time sense) – *the children*

play as the crowd moves away; sometimes *as* indicates more of a connection between events – *she continues to hide as the monster approaches*. Used only to indicate simultaneity (without implying further connection between events) *while* occurred 37 times. Both these conjunctions indicate some degree of overlap between events but further information is required to know whether the events are strictly simultaneous, whether one is included within the other, or if they simply overlap. Non-finite verbs with sub-ordinate clauses tend to indicate that the second event is included in the first – *Coughing, Mary gives the medicine to Tom*. When linking events *and* was 'ambiguous' as to whether the events occurred serially or in parallel.

Occurring only in its time sense, *then* (173 occurrences) was still relatively more frequent in the audio description corpus than the BNC. Though it is redundant as far as indicating sequence is concerned (that is already conveyed by text order) it does seem to imply the completion of the first event before the start of the next one – *Sarah chops the tomatoes then fries an egg*. Furthermore in many examples it suggests that the events meet in time, i.e. the endpoint of one equals the start of the other. (This kind of information could be useful in relation to our Task 1). The less frequent *when* (29 occurrences) and *until* (20) were used respectively to indicate the start and end of events in relation to other events or states, often suggesting that the first event led to the second – *she walks through the forest until she finds the house*.

Like *then*, *now* (40 occurrences) adds little or nothing by way of basic temporal information in these narrative monologues, however it does seem to indicate a change or contrast between two events across a passage of audio description – *Jane is dancing with George … Now she is dancing with her cousin*. Perhaps surprisingly, *after* and *before* occur relatively infrequently in the corpus (compared with the BNC) and when they are used they only serve to emphasise the sequence of events already conveyed by text order, i.e. we find 'after E1, E2' but not 'E2 after E1', and 'E1 before E2' but not 'before E2, E1'.

The adverb *again* is prominent in the corpus (141 occurrences – 2.5 times relatively more often than in the BNC). It generally indicates that an event is happening for a second time within a scene – for video retrieval purposes it might be useful to relate the two instances.

3.2.3. Information to Specify When Scenes Take Place in Story Time

The most frequent time expressions used to locate a scene on the story timeline relate to non-specific times of day: *night* (37 occurrences), *morning* (19), *evening* (11), *dusk* (6), *dawn* (3). Less frequent were expressions for non-specific times of year, i.e. months (without years), seasons and festival days (17 occurrences in total). This probably reflects the fact that the progression of time during a film is more often at the granularity of days. The relative paucity of specific times and dates (there were only a few examples) is explained in part by the fact that for many films the viewer need only understand a general time period. This may be conveyed by costumes, props and, for times of day, lighting: these will all be referred to by audio description.

Scenes are sometimes introduced with one of the time expressions mentioned above – indicating a change of time is a shortcut to indicate a new scene. Quite often *later* (32 occurrences) is used for this purpose and as such may be a useful cue for scene segmentation.

4. An Annotation Scheme for Temporal Information in Collateral Text?

Based on the preceding analysis this section discusses some tentative requirements of an annotation scheme for temporal information in collateral text: such a scheme would be a step in applying information extraction technology to the task of video indexing. The extent to which existing schemes would cater for these requirements is reviewed. A number of factors suggest that some extensions to existing schemes will be required: (i) there seems to be a need to maintain two timelines; (ii) if practical in terms of time and inter-annotator agreement, it would be desirable to record aspectual information regarding the internal structure of events and end-states; (iii) also subject to practicality, it is important for film to specify sub-event and causal relationships.

A canonicalized representation of times was proposed as part of a set of guidelines for annotating temporal expressions by Mani et al. (2001), who targeted a variety of text genres such as both print and broadcast news, and meeting scheduling dialogues. The emphasis of their approach was on detailing different classes of time expressions like points in time (when), durations (how long) and frequencies (how often) and handling context-dependent expressions. It also addressed fuzzy temporal boundaries that arise from the use of phrases that refer to times of year and times of the day, e.g. *summer* and *morning*, and addressed non-specific times, such as *a sunny day in April* (not a specific day, nor a specific year).

Of the time expressions dealt with it is points in time that seem to apply most directly in our scenario in order to locate events (at the granularity of scenes) on the story timeline (our Task 3). Though duration and frequency relate to the kinds of aspectual characteristics that we would like to describe for events, they annotate only words and phrases that express this information directly; though there were some frequent phrases in the audio description corpus for which it might be applicable – *for a moment*.

Another scheme that has been proposed is more concerned with associating temporal information with events, and annotating the temporal relationships between events (Setzer and Gaizauskas, 2000; Setzer, 2001); this scheme was developed initially for newswire texts but is extensible. Annotations are attached to the heads of finite verb groups as representatives of events, as well as to temporal expressions. It is possible to specify the type of event (Occurrence / Perception / Reporting / Aspectual) as well as the tense and grammatical aspect of the verb. The annotations have attributes to specify five event-event and event-time relationships: 'before', 'after', 'includes', 'included' and 'simultaneous'. The features of the scheme that have been summarised here are exemplified in Appendix A which shows the annotation of 9 utterances of audio description.

The annotation of event-event relationships within a scene (our Task 2) would be dealt with quite

comprehensively by Setzer's and Gaizauskas' scheme: although as many as 13 temporal relationships (from Allen) are discussed in the video retrieval literature the five used in this scheme would probably serve most purposes. Being able to annotate aspectual events, i.e. to indicate the start and end time of occurrence events, is certainly important given their frequency in the audio description corpus - cf. our Task 1. For other parts of Task 1 it might be necessary to extend the scheme to specify the start and end of events when there is no explicit time expression, or to do it relative to the time-code in the text; a further minor extension would be to allow for the annotation of states as well as events. It certainly would be desirable to be able to specify causal and sub-event relationships between events as these are crucial to the narrative structure of movies, however this would depend upon annotators' ability to apply them consistently.

5. Closing Remarks

Dealing with temporal information is an important first step towards generating machine-level representations of video content from collateral text, especially when dealing with a complex multimedia artefact, like film, and richly informative collateral text, like audio description. This work is in its early stages but the three tasks outlined here begin to give us a handle on some of the challenges involved in integrating moving images and narrative monologues. The corpus analysis showed an extensive range of temporal information that needs to be dealt with in respect to these tasks. Progress will be made by more extensive application of existing annotation schemes leading to decisions about exactly what is required by way of extensions. Such decisions need to be informed by considerations of any new scheme's practicality (is it simple enough to be applied consistently and quickly) and the extent to which it captures important information (the criteria for which will vary between video applications and users). The final test would perhaps be a comparison of video retrieval using: (i) unannotated audio description (i.e. relying on time codes and text order alone); (ii) annotated audio description (with no further processing); and, (iii) machine-based representations generated from annotated audio description.

6. Acknowledgements

This research was carried out as part of the Television in Words project (TIWO) supported by an Engineering and Physical Sciences Research Council (EPSRC) grant, GR/R67194/01. The authors would like to thank the members of the TIWO Round Table for sharing their knowledge of audio description and providing samples for our corpus. Finally, we are very grateful for the comments of two anonymous reviewers and have tried to take heed.

Appendix A

Annotation of an audio description script following Setzer's scheme

The following passage of audio description (from *The English Patient*) has been annotated following the scheme and guidelines given by Setzer (2001). The sample here exemplifies how: (i) tense and aspect features can be associated with an event's verb; (ii) how the class of an event can be noted; (iii) how relationships between events can be specified. The sequence of events inherent in the text order has not been annotated, though it could have been – only exceptions to the 'default' have been annotated, e.g. simultaneous events, and events that are mentioned in a different order to which they occur.

[11.43] Hanna <event eid=1 tense=present class=occurrence> passes </event> Jan some banknotes.
[11.55] <event eid=2 tense=present class=occurrence aspect=progressive relatedToEvent=3 eventRelType=includes> Laughing </event>, Jan <event eid=3 tense=present class=occurrence relatedToEvent=4 eventRelType=simultaneous signalID=1> falls </event> back into her seat <signal sid=1> as </signal> the jeep <event eid=4 tense=present class=occurrence> overtakes </event> the line of the lorries.
[12.01] An <event eid=5 tense=present class=occurrence relatedToEvent=6 eventRelType=after> explosion </event> on the road ahead.
[12.08] The jeep has <event eid=6 tense=present class=occurrence aspect=perfective > hit </event> a mine.
[12.09] Hanna <event eid=7 tense=present class=occurrence> jumps </event> from the lorry.
[12.20] Desperately she <event eid=8 tense=present class=occurrence> runs </event> towards the mangled jeep.
[12.27] Soldiers <event eid=9 tense=present class=occurrence> try </event> to stop her.
[12.31] She <event eid=10 tense=present class=occurrence> struggles </event> with the soldier who <event eid=11 tense=present class=occurrence> grabs </event> hold of her firmly.
[12.35] He <event eid=12 tense=present class=occurrence> lifts </event> her bodily from the ground <event eid=13 tense=present class=occurrence aspect=progressive relatedToEvent=12 eventRelType=simultaneous> holding </event> her tightly in his arms.

Recognizing and Tagging Temporal Expressions in Spanish

Estela Saquete, Patricio Martínez-Barco and Rafael Muñoz
Departamento de Lenguajes y Sistemas Informáticos. Universidad de Alicante
Estela.Saquete@ua.es
{patricio, rafael}@dlsi.ua.es

Abstract

This paper shows a system about the recognition of temporal expressions in Spanish and the resolution of their temporal reference. For the identification and recognition of temporal expressions we have based on a temporal expression grammar and for the resolution on an inference engine, where we have the information necessary to do the date operation based on the recognized expressions. For further information treatment, the output is proposed by means of XML tags in order to add standard information of the resolution obtained. Different kinds of annotation of temporal expressions are explained in another articles [WILSON2001][KATZ2001]. In the evaluation of our proposal we have obtained successful results.

1. Introduction

The study of anaphora phenomena has been carried out for a lot of researches. Most of these researches have focused on pronominal anaphora and a few of them on definite descriptions. Most of temporal expressions could be considered as a type of definite description, but a few of them are temporal adverbs like "mañana" (*tomorrow*). The research work developed in definite description is focused on establishing a relationship between anaphoric expressions and their antecedents. In these work, if the definite description is a temporal expression it has been only solved establishing the relationship but not inferring the new date. The resolution of temporal expressions involves the recognition of them and the inference of the new date.

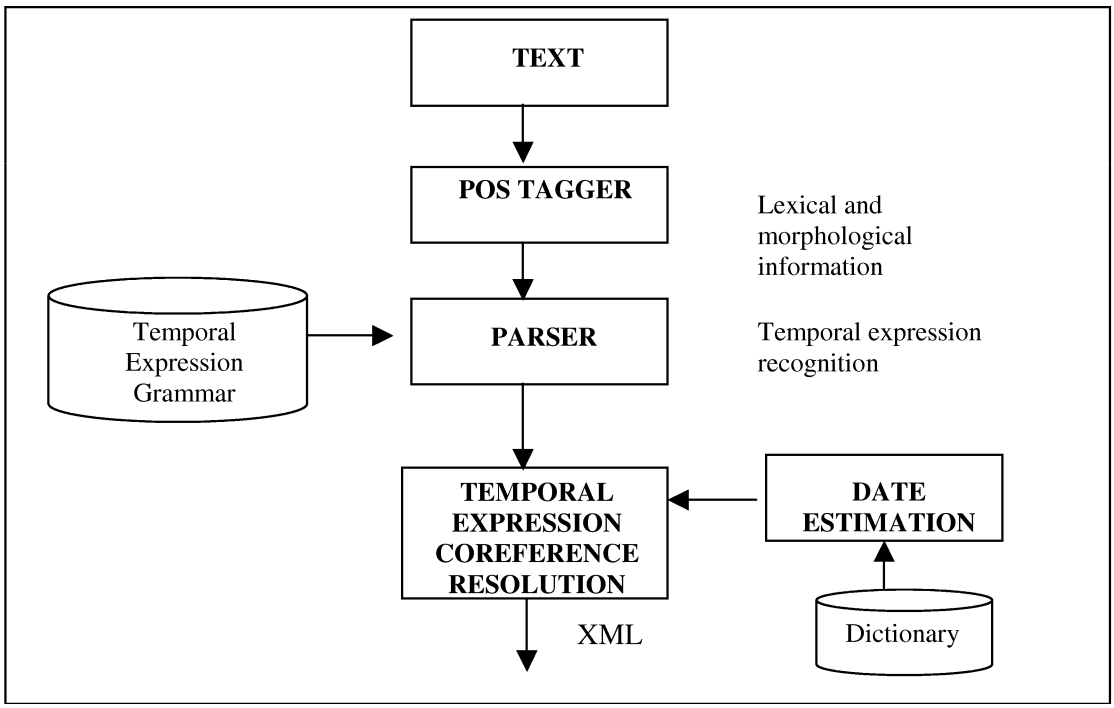

Fig. 1. Graphic representation of the system proposed

Work focused on temporal expression should to solve both tasks. In the literature we can found several studies focused on temporal expressions (Guillen et *al.* 1995) (Wiebe et *al.* 1998). These studies are based on the use of a temporal model that is able to interpret different formats for date and time expressions. Some of them are based on the application of empirical methods using the focus theory proposed in (Grosz et al. 1986).

In this paper a proposal of a grammar for the recognition of temporal expressions in Spanish is presented, as well as an approximation to the resolution of the coreference introduced by them, as is explained in (Saquete and Martínez-Barco 2000). Moreover, in this paper a set of tags is used to annotate the temporal expressions in the corpus.

In a text, there are dates with typical representations like, for example: "23/01/2000" o "23 de enero del 2000" (*23rd of January of 2000*), but we can find references to dates named previously too, for example: "dos días antes" (*two days before*), "la semana anterior" (*the previous week*), etc. This kind of coreference should be solved and mapped to dates with a standard format for a more efficient analysis of the text. For that, we use a grammar for the recognition of temporal expressions with their correspondent temporal parser, and an inference engine to solve and to map these expressions in a standard format: mm/dd/yyyy (hh:mm, for time expressions). Once the kind of reference and the interpretation of the expression are solved, the text is tagged with XML tags.

2. System structure

The system proposed is shown in Figure 1. The system has the plain text as input. These texts are tagged with lexical and morphological information using the POS-tagger developed by Pla (Pla 2000) and this information is the input of the temporal parser. The temporal parser is implemented using an ascending technique and it is based in a temporal grammar shown below. Once the temporal expressions are recognized, these are introduced into the resolution unit called Temporal Expression Coreference Resolution, which will update the value of the reference according to the date that it is referring to, and then it will generate the XML tags for each expression.

There are two different kinds of rules that are used for the grammar because there are two different kinds of temporal expressions too:

1. There are anaphoric and not anaphoric expressions. That is why there are rules for the date and time recognition (non-anaphoric expressions like "12/06/1975").

2. There are rules for the temporal reference recognition (anaphoric temporal expressions that need another complete temporal expression to be understood "*two days before*").

Temporal references could be divided in two groups: time adverbs (i.e. *yesterday, today*) and nominal phrases that refer to temporal relationships (i.e. *two years before*).

Tables 1 and 2 show some rules used for the recognition of dates and the detection of anaphoric temporal expressions, respectively.

3. Coreference resolution based on a temporal model

Previous to coreference resolution, the parser identifies temporal expressions. Temporal expressions can be anaphoric or non-anaphoric. For this reason, we have split the rules for the identification or recognition of temporal expression in two different sets. The first set is made up by the rules for the identification of non-anaphoric temporal expressions (table 1) and the second one is made up by the rule to recognize the anaphoric temporal expressions (table 2). The coreference module should be applied to the temporal expressions recognized by the rules of the second set.

For the coreference resolution we use an inference engine that contains the interpretation for every reference named before. If we compare this system with traditional anaphoric systems, the algorithm for the treatment of temporal expressions needs to carry out an additional step. In our algorithm to solve the coreference of anaphoric temporal expressions, two different tasks can be distinguished:

1. Looking for the antecedent. This task is similar to the traditional approach to anaphora resolution. The algorithm chooses the antecedent from a list of candidates. Two main candidates are usually chosen. The first candidate is related to the date of the text, i.e. the date when the newspaper was written. This date is considered as *default date,* called in this paper *FechaP*. The second candidate is the previous non-anaphoric temporal expressions, called in this paper *FechaAnt* (*two days before* has as antecedent the previous date in the text). If none is found the default date is considered as antecedent. Sometimes, the temporal expression includes prepositional phrase with information about and event or process (*the day of the final match*), in this case the algorithm should look for the date associated to the event or process from the list of candidates. The following process is carried out:

    3. By default, the newspaper's date is used as a base referent (temporal expression) if it exits. If not, the system date is used. ("ayer" *(yesterday)* Day(FechaP) –1 / Month(FechaP) / Year(FechaP).

    4. In case of finding a non-anaphoric temporal expression, it is stored as FechaAnt storing the old FechaAnt in a list of candidates. This value is updated every time that a non-anaphoric temporal expression appears in the text.

2. Providing the new date. Once the antecedent is selected, the new date should be inferred. This new step is related to provide a new date or time. The references are estimated using the antecedent selected in the previous step. This model is based on the two rules below and it is only applicable to these dates that are not *FechaP*, since for *FechaP* there is nothing to resolve

In Table 3 some of the entries of the dictionary used in the inference engine are shown. Moreover, the inference engine has the correspondence between numeric and string expressions of days and months, that is, *one* have the value *1* and *July* is *07*.

The module that makes the estimation of the dates will accede to the right entry in the inference engine in each case and it will apply the function specified obtaining a date in the format *mm/dd/yyyy or* a range of dates. So, at that point the coreference will have been resolved.

date dd + ” /” + mm + “/” + (yy)yy (12/06/1975) *(06/12/1975)*
date dd + “-“ + month + “ -“+ (yy)yy (12-junio-1975) *(12th-June-1975)*
date dd + “de” + mm + “de” + (yy)yy (12 de junio de 1975) *(12th of June of 1975)*
date (“El”) + day_of_week+ dd + ”de”+ month + “de” + (yy)yy (El domingo 12 de junio de 1975) *(Sunday, 12th of June of 1975)*
date month+ ”de”+ yy(yy) (Febrero de 1975) *(February of 1975)*
date dd + ”de”+ month + “de” + (yy)yy + “a las”+ time (12 de junio de 1975 a las 6 y media) *(12th of June of 1975 at half past six)*
dd [“01”|”02”|”03”|….|”31”]

"los"+num+"meses"+ "pasados" *(the num last months)*	[DayI/Month(fechaAnterior) - num / Year(fechaAnterior) - DayF/Month(fechaAnterior) - 1 / Year(fechaAnterior)]

Table 3. Sample of some of the entries of the dictionary

4. Tagging of temporal expressions

Several proposals for the annotation of temporal expressions have been arisen in the last few years (Wilson et *al.* 2001) (Katz and Arosio 2001) since this kind of research has started. In this section, we proposed doing this annotation using XML tags, in order to standardize anaphoric and non-anaphoric temporal expressions.

4.1. XML

In our proposal we have chosen XML to define the set of tags we are going to use. XML stands for *eXtensible Markup Language* and it provides a subset of the SGML (*Standard Generalized Markup Language*). XML offers a non-ambiguous text-based method to develop data structures. XML documents represent data by means of tags.

XML was developed by a Generic SGML Editorial Review Board formed under the auspices of the W3 Consortium in 1996 and chaired by Jon Bosak of Sun Microsystems, with the participation of a Generic SGML Working Group also organized by the W3C (W3C 2002). Since then, the use of XML has been generalizing until becoming the universal standard for data electronic exchange.

XML has specific rules that must be strictly followed in order to make a new document. The XML document must fulfill the set of constraints being established in the *Document Type Declaration* (DTD). This DTD contains the structure of the document, and the validity of a XML document could be tested through this DTD: a well-formed document is valid only if it contains a proper document type declaration and if the document obeys the constraints of that declaration (element sequence and nesting is valid, required attributes are provided, attribute values are of the correct type, etc.).

As a result, XML provides us several advantages to our proposal:

- Both persons and machines easily interpret it. As a consequence that makes easy both the manual and the automatic extraction of dates from a text.
- XML documents are easily tagged from an automatic process, but also a manual annotator could make use of commercial XML editors to develop this task.
- XML is standard.
- A DTD has been built to check the validity of each XML document. So manual and automatic annotations can be automatically tested looking for possible mistakes.

4.2. Annotation schema

An appropriate annotation schema has been defined to mark every temporal expression found. This schema is base on the following ideas:

First, every temporal expression is going to be marked. That includes the markup of dates and times that could be expressed in whatever format, including anaphoric and not anaphoric expression. In this way, the following rules are going to be applied:

a) Full date expressions, that is, non-anaphoric temporal expressions are going to be marked using the standard format for dates: mm/dd/yyyy.

10 de abril de 2002 *04/01/2002*
(*10th of April of 2002*)

b) Full date and time expressions (again, non-anaphoric expressions) are going to be marked in the same way, including in this case the time parameter, in the standard 24-hour format: hh:mm

10 de abril de 2002, a las nueve
04/10/2002, 09:00
(*10th of April of 2002, at nine o'clock*)

c) Time expressions (without explicit date, but referring to an omitted date) are anaphoric expressions. Then, the coreference resolution module is applied before tagging. Once the date of the time is calculated, date and time are tagged.

A las nueve *04/10/2002, 09:00*
(*At nine o'clock*)

d) Some kind of time expressions without explicit date are not anaphoric expressions because they do not refer to an omitted date. In this case only the time parameter is need, so the coreference resolution module is not used.

Todos los días a las nueve *09:00*
(*Everyday at nine o'clock*)

e) Anaphoric date expressions need the coreference resolution module to define the absolute expressions to which they refer to. After that, the appropriate tag will be marked.

El próximo miércoles *04/17/2002*
(*Next Wednesday*)

f) Anaphoric date and time expressions follow the previous rule, calling the coreference resolution previous to be marked.

El próximo miércoles, a las nueve
04/17/2002, 9:00
(*Next Wednesday, at nine o'clock*)

g) Non-anaphoric ranges of dates and/or time are directly tagged by means of the initial and the final date.

Del 10 de abril al 20 de abril de 2002
04/10/2002 — 04/20/2002
(*From 10 of April to 20 of April of 2002*)[1]

El 10 de abril, de 9 a 11 y media
04/10/2002, 9:00 — 11:30
(*10th of April from 9 to half past 11*)

Del 10 de abril de 2002 a las nueve al 20 de abril de 2002 a las doce
04/10/2002, 9:00 — 04/20/2002, 12:00
(*From 10 of April of 2002 at nine o'clock to 20 of April of 2002 at twelve o'clock)*

h) Anaphoric ranges of dates and/or time are previously solved using the coreference resolution module. Then the full date is marked.

[1] Direct translation from Spanish

Del miércoles al jueves 04/17/2002 — 04/18/2002
(From Wednesday to Thursday)

i) What we have called *fuzzy temporal expressions* have not a concrete date or time related to. For this reason the coreference resolution module is useless. However, in order to be identified as temporal expressions we decided to mark them using a special parameter with the "FUZZY" value.

The grammar used to identify anaphoric and not anaphoric expressions acts as a trigger launching the appropriate rule in each case.

4.3. Tag definitions

The structure of tags used to define temporal expression data is the following:

```
< DATE_TIME TYPE="value"
       VALDATE1="value"
       VALTIME1="value"
       VALDATE2="value"
       VALTIME2="value" >
       Expression
</DATE_TIME>
```

In this structure the next elements are used:

- DATE_TIME is the name of the tag for non-anaphoric temporal expressions.
- VALDATE# store the range of dates obtained from the inference engine.
- VALTIME# store the range of times obtained from the inference engine.
- TYPE attribute could have the following values: CONCRETE, PERIOD and FUZZY:
  - § CONCRETE is referring to only a date.
  - § PERIOD is referring to a period of time.
  - § FUZZY attribute is used when we really do not know the date or period of time when a temporal expression is referring to.

Moreover, VALDATE1, VALDATE2, VALTIME1 and VALTIME2 are optional attributes:

- VALDATE2 and VALTIME2 are used to establish ranges. So, if we try to tag a concrete date (TYPE adopt the value CONCRETE) then these attributes are omitted.
- VALTIME1 could be omitted if only a date is specified.
- VALDATE1 could be omitted if only a time must be specified. This is the case in which the date does not mind. For example, *todos los días a las nueve* (*everyday at nine o'clock*). However, when only a time expression is specified, such as *a las nueve* (*at nine o'clock*), the VALDATE1 of this time must be computed.

The use of XML allows us to take advantage of the XML schema in which the tag language is defined. This schema let an application know if the XML file is valid and well-formed. The schema defines the different kind of elements, attributes and entities that are allowed, and can express some limitations to combine them. Moreover, use the same syntax as XML and the schemas are extensible. Once the XML file has been generated, a parser of our XML needs to be defined to make the information useful.

Tables 4a and 4b show several examples for tagging temporal expressions (non-anaphoric and anaphoric). Table 5 shows an example of an annotated text in which the features of the used tags are shown. In this example we assume that the newspaper's date is 04/25/2000. The system, for the reference "el próximo año"*(the next year),* will return "01/01/2001-12/31/2001". For the reference "mañana" *(tomorrow)* it will return 04/26/2000.

ABSOLUTE TAGS (non-anaphoric temporal expressions)
<DATE_TIME VALDATE1="06/12/2001">12 de junio de 2001</DATE_TIME>
<DATE_TIME VALDATE1="06/12/2001" VALTIME1="20:30">12 de junio de 2001 a las ocho y media de la tarde</DATE_TIME>
<DATE_TIME VALDATE1="06/12/2001" VALTIME1="20:00" VALDATE2="06/12/2001" VALTIME2="21:00" >12 de junio de 2001 entre las ocho y las nueve de la tarde</DATE_TIME>

Table 4a. Sample of the tags generated by this system

REFERENCE TAGS (anaphoric temporal expressions)
<DATE_TIME_REF VALDATE1="06/11/2002">ayer</DATE_TIME_REF> <DATE_TIME_REF VALDATE1="01/01/2002" VALDATE2="12/31/2007">los 5 años siguientes</DATE_TIME_REF>

Table 4b. Sample of the tags generated by this system

"La oficina de Congresos de la Universidad ha propuesto 5 congresos para **<DATE_TIME_REF TYPE= "PERIOD" VALDATE1="01/01/2000" VALDATE2= "12/31/2000>** este año**</DATE_TIME_REF>**, sin embargo, el crecimiento para **<DATE_TIME_REF TYPE="PERIOD" VALDATE1= "01/01/2001" VALDATE2="12/31/2001>** el próximo año**</DATE_TIME_REF>** será superior a los 15. Por otro lado, el Director de la oficina ofrece **<DATE_TIME_REF TYPE= "CONCRETE" VALDATE1= "04/26/2000" >** mañana**</DATE_TIME_REF>** una conferencia."

(The University Conference Office has proposed 5 conferences for **<DATE_TIME_REF TYPE="PERIOD" VALDATE1="01/01/2000" VALDATE2="12/31/2000>** *this year* **</DATE_TIME_REF>**, *however, the increase for* **<DATE_TIME_REF TYPE="PERIOD" VALDATE1= "01/01/2001" VALDATE2="12/31/2001>** *the next year* **</DATE_TIME_REF>** *will be over 15. On the other hand, the Office Manager offers* **<DATE_TIME_REF TYPE= "CONCRETE" VALDATE1= " 04/26/2000" >** *tomorrow* **</DATE_TIME_REF>** *a lecture).*

Table 5. Example of annotated text

5. System evaluation

For implementing the system we need two different units, it is necessary to implement a parser and for that we have used LPA Prolog, because this language is based on rules as the parser is. The other unit is implemented in Visual Basic because this language has several time functions. This unit generated the XML tags too. The implementation of a XML parser is an optional possibility. The evaluation of the system has been done with a sample extracted from 16 articles that belong to the digital edition on the Internet of two Spanish newspapers describing different topics. The results obtained for the articles showed a precision and a recall of 95.59 % and 82.28% respectively.

The total has been calculated according to the number of successes being 195, the number of treated references is 204 and the number of total references is 237.

5.1. Error analysis

However, some fails in the system have been detected and we show their possible improvements below:

- The unit that resolves temporal references is not able to resolve undetermined temporal references like "hace unos cuantos días" (*some days before*) accurately. Here, one possible solution is the use of the semantic information. For example, if the sentence is "*some days before*", the system will suppose that is less time than a week, because we usually use the word "*week*" referring to seven days.

- It is possible that we have non-anaphoric expressions that make reference to an event or a fact and, despite they are not temporal expressions themselves, they mean a date or period of time too. For example: "ganó el mundial y al día siguiente se lesionó" (*he won the World Champion and the next day he hurt himself*).

- In newspaper articles, sometimes we find expressions like "el sábado hubo un accidente" (*Saturday there was an accident*). To resolve this expression we should know some extra information of the context where the reference is. This extra information could be the sentence verb. If it is a past verb that means that the sentence is

referring to *the last Saturday*. However, if the verb is future, it is referring to *the next Saturday*. In our system, we are not using this kind of information, so we assume that this kind of reference if referring to the last day, not the next, because the news usually tells us facts occurred previously.

6. Conclusions

In this paper a system for temporal expressions recognition in Spanish and their reference resolution has been presented, based on a temporal model proposed. The system has two different units: the parser based on a temporal expression grammar, which allows to identify these kind of expressions and a coreference resolution unit which is based in a inference engine and make a transformation of the expressions to dates, resolving their reference in this way. The evaluation of the system shows successful results of precision and recall for our proposal.

For future works, it is pretended to extend the system with the temporal references that are not treated in this paper. Moreover, the study of the verbal forms in the sentences where the references are found will improve the efficiency of the system solving some kind of expressions.

Abstract

Many natural language processing applications, such as information extraction, question answering, topic detection and tracking, and multi-document summarisation, would benefit significantly from the ability to accurately position reported events in time, either relatively with respect to other events or absolutely with respect to calendrical time. However, only recently has concerted work started on the automatic extraction of temporal information from text. The overall aim of our work is to automatically establish the temporal relations holding between events as well as between events and calendrical times in newspaper articles. This information makes it possible to create a 'time-event graph' to represent the temporal information contained in a text, and would in turn support the applications mentioned above. In this paper we first argue for the superiority of the time-event graph over a time-stamped event sequence as a target representation for extracted temporal information and discuss the importance of annotating temporal relations. We then give a brief account of the annotation scheme we have devised which allows us to annotate relational information as well as temporal referring expressions. We also discuss a pilot study in which we assessed the utility and feasibility of the scheme and the annotation tool we have developed to aid the annotation process. Finally, we discuss potential improvements in the annotation tool which are aimed at making the annotation of larger scale corpora possible.

1. Introduction

Many natural language processing applications, such as information extraction, question answering, topic detection and tracking, and multi-document summarisation, would benefit significantly from the ability to accurately position reported events in time, either relatively with respect to other events or absolutely with respect to calendrical time. However, only recently has concerted work been started on the automatic extraction of temporal information from text.

In addressing the goal of extracting temporal information from text, it is necessary to:

1. specify the target temporal representation which we wish to obtain for a text;
2. identify ancillary information which we **may** want to extract because of its utility in arriving at the target temporal representation (by analogy with, e.g. part-of-speech tagging or parsing as intermediate goals towards semantic interpretation).

For example, one candidate for target representation is an association of a calendrical time point or interval with each event in a text, i.e. a list of pairs of calendrical times and events. Arriving at this representation might require extracting additional information, such as temporal relational information, about events. For example, assigning "before 1984" to an event A might only be possible by recognising that event B occurs in 1984 and that A occurs before B. Thus, the capability to determine temporal relations between events might be a useful component capability in a temporal information extraction system, even if the information identified by such a component is not directly included in the target representation.

Our view is that target representation should be a **time-event graph** where the nodes in the graph are either times or events and the arcs are temporal relations. This is somewhat different from the "time-stamping" representation introduced in the preceding paragraph and one of our major goals in this paper is to argue that it is a superior representation.

With respect to ancillary temporal information to be extracted, our view is that time-referring expressions, event representatives, and temporal relations as signalled by, e.g. prepositions and temporal adverbials, all convey important temporal information and should be extracted. This information is necessary to derive a time-event graph for a text; but of course it is useful for creating a time-stamp representation as well – arguably both necessary and sufficient.

In this paper, we first give an overview over existing approaches to temporal annotation and information extraction in Section 2. Then in Section 3. we discuss the importance of a target representation that captures temporal relations and describe the annotation scheme we have developed to do so. Section 4. presents some results of a pilot study we have conducted based on the scheme. Further improvements to the process of annotation, to support the creation of larger annotated resources, are discussed in section 5.

2. Overview of Existing Approaches

Existing approaches to capturing temporal information in text can be divided broadly into the following three groups: (1) approaches that concentrate on an accurate and detailed annotation of temporal referring expressions, (2) time-stamping approaches that aim to associate a calendrical time with some or all events in the text, and (3) approaches that focus on the temporal relations between events and times, between events and events or both. We give a brief overview of existing work on each approach in this section.

2.1. Annotating Temporal Referring Expressions

The most extensive work on annotating temporal referring expressions so far has been done as part of the MUC language technology evaluations or the subsequent TIDES[1] and ACE [2] programmes.

2.1.1. MUC Named Entity Task

Between 1987 and 1998 the DARPA-sponsored Message Understanding Conferences (MUCs) developed a quantitative evaluation regime for message understanding (MU) systems, now generally called information extraction (IE) systems. The last MUC, MUC-7, was held in 1998, but related work continues within the ACE workshops. For more information about the message understanding conferences see MUC (1998).

While MUC evaluations typically defined several evaluation tasks, the relevant task here is the *named entity (NE) recognition* task, introduced in MUC-5. The NE task required the recognition and classification of specified named entities such as persons, locations, organisations, monetary amounts and, most importantly in the current context, time expressions (timex). The aim of the timex task was to mark up time expressions in text using SGML tags and to classify these expressions using a TYPE attribute. Type DATE referred to complete or partial date expressions and type TIME referred to complete or partial expressions of time of day. Both absolute and relative time expressions had to be marked up, although these two types were not distinguished in the annotation.

In the MUC-7 evaluation, the best systems were able to obtain F-measure scores approaching 94% on this task.

2.1.2. An Annotation Scheme for Temporal Expressions

Wilson et al. (2001) describe a set of guidelines[3] being developed within the TIDES programme for annotating time expressions and associating with them a canonical representation of the times to which they refer. A method for extracting such time expressions from multiple languages is also introduced. The main novel features as compared to the MUC temporal annotation task are:

1. In MUC the task called merely for surface time expressions to be annotated and crudely classified, whereas the Wilson et al. (2001) guidelines also call for each expression to be *evaluated*, i.e., to have associated with it a normalised representation of the time referred to.

2. The range of expressions flagged is much wider.

3. Context-dependent time expressions like *today* are handled in addition to fully specified time expressions like *September 3rd, 1997*. Context can be local (within the same sentence) or global (outside the sentence). Indexical time expressions, that require knowledge about the time of speech, like *now* are also included. A corpus study (Wilson and Mani, 2000) showed that two-thirds of time expressions in print and broadcast news are context dependent, so this feature is significant.

Wilson et al. (2001) have developed a tagger to do time expression tagging as described in the TIDES guidelines, and report F-measure scores of 96.2% on expression identification and 83.2% on evaluating these expressions.

2.2. Time-Stamping of Events

Annotating temporal referring expressions is only a first step towards extracting rich temporal information from text. The approaches introduced in this section aim at 'stamping' some or all events in a text with a calendar time – possibly the time value of an associated temporal referring expression.

2.2.1. MUC-5 and MUC-7 Time Slots

In addition to the Named Entity time expression tagging task, MUC-5 and MUC-7 also required relations between times and events to be established as part of the scenario template task. Participants were required to assign a calendrical time to certain specified event types (joint venture announcements and rocket launchings, respectively).

Scenario template filling requires the identification of specific relations holding between template elements. For example, the MUC-7 scenario template filling task concerned rocket launch events. The scenario template contains information about vehicles, pay load, launch site, mission function etc. It also contained a slot called LAUNCH_DATE, which was to be filled with a link to a time entity which in turn contained slots for a normalised representation of the start and end times of the temporal interval containing the launch event, if the interval could be determined from the text.

Temporal relations between events and other events were not explicitly addressed, though insofar as they were necessary to infer correct slot fills, systems needed to take them into account. Scores were quite low on this slot reflecting the difficulty of correctly assigning to it.

2.2.2. Assigning Time-Stamps to Event Clauses

In the MUC task, times were only to be determined for the events of interest, the scenario events. A more ambitious goal is to attempt to associate calendrical times or time intervals with *every* event in a text.

Filatova and Hovy (2001) describe a method for breaking news stories into their constituent events and assigning time-stamps to them. The time-stamps assigned are either full specified calendrical dates, sets of dates, closed date ranges (both end points specified), or date ranges open at one end or the other, indicating some time before or after the specified date.

The syntactic units conveying events are assumed to be simple clauses and they are identified using a parser which produces semantically labelled syntactic parse trees. Some problems are ignored in this approach, for example multiple verbs with different tenses in one sentence.

The time-stamper uses two time-points for anchoring. One time-point is the time of the article (at the moment only the date is used and the time of day is not taken into

[1] See http://www.darpa.mil/ipto/research/tides/.

[2] See http://www.itl.nist.gov/iaui/894.01/tests/ace/.

[3] The full set of guidelines are available as Ferro et al. (2000)

account) and the other time-point is the last time-point assigned within the same sentence. The procedure of time-stamping is as follows:

1. The text is divided into event clauses
2. All date phrases in the text are extracted
3. A date is assigned to each event clause based on either
   (a) the most recent date phrase in the same sentence, or
   (b) if this is not defined, then the date of the article.

In assigning dates various time assignment rules are used. When a date phrase is present in the sentence these rules both take into account nearby prepositions, such *on, after, before*, and carry out fuller specification. For example if the date phrase is simply a day of the week, then the article date is also used to derive a date-stamp that is fully specified with respect to year and position within the year. If no date phrase is present in the sentence then tense information is used to assign a time interval relative to the date of the article.

After all events have been stamped with a time, the event clauses are arranged in chronological order. The authors report scores of 77.85% correct time-stamp assignment to event clauses which have been manually (i.e. correctly) extracted from sample texts of a small trial corpus.

2.2.3. Temporal Semantic Tagging of Newswire Texts

The ultimate goal for Schilder and Habel (2001), as for ourselves, is to establish the temporal relations between all events in news articles.

In Schilder and Habel's approach temporal expressions are classified into *time-denoting expressions* that refer to a calendar or clock time and *event-denoting expressions* which refer to events. They view their goal as anchoring these temporal expression on the absolute time-line, so as to produce a linearly ordered anchored set of temporal entities; hence a time-stamp representation appears to be their target representation. For time-denoting expressions this may mean resolving indexicals (*now*, *yesterday*) or fleshing out expressions like *Thursday* to fully specified calendar dates. For event-denoting expressions a calendar time which is the time of the event must be associated with the event, possibly by extracting temporal relations which are signalled by prepositional phrases like *on Friday*. The set of temporal relations proposed is *before, after, incl, at, starts, finishes* and *excl* (equivalent to Allen (1983)'s relations).

They have developed a semantic tagging system for temporal expressions in newswire articles. The main part of their system is a Finite State Transducer (FST) based on handwritten rules. Their target language is German. The FST tags all time-denoting expressions, all verbs and an experimental version tags event-signalling nominal expressions. A semantic representation is then proposed, based on which inferences are drawn, especially about temporal relations. In its current state, the FST establishes temporal relations between times and events. The tagger was evaluated with respect to a small corpus (10 news articles) and an overall precision rate of 84.49% was achieved.

2.3. Annotating Temporal Relations

The work described in the preceding section aims at associating a calendar time with some or all events reported in a text, but none of these approaches view the identification of temporal relations as a explicit goal in its own right. These temporal relations are clearly of importance, even for time-stamping approaches. The work described in this section, as well as the approach we develop in the next section, address temporal relations directly.

2.3.1. Annotation of Intrasentential Temporal Information

Katz and Arosio (2001) aim to create a large multilingual corpus, in which intrasentential temporal relations are tagged in addition to standard morphological and syntactic features. To aid this, they have developed a language-neutral and theory-neutral method for annotating sentence internal temporal relations. With this corpus, Katz and Arosio (2001) hope to be able to automatically acquire the lexical knowledge required for determining temporal interpretation in narrative discourse.

A temporal interval is associated with each verb in the sentence; it is the temporal relations between these intervals that are of concern. The temporal interpretation should be closely linked to the syntactic context (which is of importance since it is not known beforehand to what degree the cues used by the speaker are lexical and to what degree they are grammatical). This linking is needed to keep track of both the semantic relations among times as well as the syntactic relations among the words in the sentences that refer to these times.

The authors add a layer of semantic annotation to already syntactically annotated text. The verbs in the sentence are linked via secondary edges labelled with a temporal relation. Precedence and inclusion and their duals are the possible relations. Indexical information is included by introducing the symbol $\circ$ for the speech time, which is automatically prefaced to all sentences prior to annotation.

A searchable multi-language annotated treebank has been created where each sentence is stored in a relational database with both syntactic and temporal annotations. This makes is possible to query the corpus ("Find the sentences containing a relative clause which is interpreted as temporally overlapping the main clause" (Katz and Arosio, 2001)).

This work is valuable, especially for linguists interested in the studying, cross-lingually, the complex interrelationship of lexical and syntactic mechanisms used to convey temporal relations between events in the same sentence. However, if one's goal is extraction of the full temporal content of a text, it is limited in only considering intrasentential temporal relations.

3. Annotating Temporal Information in Text

From the preceding overview of existing work on temporal information extraction it is clear that the bulk of work so far has gone into the identification of temporal referring expressions and the assignment of time-stamps to events. Only Katz and Arosio (2001) focus directly on the prob-

lem of identifying temporal relations between events, and in their case only between events in the same sentence.

In this section we start by arguing that a time-event graph, in which not all events are necessarily directly anchored on a time-line, is a superior target representation for a text to a time stamped representation. We then present the conceptual underpinning for the approach we advocate for annotating temporal information in text, followed by the details of the annotation scheme itself.

3.1. Why Annotate Temporal Relations?

Recall that a time-event graph is a graph in which the nodes are either times or events and the arcs are temporal relations. There are two principal arguments for preferring a time-graph representation to a time-stamp representation.

First, in many cases texts position events in time only by relation to other events and any attempt to coerce these events onto a time-line must either lose information, invent information, or rely on a notion of an underspecified time point constrained by temporal relations (i.e. introduce a representation of temporal relations by the back door).

Consider this example:

> After the plane crashed, a search was started. Afterwards the coast guard reported finding debris.

and assume that an earlier sentence specifies the calendrical time of the plane crash.

An approach attempting to map the information presented in this example onto a time-line is faced with the situation depicted in Figure 1.

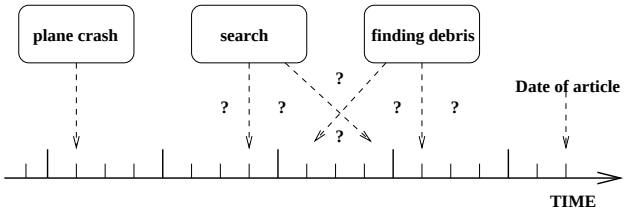

Figure 1: A Time-line Representation

While the crash event can be placed on the time-line the other two events cannot. Either time points must be guessed, or an interval be assigned. The first option is clearly not satisfactory. But if an interval is assigned the only possible interval, for both the searching and finding events is the interval from the crash till the date of the article. But if this is assigned to both events then the information about their ordering with respect to each other is lost.

A simpler representation which while not attempting to be as specific actually carries more information is shown in Figure 2.

This representation preserves the information that the searching event precedes the finding event, without forcing any early commitment to points on a time-line.

The second argument for preferring a time-event graph representation that captures event-event temporal relations as well as time-event relations is that to position events on a time-line accurately requires the extraction of event-event relational information. In the example, the placing of the searching and finding events in the interval between the plane crash and the date of the article requires the recognition that these events occurred after the crash as signalled by the words “after” and “afterwards”. Without identifying the relations conveyed by these words the searching and finding events could only be positioned before the time of the article, and not following the plane crash. Thus, even if a time-stamp representation is viewed as the best target representation, achieving it requires the extraction of temporal relational information. In this case adopting a time-event graph as an intermediate representation is still a good idea, which begs the question of why it should not simply be taken as the final target representation.

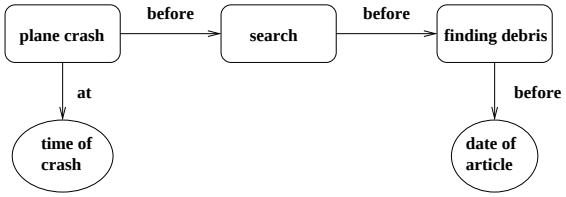

Figure 2: A Time-Event Graph Representation

3.2. Conceptualising Time

Before we describe the annotation scheme we have developed, we will very briefly explain what kind of temporal entities and relations we suppose exist. We presume the world contains the following primitives: events, states, times, temporal relations and event identity. Each primitive is described briefly below.

Events Intuitively an event is something that happens, something that one can imagine putting on a time map. Events can be ongoing or conceptually instantaneous, we do not distinguish between these. What defines an event is very much dependent on the application and domain, but generally events have to be anchorable on a time-line and they are usually conveyed in language by finite verbs or by nominalisations. Examples of events are:

> *A small single-engine plane **crashed** into the Atlantic Ocean.*
>
> *The 1996 **crash** of the TWA 747 remains unexplained.*

Times Like events, times can be viewed as having extent (intervals) or as being punctual (points). Rather than trying to reduce one perspective to the other, the focus of much of the philosophical debate on time, we shall simply treat both as *time objects*. A time object must, however, be capable of being placed on a time-line (fictional or real).

Following general convention, and the approach taken in MUC, we distinguish between two classes of time objects, DATES and TIMES, time objects which are larger or smaller than a day, respectively.

States A state is a relation between entities or the holding of an attribute of an entity which, while capable of change, is ongoing over a time span, usually longer than the time span covered by the text of interest. Examples are:

> *The plane, **which can carry four people**, ...*

*The water **is about 125 feet deep** in that area.*

Typically, a change of state constitutes an event. At this point we are less interested in states, and we have not taken them into account in our annotation scheme.

Temporal Relations Events stand in certain temporal relations to other events and to times. Times are temporally related to other times as well, but this phenomenon is not only very rarely explicitly expressed in text, it is also of lesser importance and is not taken into account here.

*The plane crashed **after** the pilot and his crew ejected.*

*A small single engine plane crashed into the Atlantic Ocean **on** Wednesday.*

The full set of temporal relations we suppose at present is { *included, includes, after, before, simultaneous* } . This is a minimal set, which was defined after analysing a number of newspaper articles, and can easily be expanded.

3.3. The Annotation Scheme

Given this conceptual framework, we can describe the annotation scheme we have defined. For more details see Setzer and Gaizauskas (2000).

Annotating Events Events are marked by annotating a representative in the clause conveying the event. The first choice for a representative is the head of the finite verb group. If a nominalisation conveys the event, then the head of the nominalisation serves as the representative. In the rare case of an event being conveyed by a non-finite clause, the non-finite verb is marked as the representative.

An events carries attributes for some or all of the following properties: unique event ID, event class, verb tense, verb aspect, other event to which it is related and temporal relation by which it is related, time object to which it is related and temporal relation by which it is related, the word(s) by which the temporal relation is signalled, and the ID of events it might have as an argument. For example, ignoring temporal relations for the moment:

A small single-engine plane
<event eid=16 class=OCCURRENCE tense=past>
crashed
</event>
into the Atlantic Ocean about eight miles off New Jersey

Annotating Times We distinguish between *simple* and *complex* time referring expressions. Simple time referring expressions refer to times directly, as in example (1). Complex time referring expressions, as in (2), refer to a point in time by relating (*after*) an interval (*17 seconds*) to an event (*hearing the sound*). The point in time referred to is the point at the end of the interval.

(1) *last Thursday*

(2) *17 seconds after hearing the sound ...*

For simple time referring expressions we annotate the whole text span conveying the time-object:

<timex tid=5 type=DATE calDate=12041997>
last Thursday </timex>

Each time referring expression has a unique ID, an attribute flagging whether it is a time or a date, and an attribute carrying the calendar date the expression refers to.

Complex time referring expressions, like the one in example (2), include a time interval (*17 seconds*), a preposition (*after*) and an event (*hearing the sound*) or time. The way these are annotated is similar to the way events are annotated. The interval is chosen as the representative for the time referring expression and related to the event expression via the temporal relation, usually signalled by the preposition.

<timex tid=5 type=complex eid=3 signalID=7
relType=after> 17 seconds </timex>
<signal sid=7> after <signal>
<event eid=3> hearing</event> the sound...

Annotating Temporal Relations Events and times can be related to other events or times. If two events are related then one of the events carries the ID of the other as well as the temporal relation in which they stand to each other. If an event is related to a time then the event carries the ID of the time object and the temporal relation. In either case, if the relation is signalled explicitly in the text, then the ID of this signal is an attribute as well, as the following two examples illustrate.

All 75 people on board the Aeroflot Airbus
<event eid=4 class=OCCURRENCE tense=past
relatedToEvent=5 eventRelType=simultaneous
signal=7>
died </event>
<tr_signal sid=7> when </tr_signal>
it
<event eid=5 class=OCCURRENCE tense=past >
ploughed </event>
into a Siberian mountain.

A small single-engine plane
<event eid=9 class=OCCURRENCE tense=past
relatedToTime=5 timeRelType=included
signal=9>
crashed </event>
into the Atlantic Ocean about eight miles off
New Jersey
<tr_signal sid=9> on </tr_signal>
<timex tid=5> Wednesday </timex>.

If the temporal relation is implicitly expressed, then the only difference is that the attribute for the signal is simply left out.

One problem with this annotation scheme is that it is not possible to relate one event to two or more other events or times, though by and large we have not found this to be a problem in annotating real text. This problem has been addressed by the TERQAS[4] workshop, which is working towards defining a general time markup language and has adopted many aspects of the current annotation scheme.

[4]See http://www.cs.brandeis.edu/ jamesp/arda/time/.

The solution proposed there is to introduce independent SGML `LINK` entities, which consume no text, to serve as relational objects tying events and times together. One event can then participate in as many links as is necessary.

4. The Pilot Study

To study the feasibility of the annotation scheme and to gain insight into the linguistic mechanisms conveying temporal information in text, we have applied the annotation scheme to a small trial corpus.

4.1. The Corpus

The trial corpus consists of 6 newswire articles taken from the New York Times, 1996, which were part of the MUC7 (MUC, 1998) training data. Basic statistics about the corpus are presented in table 1.

	sentences	words	number of annotators
text1	26	448	3
text2	18	333	2
text3	13	269	3
text4	13	213	2
text5	10	211	3
text6	13	399	3
total	93	1873	3

Table 1: The corpus

Each text was annotated by either two or three annotators, in addition to one of the authors, who produced what in the following is taken to be the 'gold standard' or 'key' annotation.

4.2. The Process of Annotation

The annotation takes place in two stages, both of which are described briefly in this section. To aid the annotator with her or his task, we have developed an annotation tool which not only allows the annotation of the information required by the scheme but which also interactively supports the annotator during the second phase, where additional temporal relations are established.

Stage I During Stage I, all event and time expressions are annotated as well as all signal expressions. Afterwards, those temporal relations that are explicitly expressed, e.g. by temporal prepositional phrases or subordinate clauses, and hold between events or events and times are established and stored as event attributes. Some implicitly expressed temporal relations are also established during this stage, for example, when events are clearly positioned in time but the signal expression has been omitted, as in *The army said Friday [...]*. In addition, *ing*-clauses without a subject can also be used to implicitly express a temporal relation between two events and are annotated during this stage.

Stage II The annotation scheme we have developed is aimed at establishing as many temporal relations in the text as possible. To relieve the burden on the annotator, and to increase the number of temporal relations annotated, we introduced stage II, which is cyclical in nature. Based on the information available, which in the beginning consists of the events, times and the temporal relations annotated in stage I, all inferences possible are drawn, according to an axiomatisation of the temporal relations *included, includes, after, before, simultaneous*. This is conducted automatically by the annotation tool which computes the deductive closure over these temporal relations. If the temporal relation between any pair of events or events and times is still unknown, the annotator is prompted for one of these [5] and, again, all possible inferences are automatically drawn. The process continues until every event-event and event-time pair in the text has been related.

4.3. The Results

In this section, we briefly describe the distribution of temporal phenomena over the trial corpus, as far as this is relevant to the issues discussed in this paper. Note that although this is a trial corpus, the results are indicative. We will not talk here about recall and precision values of the individual annotators with respect to the gold standard here – see section 5. For more information about the pilot study and its outcome see Setzer (2001).

Table 2 shows the number of event expressions, time expressions, and the number of event-event relations annotated in each text of the corpus in Stage I of the annotation process – i.e. these are the temporal relations that are explicitly expressed in the texts.

	# sentences	# words	# event expr.	# event-event relations	# event-time relations
text1	26	448	40	10	12
text2	18	333	30	10	5
text3	13	269	19	7	3
text4	13	213	27	5	0
text5	10	211	16	1	4
text6	13	399	26	13	5
total	93	1873	158	46	30

Table 2: Number of event expressions and explicit temporal relations per text

Table 3 shows for each text the number of event and time expressions in the text, the number of explicit temporal relations annotated in Stage I, the number of relations inferred from these without any further input from the annotator, the number of relations solicited from the annotator (i.e. the implicit temporal relations), and the number of inferred temporal relations overall.

4.4. Discussion

In Section 3.1. we criticised the time-stamped event sequence as a target representation on two grounds:

1. Forcing events to be placed on a time-line may result in the loss of event-event ordering information,

[5] Note that *unknown* is a possible value for a temporal relation here.

	event + time expr.	annotated ev.-ev. and ev.-time relations	inferred relations based on annotated relations	solicited rel.	total inferred relations
text1	32 + 11	10 + 12	222	124	1005
text2	26 + 5	10 + 5	122	93	380
text3	17 + 3	7 + 3	21	49	141
text4	18 + 0	5 + 0	8	45	120
text5	10 + 4	1 + 4	13	18	110
text6	24 + 5	13 + 5	107	52	514
total	127 + 28	46 + 29	493	381	2270

Table 3: Annotated, solicited, and inferred temporal relations

since the time-stamps assigned to distinct events may be identical even though we know the events occurred at separate times and know their order.

2. Event-event relational information must be extracted in order to position events on a time-line. Given this, why not choose a target representation that includes this richer information.

While both of these observations are true in general, ideally we would like to substantiate them empirically and quantitatively with respect to the trial corpus. Unfortunately we have not as yet been able to carry out the analysis for the whole corpus. However, we have chosen one text from the corpus (text6) and investigated it in detail.

To corroborate the first point above, we read text6 and, assuming perfect knowledge of the temporal information contained, then represented this information on a time-line, associating an interval with each event. In other words, without worrying about *how* the temporal information is extracted we time-stamped each event, where each time-stamp contains a start and end time expressed as calendar dates or, for at most one of the times, a symbol indicating the time is unknown.

For example, the sentences *A senior investigator looked at the wreckage Tuesday* and *Flight 800 exploded midair 20 days before Tuesday and then plunged into the ocean*[6] can be represented on a time-line as shown in Figure 3.

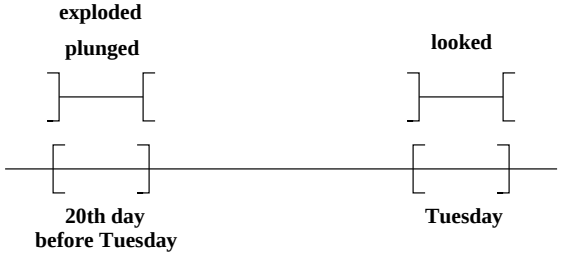

Figure 3: Example of a time-line Representation

Note that the events *exploded* and *plunged* have to be associated with the interval which encompasses the 20th day before Tuesday. We have lost the information that the plane plunged into the ocean **after** the explosion. This information can be easily represented in a time-event graph, as shown in figure 4.

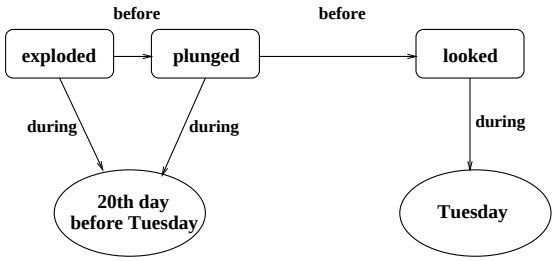

Figure 4: Example of a time-event graph Representation

Overall, 7 event-event relations that were explicitly mentioned in the text were lost in the time-line representation. While we have not performed the detailed analysis to let us say how many of the 514 inferred temporal relations in text6 are dependent on these 7 relations, it seems fair to assume that a significant number are.

To corroborate the second point we investigated how many of the 107 relations inferred for text6 from the explicitly annotated event-event and event-time relations resulted in new event-time relations involving events for which no event-time relation existed already. This corresponds to the intuitive notion of how many events are placeable on the time-line solely due to event-event relational information. For text6 we discovered that 20 of the 107 new relations were time-event relations for events for which no previous time-event relation existed. These 20 relations mentioned 4 distinct events (i.e. these 20 relations involved relating 4 events to different times, perhaps redundantly, but also potentially defining separate start and end points for intervals associated with them). Thus, 4 of the 24 events in text6 can be placed on a time-line using event-event relational information which is explicitly present in the text – positional information that otherwise would either be lost or require knowledge of implicit relations to extract.

Finally, we can make the general observation of the trial corpus that from 127 event-event relations plus 28 event-time relations, a total of 2270 additional temporal relations has been inferred. Even though we do not have the exact figure of how many of these inferred temporal relations are based on annotated event-event relations, it seems likely that the event-event relations contribute significantly to the number of relations inferred. We base this observation on the fact that there are nearly twice as many event-event relations as event-time relations annotated, and that subsequent inferences in the deductive closure calculation build on these initial relations. This observation adds weight to our claim that annotating event-event relations is important for temporal information extraction.

5. Improvements to the Annotation Process

The pilot study has shown that the interannotator agreement and the recall and precision figures need to be improved and that the burden on the annotator needs to be lessened, before the annotation scheme can be used to cre-

[6]The sentences have been slightly altered to make them more comprehensible out of context, but the temporal information they convey is the same as in the original text.

ate a larger corpus. Larger corpora will be necessary to train and evaluate temporal information extraction systems.

In Setzer and Gaizauskas (2001) we identified five main causes of low annotator precision and recall scores (with respect to the gold standard): imprecision/incompleteness of the guidelines; imperfect annotator understanding of the task; intrinsic difficulty of identifying the appropriate temporal relation in some cases; annotator fatigue; and annotator carelessness. In this section we do not address all of these problems, but focus on a number of proposals to enhance the annotation process, thereby lightening the load on annotators and increasing the accuracy of the annotations.

Pre-tagging An automatic first annotation pass could be used to reduce the amount of manual annotation and to raise recall. A part-of-speech tagger or word group parser, could be used to mark up finite verbs and signals and a time expression tagger such as Wilson et al. (2001)'s could be used to tag time referring expressions. Using the corpus as an indication, we know that a large percentage of the finite verbs will indicate events and the annotator can easily add attribute information to those or delete the mark up of mistakenly flagged verbs which do not indicate events. The high accuracy of time expression taggers mean that most of the work of tagging time expressions would be done automatically with the annotator left only to confirm details and scan for missed expressions.

Signals are a slightly different case. These are mostly prepositions and subordinating conjunctions, but a smaller number will have to be marked up. Here we have two options. We can mark up all prepositions and conjunctions and leave it to the annotator to delete inappropriate annotations, which is an easy process. Alternatively we could only automatically annotate those prepositions which are followed by a time referring expression. This approach carries the danger of not pre-annotating all signals, and the annotator, concentrating on the pre-annotated sections, might not catch all signals.

Intelligent Interaction with the Annotation Tool: Question Ordering The second phase of stage II of the annotation process, during which the deductive closure over the temporal relations is calculated and the annotator is prompted for unknown temporal relations, is problematic for the following reasons.

1. It is a long process, during which the annotator was prompted for 62 temporal relations per text on average, even for the short texts in the pilot corpus.

2. There is, for now, only marginal consistency checking and it is not possible to correct errors. Once the annotator notices that she or he made a mistake earlier in the process, then the whole stage II annotation process has to be restarted.

One possible solution for the first problem would be to optimise the order in which unknown temporal relations are prompted for. As we explained in section 4.2., after each temporal relation solicited from the user, all possible inferences are drawn. The larger the number of the inferences, the smaller the number of remaining unknown temporal relations will be. The following simple example illustrates the effect non-optimal soliciting can have. Imagine four events, forming a 'precedence chain':

$$e_1 < e_2 < e_3 < e_4$$

Imagine also that the link between e_2 and e_3 is missing in the response:

$$e_1 < e_2 \qquad e_3 < e_4$$

If the first question establishes the temporal relation holding between e_2 and e_3, then all other temporal relations can be inferred, based on the transitivity of before. The temporal model can be completed with one question. However, the order of questioning could be very different, establishing the temporal relations between e_1 and e_4, then between e_1 and e_3, e_2 and e_4 and then between e_2 and e_3. In this case four questions are asked to establish the relations holding between them.

Thus, question order can be important in determining how many questions the annotator ultimately gets asked. Clearly, one wants to minimise the number of questions asked, but it is not clear (to us) whether there is a question order that is guaranteed to minimise this number, and if so how to determine it. We propose to investigate initially a naive approach in which given two temporally-ordered event chains we first ask questions which attempt to link their end points, simply on the grounds that such questions could lead to maximal gains. However, considerably more empirical and theoretical investigation needs to be carried out here.

Intelligent Interaction with the Annotation Tool: Correcting Mistakes The second point requires a more elaborate solution. Once an incorrect temporal relation has been added an indeterminate number of further incorrect inferences may have been drawn on the basis of it. Two solutions suggest themselves:

1. Provide the possibility of check-pointing, i.e. saving intermediate stages to which the annotator can return when an error has been detected. This could be done automatically after each new user-solicited relation is added. This has the advantage of being easy to implement but the disadvantage of erasing possibly correct temporal relations added after the error, but independently of it, with the consequence that work that will have to be redone unnecessarily.

2. Implement a sort of truth maintenance system (Doyle, 1987; de Kleer, 1987), whereby only the incorrect temporal relation and those temporal relations which were inferred from it are deleted. This has the advantage of minimising the amount of work the annotator needs to redo unnecessarily, but the disadvantage of being more complex to implement.

Clearly the second solution is the better in the long run, as annotator effort is the chief quantity to conserve. We are working on solution whereby all temporal relations added to the temporal fact database record with them a justification which includes a reference to any facts from which they have been derived. Removing a temporal fact f then becomes a recursive procedure which begins with a search

for all facts f' whose justification mentions f followed by a recursive call to delete f'. This will ensure that all dependents of f will be removed, while not touching any facts, solicited or derived, that may have been added after f in the annotation process, but which are logically independent of it.

6. Conclusion

We have argued that when extracting temporal information from texts a target representation, such as a time-event graph, which explicitly admits event-event temporal relations as well as time-event relations, is superior to one which does not, such as a time-stamped event sequence representation. In essence the arguments are that a time-stamp representation forces overspecification leading to information loss, and that event-event relations must be extracted even if a time-stamp representation is the target, and hence might as well be retained.

We also described the annotation scheme we have developed, which enables us to annotate temporal relations as well as events and time referring expressions, thus providing the necessary information to build time-event graphs for texts. A trial corpus which we constructed based on this scheme was described and used to corroborate the argument in support of the time-event graph approach.

One potential practical argument against the time-event graph approach is that building annotated resources capturing the required information is costly and error-prone. In the final section of the paper we introduced ideas for improving quality and reducing effort in the annotation process, improvements which we hope will make future larger scale application of the annotation scheme feasible.

Tense and Implict Role Reference

Joel Tetreault

tetreaul@cs.rochester.edu

Abstract

This paper presents a probe study into the use of temporal information in the resolution of implicit roles. It has been shown that temporal information can influence rhetorical relations between utterances which in turn can influence the resolution of referential entities. We describe a focusing-based algorithm for resolving implicit roles using such information and test the algorithm on an annotated corpus. Our results show that temporal information can be useful in resolving implicit roles in some cases, but a much larger and varied corpus is needed to strengthen this claim.

1. Introduction

This paper describes preliminary work relating tense to implicit role reference. Past work has shown that tense can influence the resolution of other reference types such as pronouns as well as discourse structure ((Webber, 1988a) and (Hwang and Schubert, 1992)). We extend this claim to the reference of implicit roles. Verbs have certain required roles, which refer to discourse entities, that are necessary for comprehending the verb phrase, and thus aid in natural language processing. Roles that do not have explicit antecedents in the verb phrase are deemed implicit. We annotated a small corpus for NPs and VPs and tense information and show, in some cases, that one can improve resolution rates of implicit roles by using simple heuristics incorporating tense with focusing. To our knowledge, this is the first time that an automated corpus study has been done analyzing the effects of temporal information in reference.

First, we describe implicit role reference in more detail and how temporal information can be used in resolving implicit roles. In section 3, we describe our annotation scheme, in section 4, our focusing-based algorithm for implicit roles and finally the results of our algorithm on an annotated corpus.

2. Implicit Role Reference

We claim that in addition to canonical reference types such as pronominal reference, VP ellipsis, and discourse deixis, verb phrases have certain required roles that can be viewed as anaphoric. These required roles refer to discourse entities and are necessary for the interpreter to understand the verb phrase, and thus the complete utterance. For example, in order to use the verb "take" one needs to understand that an entity is being moved, that it is being moved to one place from some other place, and that there is some entity that is responsible for moving it.

Implicit role reference has been briefly studied as a side effect of bridging and discourse relations ((Poesio, 1994) and (Asher and Lascarides, 1999)) but no major empirical work has been done in the area.

Resolution of implicit roles occurs frequently in naturally occurring dialog. Consider the following, modified from Asher and Lascarides (p. 90):

```
(1)  Take engine E1 from Avon to Dansville.
(2a) Pick up the box-
car and take it to Broxburn.
(2b) And then take the box-
car from Corning.
(2c) Also take the boxcar.
(3)  Leave E1 there but move the box-
car some more to Evansville.
```

For the sake of simplicity, assume that the verb "take" has these roles: "Theme": the entity being moved; "To-Loc": the location we are taking the "theme"; and "From-Loc" the location we are leaving.

In utterance (2a) one needs to know the At-Loc of the boxcar, in order to send it to Broxburn. This role is implicit and is resolved to Dansville. In order to resolve "there" in utterance (3) after utterance (2b) one must resolve the implicit "From-Loc" in "take" in the previous sentence. But the main point is that in a natural language understanding/planning system, one must keep track of entities and their locations in order for it to plan and carry out the task.

Asher and Lascarides point out that use of rhetorical roles, specifically whether utterances are in a narrative or parallel relationship, can aid in reference resolution. For example, the relationship between (1) and (2a) is a narrative while (1) and (2c) is parallel. While it is hard to annotate rhetorical relations we believe that one can approximate them by calculating the temporal relation between the two utterances. For instance, if we know that there is a narrative relation then we know that the entity that serves as the To-Loc role will probably serve as the From-Loc role in the next utterance, since entities move from the place they were just taken.

In our corpus we found the following distribution (see Figures 1 & 2) for the roles we focus on in this study (From-Loc and To-Loc) and their antecedents. These figures show that for a given role, how many sentences back (depth) its antecedent is found and in what role focus list it is located in. The trend is that antecedents for a From-Loc or To-Loc are predominantly found in the current utterance or the previous two utterances.

We describe our work in implicit roles in more detail in (Tetreault, 2002).

Depth	From-Loc	To-Loc

3	0	0	0
4	1	0	1
5+	0	1	0
%	14.3%	28.6%	57.1%

Figure 2: To-Loc

3. Annotation

We use a subset of the TRAINS-93 Corpus (Heeman and Allen, 1994) annotated with coreference information for pronouns (Byron and Allen, 1998). The dialogs typically consist of short sentences, usually 10 words or less and are annotated using a sgml-style encoding. Our corpus consists of a 86-utterance dialog in which two human participants are given a task involving moving commodities and trains around a fictional world. We manually annotated each NP with an unique ID and its class (engine, tanker, location, food). Each VP was annotated with an ID, a time ID, and what NP ID(s) each role refers to. If a role is not mentioned explicitly in the text such as the "at-loc" role in (2a), then it is marked as implicit. The roles from each verb are taken from the TRIPS natural language system lexicon (Allen et al., 2000). For all the roles that are marked in this study (instrument, theme, from-loc, to-loc) roughly 30% are implicit.

A time point is associated with each verb event and constraints with previously mentioned time points are included in the time tag. The first element of each time tag is the time point associated with that event and is a string of a character followed by a number such as "t0." There are two types of constraint relations: either time x precedes a time y: "$x < y$" or x follows y: "$x > y$". Multiple constraints for a time point are encoded by linking the individual constraints with an ampersand: "$t1 > t2 \& t1 < t0$" which says that t1 comes after t2 and t1 precedes t0. It should be noted that this is a very naive encoding scheme and that complex verb tenses are reduced to their root forms. A sample annotation (modified for readability) is shown in Figure 3.

Annotation of time points was difficult because the goal of each dialogs was to create a plan not to execute a plan in real-time. This means that the two speakers will often talk abstractly about parts of the plan and create hypothetical plans that may be abandoned if the speakers feel that they would not meet the constraints outlined by the experiment. Often utterances such as "We will need to move the boxcar to Avon by midnight" would appear and be followed by statements related to the introduced task. For our purposes, these multiple stand-alone plans complicate annotation because all time points in the discourse are not necessarily related. To deal with this, we give each sub-plan or hypothetical plan its own code, so one sub-plan may have its events labeled with "u": "$u0, u1, u2...$" while another distinct plan would have "v."

4. Algorithm

We have developed a preliminary model for resolving implicit roles that uses a combination of focusing and temporal reasoning. Our algorithm for resolving implicit roles in a discourse is as follows: first, as one progresses through the discourse, each utterance maintains a focus list for each role, such that when a NP is encountered, its discourse entity representation is placed at the top of the appropriate focus stack(s). When a verb is encountered, we check all of its roles and place explicit ones (those found in surface form of the sentence) on the top of the appropriate focus stack. If a role is implicit then it is resolved as determined by its type:

- Instrument: search through current utterance first for an entity that meets the verb's constraints. If one is not found, then search through each past utterance's focus stacks: looking at the instrument and theme stacks in that order.
- Theme: same as above except that the search order of instrument and theme focus stacks is reversed
- From/To-Loc: use temporal reasoning to determine what order to search past To-Loc and From-Loc lists for each utterance.

Take Engine E1 from Avon to Dansville. Pick up the boxcar.

<ve id=ve122 time=t0 theme=ne12 from-loc=ne5 to-loc=ne6> **Take** <ne id=ne12>**engine E1**</ne> **from** <ne id=ne5>**Avon**</ne> **to** <ne id=ne6>**Dansville**</ne></ve>. <ve id=ve123 time=$t1 > t0$ from-loc=ne6 theme=ne13 implicit=from-loc> **Pick up** <ne id=ne13>**the boxcar**</ne></ve>.

Figure 3: Example Annotation

Time, R-L	78.9%	44.5%	69.3%	55.6%	66.7%
Total	19	9	26	9	

Figure 4: Implicit Role Reference Results

Our temporal reasoning scheme amounts to determining whether the current sentence u_j is in a narrative or parallel relation with a preceding utterance u_i being searched through for an antecedent. Since we annotated event times we can use the following simple algorithm to assign a narrative or parallel relation: If u_j's event time occurs after u_i's event time then we assume that a narrative relation holds between the two and that a From-Loc role in u_j should search through the To-Loc list in u_i. This is because in a narrative, there is a linear movement from place to place. If no such temporal relation is found, then we assume that a parallel relation holds between u_j and u_i and we search the From-Loc of u_i for antecedents first. The same method is used for To-Loc roles.

5. Results

We implemented the implicit role algorithm in a LISP system and and tested it on our dialog. Figure 4 shows the percentage correct for each version of the algorithm on each implicit role. The first two versions of the algorithm do not use temporal reasoning, while the last two do. R-L indicates that each focus list is searched from right to left, or from most recent to least recent. L-R indicates that the focus list is searched in reverse order, meaning that the subject of that utterance would be prominent. The last line is the number of times that role appears implicitly in the corpus.

6. Discussion

The conclusion of this study is that simple temporal reasoning has a mixed effect on the resolution rate of a verb's implicit roles. While there is a moderate improvement over the resolution of To-Loc's (55.6% to 44.5%), the naive method for resolving From-Loc's clearly outperforms its temporal reasoning counterpart (88.5% to 69.3%). Since our corpus is so small it is hard to draw concrete conclusions on whether not temporal reasoning works, especially since a most-recent strategy performs very well. This is not too surprising however since our statistics show that implicit roles typically have antecedents found locally.

It should be noted that this is a work in progress. Our annotation scheme is very basic and our error analysis shows that many of the From-Loc errors using temporal reasoning are due to deficiencies in the annotation (such as reducing complex verb phrases to their one root verb). We believe that a more detailed annotation of tense would make result in a finer temporal ordering which would improve performance. Another area of concern is our very small corpus. Many empirical studies such as (Strube, 1998) and (Tetreault, 2001) have corpora of hundreds or even thousands of annotated sentences. The larger and more varied the corpus, the more reliable the results. We also acknowledge the fact that automating the annotation of temporal relations is complicated task all to itself and that it is an area of future research.

Recent work on this corpus has looked into the effects of breaking up conjoined utterances on reference resolution as suggested by (Kameyama, 1998). and implemented by (Strube, 1998). We found that this simple metric improved scores for all implicit roles (without using temporal reasoning) as well as for pronouns in another corpus (Tetreault, 2001). We tested temporal reasoning with the utterances broken apart and found it did not improve the score any higher.

Currently, we are annotating a much larger corpus of a similar domain (emergency rescue planning for a city). We hope that using this new data will address the problems discussed above.

In short, preliminary results indicate that temporal reasoning could be useful in reference resolution, but a better annotation scheme and a larger corpus are needed to strengthen this claim.

7. Acknowledgments

I would like to thank James Allen for many discussions on implicit role reference and tense. I am also grateful to Mark Core and Donna Byron for their comments. Partial

support for the research reported in this paper was provided by the DARPA research grant no. F30602-98-2-0133 to and the ONR grant no. N00014-01-1-1015, both to the University of Rochester.

Abstract

This paper describes the work carried out to improve the robustness of the morphological analyser/generator for Basque which can be adapted to several domains and variants of the language. This analyser is used as a lemmatiser in several IR applications such as an Intranet search engine.

We present an enhanced analyser that deals not only with standard words but also with linguistic variants (including dialectal variants and competence errors) and words, whose lemmas are not included in the lexicon, by relaxing the constraints of the standard analyser. In addition to this, a user's lexicon can be added to the system in order to customise the tool. This user's lexicon can be obtained by means of a semiautomatic process.

1. Introduction

The starting point of this research is a general morphological analyser/generator described in (Alegria et al., 1996), which reported 95% of coverage. This poor result was due (at least partially) to the recent standardisation and the widespread dialectal use of Basque.

Although in some systems lemmas corresponding to unknown words are included in the main lexicon in a previous step, this solution is not satisfactory if we want to build a flexible system. We decided that it was necessary to manage a user's lexicon, for linguistic variants and forms whose lemmas were not in the lexicon, if we wanted to develop a comprehensive or adapted analyser.

However, the enhancement of coverage leads, in some cases, to produce overgeneration, and, consequently, to increase ambiguity. Although this ambiguity is not real, it causes poor results (lower precision) in applications based on morphology or lemmatisation. Another important issue was the improvement of precision. We studied the results of the analyser and saw that most errors (50%-75%) were made when dealing with proper names. Therefore, we propose some solutions to avoid about 50% of the errors.

2. Architecture of the morphological analyser

Morfeus is a robust morphological analyser for Basque. It is a basic tool for current and future work on NLP of Basque. Some of the tools based on it are a tagger (Ezeiza et al., 1998), an Intranet search engine (Aizpurua et al., 2000) and an assistant for verse making (et al., 2001).

The analyser is based on the two-level formalism. The two-level model of computational morphology was proposed by Koskenniemi (Koskenniemi, 1983) and has had widespread acceptance due mostly to its general applicability, declarativeness of rules and clear separation of linguistic knowledge and program.

This tool is implemented using lexical transducers. A lexical transducer (Karttunen, 1994) is a finite-state automaton that maps inflected surface forms to lexical forms, and can be considered an evolution of the two-level morphology. The tool used for the implementation is the *fst* library of *Inxight*[1] (Karttunen and Bessley, 1992; Karttunen, 1993; Karttunen et al., 1996). A detailed description of the transducers can be found in (Alegria et al., 2001).

We have defined the architecture of the analyser using three main modules (Schiller (Schiller, 1996) and others propose only two levels):

1. The standard analyser that uses a general lexicon and a user's lexicons. This module is able to analyse/ generate standard language word-forms. In our applications for Basque we defined about 75,000 entries in the general lexicon, more than 130 patterns of morphotactics and two rule systems in cascade, the first one for long-distance dependencies among morphemes and the second for morphophonological changes. The three elements are compiled together in the standard transducer. To deal with the user's lexicon the general transducer described below is used.
2. The analysis and normalization of linguistic variants (dialectal uses and competence errors). Due to non-standard or dialectal uses of the language and competence errors, the standard morphology is not enough to offer good results when analysing real text corpora. This problem becomes critical in languages like Basque in which standardisation is in process and dialectal forms are still of widespread use. For this process the standard transducer is extended with new lexical entries and phonological rules producing the *enhanced transducer*.
3. The guesser or analyser of words without lemmas in the lexicons. In this case the standard transducer is simplified removing the lexical entries in open categories (nouns, adjectives, verbs, …), which constitute the vast majority of the entries, and is substituted by a general automata to describe any combination of characters. So, the *general transducer* is produced combining this general set of lemmas with affixes related to open categories and general rules.

[1] Inxight Software, Inc., a Xerox Enterprise Company (www.inxight.com)

The analyser of non-standard words (steps 2 and 3) may sometimes produce overgeneration, and it is important to reduce this ambiguity as soon as possible.

3. Customizing the analyser

In order to deal with unknown words, a general transducer has been designed to relax the need of lemmas in the lexicon. This transducer was initially (Alegria et al., 1997) based on an idea used in a speech synthesis system (Black et al., 1991) but it has been now simplified. Daciuk (Daciuk, 2000) proposes a similar way when he describes the *guessing automaton*, but the construction of our automaton is simpler.

The new transducer is the standard one modified in this way: the lexicon is reduced to affixes corresponding to open categories and generic lemmas for each open class, while standard rules remain. There are seven open classes and the most important ones are: common nouns, personal names, place nouns, adjectives and lexical verbs. Grammatical categories and semantic ones (personal names or place names) are separated because they have different declension.

So, the standard rule-system is composed of a mini-lexicon where the generic lemmas are obtained as a result of combining alphabetical characters and can be expressed in the lexicon as a cyclic sublexicon with the set of letters (some constraints are used with capital/non-capital letters according to the part of speech). In fig. 1 the graph corresponding to the mini-lexicon is shown.

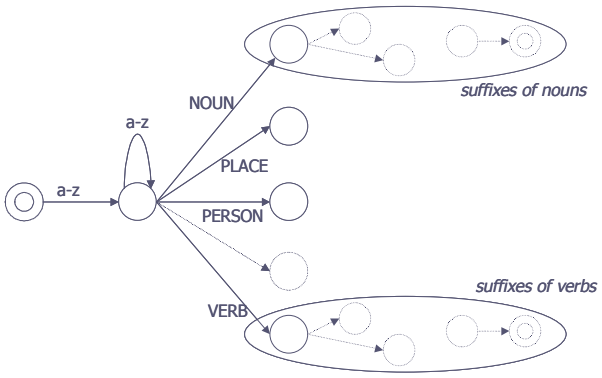

Figure 1. Simplified graph of the mini-lexicon

This transducer is used in two steps of the analysis:

1. in the standard analysis, in order to analyse declension and derivation of lemmas in the user's lexicon.
2. in the analysis without lexicon (called *guesser* in taggers).

The user's lexicon is composed of a list of lemmas along with their parts of speech defined by the users. The general transducer suggests possible interpretations of the word, and these lemmas are searched in the user's lexicon. When any lemma and class given by the general transducer matches the information on the user's lexicon, the analyser selects the corresponding interpretation and gives it as a result.

So, the user's lexicon is an editable resource which can be inferred from corpora or be managed on-line by the user. The use of this lexicon combined with the general transducer allows to customise the applications and it has been included successfully in three tools:

1. A spelling corrector for Basque (Aldezabal et al., 1999) in which for each lemma included in the user's lexicon any inflected form or derivative is accepted.
2. An Intranet search engine (Aizpurua et al., 2000) in which lemmatisation plays an important role and which can be customised when adapted to a special domain. In this case a semiautomatic process is carried out. First, the whole analyser (in the three steps above mentioned) is used to analyse a big corpus and the possible lemmas obtained by the guesser. After being sorted by frequency, they are presented to the user in order to include them in the user's lexicon[2]. The site www.zientzia.net, devoted to scientific documents, was built in this way.
3. A general part-of-speech tagger including customisation similar to the search engine.

4. Increasing coverage

The analyser was designed with the main objective of being robust, that is, capable of treating both standard and non-standard forms in real texts. For this reason, the morphological analyser has been extended in two ways:

1. The treatment of linguistic variants (dialectal variants and competence errors) (Aduriz *et al.*, 1994)
2. A two-level mechanism for lemmatisation without lexicon to deal with unknown words, which has been explained above

Important features of this design are homogeneity, modularity and reusability because the different steps are based on lexical transducers, far from *ad hoc* solutions, and these elements can be used in different tools. This could be considered a variant of constraint relaxation techniques used in syntax (Stede, 1992), where the first constraint demands standard language, the second one combines standard and linguistic variants, and the third step allows free lemmas in open categories. Only if the previous steps fail, the results of the next step are included in the output. Oflazer also uses relaxation techniques in morphology (Oflazer, 1996).

With this design the obtained coverage is 100% and precision over 99.5%. The ambiguity measures of the morphological analyser, taken from a balanced corpus of about 27,000 tokens and from a news collection of about 9,000, are shown in table 1. These measures have been obtained using all the morphological features.

Ambiguity Rate	Interpretations per ambiguous token	Interpretations per token
66.95%	4.38	3.26

Table 1: Ambiguity measures[3]

However, sometimes overgeneration is produced in order to improve robustness. Overgeneration increases ambiguity but often this ambiguity is not real and causes poor results (low precision) in applications based on morphology such as spelling correction, morphological generation or tagging.

[2] At this moment it is a not friendly off-line process

[3] Ambiguity Rate: #ambiguous_token / #token; Interpretations per token: #analyses / #token; Interpretations per ambiguous token: #analyses_ambiguous_token / # ambiguous_token

	Distribution	Ambiguity Rate	Interpretations per ambiguous token	Interpretations per token	Precision
standard	77.90%	80.73%	3.81	3.27	99.73%
variant	1.75%	80.53%	4.23	3.60	92.31%
unknown	2.65%	99.79%	18.05	18.01	98.12%
average	100.00%	66.95%	4.38	3.26	99.61%

Table 2: Ambiguity measures in the output of the analyser

corpus6	29,939	60.54%	11.50%	7.90%	20.06%

Table 3: Distribution of tokens in different types of corpora

5. Decreasing ambiguity

The ambiguity for linguistic variants and unknown words is higher and the precision measures are poorer, but they form a small group of the input words (5%-10%) and the influence on average results is not significant.

The morphological analyser may sometimes overgenerate analyses of linguistic variants and unknown lemmas (table 2). Even if most words in texts are analysed in the first phase (see table 3), the small proportion of non-standard words constitutes a great amount of the superfluous interpretations. Yet, the rate of non-standard words varies depending on the type of corpus.

For instance, corpus3 is a balanced corpus with a high rate of standard Basque texts. On the contrary, corpus6 is a subset of texts from corpus3 written mainly in two dialects. Obviously, this corpus has a higher rate of non-standard uses. Corpus1 is a compilation of texts from the Web, and, generally, there is a trend to write these documents following standard rules of the language. Finally, corpus2, corpus4 and corpus5 are texts from the Basque newspaper *Euskaldunon Egunkaria*, and, even if the language variant used on them is standard, there is a relatively high amount of unknown words.

The treatment of non-standard words has been added to the previously developed analyser for two main reasons:

1. The average number of interpretations in non-standard words is significantly higher than in standard words (see table 2).
2. There could be multiple lemmas for the same or similar morphological analysis. This is a problem when we want to build a lemmatiser. For example, if *bitaminiko* (vitaminic) is not in the lexicon the results of the analysis of *bitaminikoaren* (from the vitaminic) as adjective can be multiple: *bitamini+ko+aren*, *bitaminiko+aren* and *bitaminikoaren*, but the only right analysis is the second one.

We think that it is important to reduce the ambiguity at this stage, so that the input of subsequent processes is more precise. But, we do not use information about surrounding words because a tagger will be used later. The process is limited to the word we want to treat, and we only need to know, in some cases, if the previous token was a full stop.

This module consists of different methods for linguistic variants and unknown words, because overgeneration is produced by different facts in each case, as will be described below.

5.1. Disambiguation of linguistic variants

In the case of linguistic variants a heuristic tries to select the lemma that is "nearest" to the standard one according to the number of non-standard morphemes and rules applied. It chooses the interpretation that has less non-standard uses for each POS tag.

For example, analysing the word-form *kaletikan* (dialectal form) two possible analyses are obtained: *kale+tik* (from the street) and *kala+tik* (from the cove). Both analyses have a non-standard morpheme (*-tikan*) but the first analysis is more probable because it applies no other transformation rule and to obtain the second one it has been necessary to apply another rule at the end of the lemma to transform *kale* into *kala*.

Thus, we must decide which of the analyses need to be selected or discarded based on the amount of transformation rules applied to obtain each analysis, but the enhanced transducer does not detail this information. The output of the enhanced transducer displays the normalised lemma/morphemes along with their corresponding morphological features. In the case of non-standard morphemes linked in the lexical database to their normalised form, the analysis details both normalised and variant morphemes.

Thus, the procedure uses these results to select the most probable lemmas for each POS tag. The results of applying this procedure are shown in table 4. The error rate of the procedure is 1.7%, so the error rate added to the whole process is 0.03%. It does not mean a significant drop in overall ambiguity, but it discards 40% of superfluous analyses.

[4] This group represents punctuation marks and other symbols.

	Ambiguity Rate	Interpretations per ambiguous token	Interpretations per token	Precision
before	80.53%	4.23	3.60	92.31%
after	75.35%	2.98	2.49	90.42%

Table 4: Ambiguity measures on linguistic variants before and after the procedure

	Ambiguity Rate	Interpretations per ambiguous token	Interpretations per token	Precision
initial	99.79%	18.06	18.01	98.12%
typographical	99.58%	8.18	8.15	96.46%
derivational	99.58%	7.94	7.91	96.46%
proper names	85.21%	6.93	6.05	95.94%
statistical 3+2+1	83.33%	3.99	3.49	91.98%

Table 5. Ambiguity measures on unknown words using all the procedures

	Distribution	Ambiguity Rate	Interpretations per ambiguous token	Interpretations per token	Precision
standard	77.90%	80.73%	3.81	3.27	99.73%
variant	1.75%	75.35%	2.98	2.49	90.42%
unknown	2.65%	85.21%	4.06	3.61	93.02%
average	100.00%	66.46%	3.80	2.86	99.43%

Table 6. Ambiguity measures in the output of the improved analyser

However, this heuristic treats every rule equally, but not all of them have the same probability of being applied. We think that it could be interesting to use a probabilistic transducer (Mohri, 1997) to improve the precision measures of both the analyser and the disambiguation procedure of variants.

5.2. Disambiguation of unknown words

We have tested several procedures to detect and treat unknown words using different criteria:

1. Typographical disambiguation. Some analyses are discarded based on capital letters.
2. Disambiguation of derivational words to counterbalance overgeneration of the analyser. The goal of this procedure is to discard one of several interpretations when the morphological analyser assigns analyses as derivational and non-derivational word.
3. Identification and disambiguation of proper names not included in the lexicon. Some analyses can be disambiguated when identical lemmas are found in the same document.
4. Disambiguation based on both statistical and linguistic information. These statistics relates final trigrams of characters and POS tags. is used. The main features of the heuristic are: a) for each POS tag, leave at least one interpretation; b) assign a weight to each lemma according to the final trigram and the POS tag; c) select the lemma according to its length and weight –best combination of high weight and short lemma.

These procedures were designed to be applied consecutively. To decide the order in which they must be applied, we tried different combinations.

Finally, table 5 shows the best result of applying all the procedures in cascade.

This treatment has been designed to discard some of the interpretations of unknown words. Even if unknown words are only 2%-3% of the words, they constitute 15%-20% of the analyses. After applying the procedures, they only represent 3%-4.5% of the analyses, depending on the combination of procedures we use, and the average number of interpretations decreases from 18-19 down to 3,5-4,5. The overall results of treating the reference text are shown in table 8. This has been measured using the second level tagset both for disambiguation of linguistic variants and for statistical disambiguation of unknown words, thus leaving (at least) one lemma per class and subclass.

Precision decreases in average around 0.2%, even if the results for unknown words fall from 98% to 93%. Finally, we want to point out that each combination of the procedures may be used for different applications.

6. Improving precision

The main reason for these errors is the incremental architecture of the analyser. The first step in the process, the standard analyser, causes wrong interpretations, primarily when very short or very rare lemmas are involved in the analysis. However, the process stops when the analyser finds (at least) one interpretation of the word.

A clear example of these misinterpretations is *Barak*. This name, when it appears in its base form, is interpreted as *bara*, a common noun of very low frequency. When it appears inflected, i.e. *Barak-ek* (*Barak* in ergative case), the standard analyser assigns no interpretation and the analyser without lexicon interprets it correctly as a proper noun.

	Distribution	Ambiguity Rate	Interpretations per ambiguous token	Interpretations per token	Precision
standard	77.88%	81.02%	3.86	3.32	99.88%
variant	1.66%	81.36%	4.40	3.76	96.51%
unknown	2.76%	99.90%	18.20	18.18	98.34%
average	100.00%	67.21%	4.46	3.32	99.80%

Table 7: Ambiguity measures in the output of the analyser

Most of the errors are avoidable enriching the user's lexicon, but it is necessary to improve the results when this is not done.

So we must avoid rare and improbable analyses when a word has an initial capital letter. In order to avoid odd analyses we have marked short or conflicting lemmas with low probability as rare in the lexical database. Using this information, when all the possible interpretations for a word are marked as rare, the process follows using the next module. If at the next step the analyser does not find a non-rare analysis for the word, the word will be tagged just as the standard analyser did.

In the case of low frequency lemmas, words written with initial capital letter are also analysed by the guesser and only proper name interpretations are added to the ones suggested by the standard analyser.

In order to increase the precision in the analyser of linguistic variants, we limit the number of rules applied to obtain the interpretations. If all the interpretations have been obtained applying a higher value of rules than the threshold, the word will be treated using the guesser, thus, discarding the other interpretations.

We have implemented these proposals and the results are encouraging (see table 7). As a result, we have avoided 50% of the errors relaxing the constraints of the morphological analyser.

7. Conclusions

We have presented the work carried out to improve the robustness of a morphological analyser and to adapt it to new domains. We have made a proposal for the architecture of a morphological analyser combining different transducers to increase flexibility, coverage and precision. The design we propose is quite new as far as we know and we think that our design could be interesting for the robust treatment of other languages.

On the other hand, we have also defined some local disambiguation procedures, which don't take into account the context of the word, so as to discard many of the overgenerated analysis for non-standard words. The results of the research are very encouraging.

Finding the balance between generic and domain-specific knowledge: a parser customization strategy

Myroslava O. Dzikovska, James F. Allen, Mary D. Swift

{myros, james, swift}@cs.rochester.edu

Abstract

Adapting spoken dialogue systems across domains presents a challenge of finding the balance between wide-coverage parsers which can be easily ported but are slow and inaccurate, and domain-specific parsers which are fast and accurate but lack portability. We propose a method for customizing a wide-coverage, domain-independent parser to specific domains. We maintain a domain-independent ontology and define a set of mappings from it into a domain-specific knowledge representation. With this method, we customize the semantic representations output by the parser for reasoning, and we specialize the lexicon for the domain, resulting in substantial improvement in parsing speed and accuracy.

1. Introduction

Developers of spoken dialogue systems for multiple domains are faced with the challenge of finding the optimal balance between domain-independent and domain-specific parsers. There are wide-coverage parsers (e.g. XTag (Doran et al., 1994), LINGO (Copestake and Flickinger, 2000)) that are domain-independent and therefore easy to port to new domains, but they are often not efficient or accurate enough. The typical approach is to hand-craft parsers specifically for each domain (see for example (Goddeau et al., 1994)), but the performance gains in accuracy and efficiency are offset by their lack of portability, requiring additional effort to adapt them to new domains. We propose an alternative approach to address this challenge with a method for customizing a wide-coverage, domain-independent parser developed for spoken dialogue applications to specific domains. We maintain two ontologies: domain-independent for the parser, and domain-specific for the knowledge representation, and define a set of mappings between domain-specific knowledge sources and the semantic representations output by the parser. This method improves upon the generic parser output by specifically tailoring the semantic representations output by the parser for use by the reasoning components in the system. We also use the mappings to specialize the lexicon to the domain, resulting in substantial improvement in parsing speed and accuracy.

The customization method described here was developed in the process of adapting the TRIPS dialogue system (Allen et al., 2001) to several different domains, such as a transportation routing system (Allen et al., 1996) and a medication scheduling adviser. We assume a generic dialogue system architecture (Allen et al., 2000) that includes a speech module, a parser, an interpretation manager (responsible for contextual processing and dialogue management), and a back-end application responsible for the general problem-solving behavior of the system.

Adapting the spoken dialogue system across domains results in tension between the representation of generic vs. specific information in the ontology. To facilitate development when porting the parser to new domains, we want to retain the syntactic and semantic information that is consistent across domains. However, each domain comes with its own semantic information relevant to the application. For example, the representation of physical objects for the transportation domain requires specifying whether an object is suitable cargo for a transportation action, such as different types of food or supplies. In this respect, the distinctions between, say, oranges and potatoes are irrelevant, since they are equally good as cargo. These distinctions become highly relevant in the medical domain, where food-medicine interactions are important. Ideally, we want to customize the ontology to the domain for the most efficient reasoning. This becomes ever more important when using specialized reasoners with pre-defined input representations, for example, a database query system that must have specific template slots filled. Thus our goal is to preserve the language information that is similar across domains, while addressing specialization issues unique to each domain as much as possible, and keeping the development time spent on custom domain adaptation to a minimum.

To reuse the syntactic information, the AUTOSEM system(Rosé, 2000) uses a syntactic lexicon COMLEX(Macleod et al., 1994) as a source of syntactic information, and manually links subcategorization frames in the lexicon to the domain-specific knowledge representation. The linking is performed directly from syntactic arguments (e.g. subject, object ...) to the slots in a frame-like domain representation output by the parser and used by the reasoners. Rosé shows that her approach speeds up the development process for developing tutoring systems in multiple domains.

Our approach introduces an intermediate layer of abstraction, a generic ontology for the parser (the **LF Ontology**) that is linked to the lexicon and preserved across domains. The parser uses this ontology to supply meaning representations of the input speech to the interpretation manager, which handles contextual processing and dialogue management and interfaces with the back-end application. The domain-specific ontology used for reason-

ing (the **KR ontology**) is localized in the back-end application. We then customize the communication between the parser/interpretation manager and the back-end application via a set of mappings between the LF and KR ontologies. At the same time, the domain-independent ontology preserves semantic information consistent across domains that can be used by the Interpretation Manager for reasoning or reference resolution.

This separation allows us to write mappings in semantic terms without addressing the details of the grammar and subcategorization frames, using a higher level of abstraction. The developers writing the mappings does not need to understand details pertaining to syntax such as those included in COMLEX subcategorization frames, and can instead use descriptive labels assigned to generic semantic arguments (e.g. AGENT, THEME etc.). They can also take advantage of the hierarchical structure in the domain-independent ontology and write mappings that cover large classes of words. Finally, the mappings are used to convert the generic representation into the particular form utilized by the back-end application, either a frame-like structure or a predicate logic representation.

2. The Generic Lexicon

The LF ontology is close in structure to linguistic form, so it can be easily mapped to natural language and used in multiple domains. It classifies entities (i.e., objects, events or properties) primarily in terms of argument structure. Every LF type declares a set of linguistically motivated thematic arguments, a structure inspired by FRAMENET (Johnson and Fillmore, 2000), but which covers a number of areas where FRAMENET is incomplete, such as planning. We use the LF ontology in conjunction with a generic grammar covering a wide range of syntactic structures and requiring minimal changes between domains. For example, adapting the parser from the transportation to the medical domain required adding LF types for medical terms (our generic hierarchy was incomplete in this area) and corresponding vocabulary entries, but we did not need to change the grammar or existing lexical entries, and we continue to use the same lexicon in both domains.

The LF types in the LF ontology are organized in a single-inheritance hierarchy. Obviously, some sort of multiple inheritance is required, because, for example, a person is a living being, but also a solid physical object (as opposed to a formless substance such as water). We implement multiple inheritance via semantic feature vectors associated with each LF type. The features correspond to basic meaning components and are based on the EuroWordNet (Vossen, 1997) feature system with some additional features we have found useful across domains. While the same distinctions can be represented in a multiple inheritance hierarchy, a feature-based representation makes it easy to implement an efficient type-matching algorithm based on (Miller and Schubert, 1988). More importantly, using feature vectors allows us to easily change semantic information associated with a lexical entry, a property utilized during the customization process described below.

Word senses are treated as leaves of the semantic hierarchy. For every word sense in the lexicon, we specify the following information:

- Syntactic features such as agreement, morphology, etc.;
- LF type;
- The subcategorization frame and syntax-semantics mappings.

To illustrate, consider the verb *load* in the sense *to fill the container*. The LF type definition for *LF_LOAD* is shown in Figure 1. It specifies generic type restrictions on the arguments which are then propagated in the lexical entries. Intuitively, it defines a loading event in which an intentional being (AGENT) loads a movable object (THEME) into another physical object that can serve as a container (TO-LOC). The lexicon entry for *load* is linked to LF_Load and contains two possible mappings from the syntax to the LF: one in which the THEME is realized as direct object, corresponding to *load the oranges into the truck*, and another in which the THEME is realized as prepositional complement, corresponding to *load the truck with oranges*. The restrictions from the THEME argument are propagated into the lexicon, and the parser makes use of them as follows: only objects marked as *(mobility movable)* are accepted as a direct object or prepositional *with* complement of *load*.

```
(define-type LF_LOAD
 :sem (situation (aspect dynamic)
                 (cause agentive))
 :arguments
  (AGENT (phys-obj (intentional +)))
  (THEME (phys-obj (mobility movable)))
  (TO-LOC (phys-obj (container +)))
)
```

Figure 1: The LF type definition for LF_LOAD. In the lexicon, feature vectors from LF arguments are used to generate selectional restrictions based on mappings between subcategorization frames and LF arguments

The parser produces a flattened and unscoped logical form using reified events (Davidson, 1967). A simplified representation showing the semantic content of *Load the oranges into the truck* is shown in Figure 2. [1] For every entity, the full type is written as LF-parent*LF-form, where the LF-parent is the type defined in the LF ontology, and the LF-form is the canonical form associated with the word, for example, LF_VEHICLE*truck.

3. The KR customization

To produce domain-specific KR representations from the generic LF representations, we developed a method to customize parser output. The current system supports two knowledge representation formalisms often used by reasoners: a frame-like formalism where types have named

[1] For simplicity, we ignore speech act information in our representations

(TYPE e LF_LOAD*load)
(AGENT e *YOU*) (THEME e v1) (TO-LOC e v2)
(TYPE v1 LF_FOOD*orange)
(TYPE v2 LF_VEHICLE*truck)

Figure 2: The LF representation of the sentence *load the oranges into the truck.*

```
(a)
(LF-to-frame-transform load-transform
       :pattern (LF_LOAD LOAD)
       :arguments (AGENT :ACTOR)
                  (THEME :CARGO)
                  (TO-LOC :VEHICLE))

(b) (define-class LOAD
     :isa ACTION
     :slots
       (:ACTOR AGENT)
       (:CARGO COMMODITY)
       (:VEHICLE (OR TRUCK HELICOPTER)))

(c) [LOAD
      :ACTOR [PERSON +YOU+]
      :CARGO [ORANGE V1]
      :VEHICLE [TRUCK V2]]
```

Figure 3: LF-to-frame-transform. (a) The transform for LF_LOAD type; (b) the definition of LOAD class that the transform maps into; (c) The KR frame that results from applying this transform to the load event representation in Figure 2.

slots, and a representation that has predicates with positional arguments. The KR ontology must have subtype support, and for the lexicon specialization process described in the next section, type restrictions on the arguments of frames/predicates, though it need not be so in the most general case.

We use two basic transform types to map generic representations produced by the parser into the KR representation: LF-to-frame-transforms, shown in Figure 3, and LF-to-predicate-transforms, shown in Figure 4.

The LF-to-frame transforms convert LF types into KR frame structures by specifying the KR frame that the LF type maps into, and how the arguments are transformed into the frame slots. These transforms can be simple and name the slot into which the value is placed, or more elaborate and specify the operator expression that is applied to the value. The LF-to-predicate transforms are used to convert the frame-like LF structures into predicates with positional arguments. They specify a KR predicate that an LF type maps into and the expression that is formed.

After the parser produces the logical form, the Interpretation Manager decides which transform to apply to a given LF with the following algorithm:

- Find all transforms that are consistent with the LF or its ancestors;

```
(a)
(LF-to-pred-transform load-transform
 :pattern (LF_LOAD
           (LOAD *AGENT *THEME *TO-LOC)
          ))

(b) (define-predicate LOAD
       :isa ACTION
       :arguments
       (1:AGENT 2:COMMODITY
        3:(OR TRUCK HELICOPTER)))

(c) (AND (LOAD +YOU+ V1 V2)
         (COMMODITY V1) (TRUCK V2))
```

Figure 4: LF-to-predicate-transform. (a) The transform for LF_LOAD type; (b) the definition of LOAD predicate that the transform maps into; (c) The KR formula that results from applying this transform to the load event representation in Figure 2.

- Select the most specific transform that applies, that is, the transform that uses only the roles realized in this particular LF representation, that has all obligatory mappings filled, and for which the types of the LF arguments are consistent with the type restrictions on the class arguments;
- If there are several candidates, choose the transform that uses the most specific LF, and, if there are several for the same LF, the transform that maps into the most specific KR class;
- Apply the transform to the LF type and all its arguments to produce the new representation.

For example, the parser produces the logical form in Figure 2 for *load the oranges into the truck*. The Interpretation Manager determines that the most specific transform consistent with the arguments is the `load-transform`. If the back-end reasoners use the frame representation, then we use an LF-to-frame transform and obtain the frame shown in Figure 3. Alternatively, a system using predicates with positional arguments as its representation uses an LF-to-predicate transform and obtains the (simplified) representation shown in Figure 4.

Our examples show the simplest versions of the transforms for exposition purposes. The actual implementation permits a variety of constructs that we cannot illustrate due to space limitations, including the application of operators to arguments, default transforms that apply to LF arguments if no mapping is specified in LF-to-frame transform, and the use of the lexical forms in transforms when the KR uses similar terms. For example, from the point of view of the language ontology, medication names have similar distributions across syntactic contexts, and therefore are represented as leaves under the LF_DRUG type, e.g. LF_DRUG*prozac, LF_DRUG*aspirin. The KR ontology makes pragmatic distinctions between them (e.g. prescription vs. over-the-counter medicines), but uses the names as

leaf types in the hierarchy. We can write a single template mapping for all LF_DRUG children that does the conversion based on the lexical form specified in the entry. This allows us to convert the generic representation produced by the parser to a representation that uses the concepts and formalism suited to the domain.

4. Specializing the lexicon

The KR customization described above can be implemented as a two-stage process with a generic grammar and lexicon and a post-processing stage. We also use the mappings to speed up the parsing and improve semantic disambiguation accuracy by integrating the domain-specific semantic information into the lexicon and grammar.

We pre-process every entry in the lexicon by determining all possible transforms that apply to its LF. For each transform, we create a new sense definition identical to the old generic definition plus a new feature *KR-TYPE* in the semantic vector. The value of *KR-type* is the KR ontology class that results from applying this transform to the entry. Thus, we obtain a (possibly larger) set of entries which specify the KR class to which they belong. We then propagate type information into the syntactic arguments, making tighter selectional restrictions in the lexicon. We also increase the preference values for the senses for which mappings were found. This allows us to control the parser search space better and obtain greater parsing speed and accuracy.

Consider the following example. Given the definition of the verb *load* and LF_Load in Figure 1, and the definitions in Figure 3, the algorithm proceeds as follows:

- As part of generating the lexical entry for the verb *load*, the system fetches the definition of *LF_load* and the semantic vectors for it and its arguments;
- Next, the system determines the applicable LF-to-frame-transform, `load-transform`;
- Based on the transform, *KR-type load* is added to the feature vector of *load*;
- Since the mapping specifies that the LF argument THEME maps to KR slot *CARGO*, and the class definition contains the restriction that cargo should be of class *COMMODITY*, *KR-type commodity* is added to the feature vector of the THEME argument. Similar transforms are applied to the rest of the arguments.

As a result, in the lexicon we obtain a new definition of *load* with 2 entries corresponding to the same two usages described in section 2., but with stricter selectional restrictions. Now suitable objects or prepositional complements of *load* must be not only movable, but also identified as belonging to class COMMODITY in our domain. Since similar transforms were applied to nouns, oranges, people and other cargoes will have a *KR-type* value that is a subtype of COMMODITY inserted in their semantic feature vectors.

As a result of the specialization process, the number of distinct lexical entries will increase because there is not a one-to-one correspondence between the LF and KR ontologies, and several transforms may apply to the same LF depending on the syntactic arguments that are filled. A new entry is created for every possible transform, but during parsing the selectional restrictions propagated into the entries will effectively select the correct definitions. The Interpretation Manager thus knows the correct KR types assigned to all entities in the logical form output by the parser and the corresponding transforms, and only needs to apply them to convert the LF expression into the form used by the back-end reasoners.

	Generic	Transportation	Medical
# of senses	1947	2028	1954
# of KR classes	-	228	182
# of mappings	-	113	95

Table 1: Some lexicon statistics in our system

	Transportation	Medical
# of sentences	200	34
Time specialized (sec)	4.35 (870)	2.5 (84)
Time generic (sec)	9.7(1944)	4.3 (146)
Errors specialized	24%(47)	24% (8)
Errors generic	32% (65)	47% (16)

Table 2: Average time per lattice and the sentence error rate for the grammar specialized by our method compared to our generic grammar. Numbers in parentheses denote the total time and error count for the test set.

Lexicon specialization considerably speeds up the parsing process. We conducted an evaluation comparing parsing speed and accuracy on two sets of 50-best speech lattices produced by our speech recognizer: 34 sentences in the medical domain and 200 sentences in the transportation domain. Table 1 describes the ontologies used in these domains. The results presented in Table 2 show that lexicon specialization considerably increases parsing speed and improves disambiguation accuracy. The times represent the average parsing time per lattice, and the errors are the number of cases in which the parser selected the incorrect word sequence out of the alternatives in the lattice [2].

At the same time, the amount of work involved in domain customization is relatively small. The generic lexicon and grammar stay essentially the same across domains, and a KR ontology must be defined for the use of back-end reasoners anyway. We need to write the transforms to connect the LF and KR ontologies, but as their number is small compared to the total number of sense entries in the lexicon and the number of words needed in every domain,

[2] We considered correct the choices where a different pronoun, an article or a tense form were substituted. For example *can I tell my doctor* and *could I tell my doctor* were considered equivalent for purposes of this evaluation. However, we counted as errors the equally grammatical substitutions that selected a different word sense, e.g. *drive the people* vs. *get the people*

this represents an improvement over hand-crafting custom lexicons for every domain.

5. Conclusion

The customization method presented here allows the use of a lexicon and grammar with generic syntactic and semantic representations for improved domain coverage and portability, while facilitating the specialization of the lexicon and the representation produced by the parser to the needs of a particular domain. With this method we can produce specialized grammars for more effi cient and accurate parsing, and allow the parser, in cooperation with Interpretation Manager, to produce semantic representations optimally suited for specifi c reasoners within the domain.

Abstract

Constructing modular applications from existing parts is difficult if there are mismatches due to input or output semantic differences during module interconnection. In order to minimize the effort of building such applications, and also as a guideline for designing modular applications from scratch, we propose an architecture in which modules are able to interface with each other without having to be reprogrammed. The architecture can be completely described using a small number of concepts. These factors allow rapid application building and reconfiguration with minimal manual intervention, potentiating module reuse and reducing the effort invested in building new applications.

1. Introduction

When building modular applications, it is possible to use parts that have been constructed by third parties, that solve part of the global problem. While this way of work is desirable because it promotes reuse, reducing the global development effort, it is all but straightforward: in fact, integrating foreign modules is almost never a simple task. The integration effort may become so expensive that it may seem better to build everything from scratch.

Managing these architectures is, thus, a challenging task and their complexity can be a serious hurdle when trying to bring together different components. Although not limited to the group, this problem also occurs when building natural language processing (NLP) applications and on various levels: from file-format handling or network-level communication to interaction between modules in a large application.

Here, we are concerned primarily with the latter aspect, even though the discussion could be applied to other levels, e.g. communication issues in a distributed application. We consider such lower-level aspects transport issues, though, that may be dealt with separately. Thus, CORBA (OMG, nda) and similar architectures are not an issue, since what we are concerned with is the way modules within an application exchange data and how to describe the way they do it.

We have two goals: to define a uniform way for modules to produce/consume data; and to define a uniform module interoperability model. We intend for these aspects to be realized complementarily: the latter will be a consequence of the former. In aiming at reaching these goals we are also promoting reuse and easy construction/configuration, since we provide a way for describing module interfaces for use with existing resources.

This document is organized as follows: the data model is defined in section 2.; a working example is presented in section 3.; and, finally, some concluding remarks and directions for evolution are presented.

2. Model

This section presents the architectural model. The first part presents structural aspects; the second part details the data model; the third part deals with semantics; and the fourth part details the implied application specification.

2.1. Structural aspects

We consider modular applications in which the modules exchange data through connections between their ports. These objects as well as their properties and relationships are presented here.

Definition 1 (portsets) *Let $\mathbb{M}$ be the set of all modules in an application. For a module m, the following portsets are defined: $\mathbb{O}^m$ (all output ports); $\mathbb{I}^m$ (all input ports); and $\mathbb{P}^m = \mathbb{I}^m \cup \mathbb{O}^m$ (all ports). In addition, $\mathbb{I}^m \cap \mathbb{O}^m = \varnothing$. We use p_i^m to denote the i-th port of m (i ranges over the corresponding portset).*

The definition for connection, while still a structural aspect, is better presented below (see def. 6).

2.2. Data model

Definition 2 (unrestricted grammar) *Unrestricted grammars (Lewis and Papadimitriou, 1981, def. 5.2.1.) are quadruples $G = (V, \Sigma, R, S)$, where V is an alphabet; Σ is the set of terminal symbols ($\Sigma \subseteq V$); $(V - \Sigma)$ is the set of nonterminal symbols; S is the start symbol; and R is the set of rules (finite subset of $(V^*(V - \Sigma)V^*) \times V^*$). Direct derivation (eq. 1), derivation (eq. 2), and generated language (eq. 3) are defined as follows:*

$$u \underset{G}{\Rightarrow} v \text{ iff } w_1, w_2 \in V^*, (u', v') \in R, \quad u = w_1 u' w_2 \wedge v = w_1 v' w_2 \tag{1}$$

$$w_0 \underset{G}{\Rightarrow} w_1 \underset{G}{\Rightarrow} \cdots \underset{G}{\Rightarrow} w_n \Leftrightarrow w_0 \overset{*}{\underset{G}{\Rightarrow}} w_n \tag{2}$$

$$L(G) = \{w \mid w \in \Sigma^* \wedge S \overset{*}{\underset{G}{\Rightarrow}} w\} \tag{3}$$

Σ is the union of three disjoint sets (eq. 4): Σ_k, the keyword set – the vocabulary for data description; Σ_d, used for writing data items; and Σ_i, used for writing intrinsic syntactic elements.

$$\Sigma = \Sigma_k \cup \Sigma_d \cup \Sigma_i \tag{4}$$

Definition 3 (data grammar; type grammar) *Consider port p and two grammars (as in def. 2): $\check{G}(p)$ – for*

writing data (the down-turned mark refers to data grammar entities); and $\hat{G}(p)$ – for writing datatypes (the upturned mark refers to datatype grammar entities).

These grammars must share the keyword set (denoted by $\Xi(p)$ (eq. 5)) and must be such that entities belonging to $L(\check{G}(p))$ describe the datatypes of the entities belonging to $L(\hat{G}(p))$. Each of the former entities works as a third grammar restricting $\hat{G}(p)$: it is used to validate data written according to the lowermost-level grammar.

$$\check{\Sigma}_k(p) = \hat{\Sigma}_k(p) = \Xi(p) \tag{5}$$

Definition 4 (data; datatype; correctness; validity) *Consider port p: $dat(p) \in L(\check{G}(p))$ denotes the data at p. We define port datatype, $typ(p) \in L(\hat{G}(p))$, as a data type specification according to $L(\check{G}(p))$ and $L(\hat{G}(p))$ (the third-level entities mentioned before). The following relation exists between a datastream and its associated datatype:*

$$typ(p) \rightsquigarrow dat(p) \tag{6}$$

Data is correct if it belongs to the language generated by the associated grammar: $dat(p) \in L(\check{G}(p))$, by definition; but it may happen that $dat(q) \notin L(\check{G}(p))$ (for some other port q) – in this case, $dat(q)$ would be incorrect according to $\check{G}(p)$.

Data is valid if $typ(p) \rightsquigarrow dat(p)$, i.e., the data stream follows the datatype definition (besides respecting the underlying grammar's rules).

The complete discussion of $typ(p)$ would only be complete taking into account the semantics of $L(\hat{G})$, but that is out of the scope of this document.

Taking into account the definitions in this section, we now give an example. Consider port p and a data representation containing the following XML (W3C, 2001a) fragment:

$dat(p) =$

```
[...]
<class name="nc">dog</class>
[...]
```

Then the terminal symbol sets would be (at least):

$$\check{\Sigma}_i(p) = \{\texttt{<}, \texttt{>}, \texttt{=}, \texttt{/}, \texttt{"}\}$$
$$\check{\Sigma}_k(p) = \Xi(p) = \{\texttt{class}, \texttt{name}\}$$
$$\check{\Sigma}_d(p) = \{w \mid w \notin \check{\Sigma}_i(p) \cup \Xi(p)\}$$

Consider a datatype description, for the data representation above, of which the following XML Document Type Definition (DTD) fragment is a part:

$typ(p) =$

```
[...]
<!ELEMENT class (#PCDATA)>
<!ATTLIST class name CDATA #REQUIRED>
[...]
```

Then the terminal symbol sets would be (at least):

$$\hat{\Sigma}_i(p) = \{\texttt{<}, \texttt{>}, \texttt{!}, \#, \texttt{ELEMENT}, \texttt{PCDATA}, \texttt{ATTLIST}, \texttt{CDATA}, \texttt{REQUIRED}\}$$
$$\hat{\Sigma}_k(p) = \Xi(p) = \{\texttt{class}, \texttt{name}\}$$
$$\hat{\Sigma}_d(p) = \{w \mid w \notin \hat{\Sigma}_i(p) \cup \Xi(p)\}$$

Thus verifying the grammar pair selection conditions (def. 3 and eq. 5).

2.3. Semantic aspects

This section deals with semantic aspects and restrictions that have to be observed when handling connections.

Each module has sole control over its internal semantics, in particular, in what concerns data semantics (defined by the receiver).

Definition 5 (semantics) *Consider port p and some interpretation function I (defined by the module's inner semantics): $sem(p)$ denotes the semantics required at p for normal processing behavior; $sem(dat(p))$ represents the data stream's semantics at p: computed by I (eq. 7). The data stream's semantics must subsume the port's semantics (eq. 8).*

$$sem(dat(p)) = I(dat(p)) \tag{7}$$
$$sem(p) \sqsubseteq sem(dat(p)) \tag{8}$$

Although we have no way of knowing how a module will interpret a piece of data, we can still write the following relations if we consider $\mathbb{D}$, the function denoting its argument's domain, and $\equiv$ the usual identity operator:

$$[\, typ(p) \rightsquigarrow dat(p) \,] \Leftrightarrow [\, I(typ(p)) \equiv \mathbb{D}(I(dat(p))) \,] \tag{9}$$

and thus (from 7, 9, and $\mathbb{D}$'s definition):

$$sem(dat(p)) \in I(typ(p)) \tag{10}$$

Definition 6 (connection) *Consider modules m and n and ports $p_i^m \in \mathbb{O}^m$ and $q_j^n \in \mathbb{I}^n$. Let predicate $con(p_i^m, q_j^n)$ be true if a connection exists between the pair. In the semantics domain, the output port's semantics must subsume the input's, i.e., condition 11 must be met.*

$$sem(q_j^n) \sqsubseteq sem(p_i^m) \tag{11}$$

Definition 7 (semantics mapping function) *When establishing a connection between two ports, p_i^m and q_j^n, if $typ(p_i^m) \neq typ(q_j^n)$, we need a semantics mapping function, $\theta_{i,j}^{m,n}$, for translating semantics across the connection (eq. 12, but also eq. 13). Furthermore, for the ports to be connectable, the receiving port's semantics must be subsumed by a transformation of the semantics of the previous module's output (cond. 14).*

$$\theta_{i,j}^{m,n} : typ(p_i^m) \rightarrow typ(q_j^n) \tag{12}$$
$$\theta_{i,j}^{m,n} : L(\check{G}(p_i^m)) \rightarrow L(\check{G}(q_j^n)) \tag{13}$$
$$sem(dat(q_j^n)) \sqsubseteq sem(\theta_{i,j}^{m,n}(dat(p_i^m))) \tag{14}$$

It is impossible, however, to guarantee a correct translation in the semantics domain, since, ultimately, input semantics is defined by the data consumer: we approach semantics conversion through datatype-directed data conversion. Since this conversion uses outside information about the ontologies of both sender and receiver, $\theta_{i,j}^{m,n}$ cannot be automatically generated solely from the information available at each end. Nevertheless, $\theta_{i,j}^{m,n}$ can be defined extensionally for each $typ(p_i^m)$.

We assume that it is always the receiver's responsibility to convert the data, since the data producer may be unable to determine how its results will be used. In the current discussion, we will also assume that condition 14 always holds, either because $\theta_{i,j}^{m,n}$ can satisfy it or, if that is not the case, because missing data parts can be supplemented by defaults when computing $sem(q_j^n)$.

2.4. Specifying the application

The model above gives rise to a data-oriented module interconnection architecture in which modules send/receive information to/from each other through typed channels that are uniquely defined by the datatypes at each end-point and by the corresponding translation function.

Since the architecture is not concerned with the modules' inner semantics, all that is needed to describe it completely are the collections of port datatypes and translation functions associated with connected ports. These collections are represented, respectively, by T, the datatype matrix, and by Θ, the translation matrix.

The datatype matrix is defined for all modules and their ports. Entries that do not correspond to actual ports are empty.

$$\underset{m_i \in \mathbb{M}}{T} = \begin{bmatrix} typ(p_1^{m_1}) & \cdots & typ(p_1^{m_\mathcal{M}}) \\ \vdots & & \vdots \\ typ(p_\mathcal{P}^{m_1}) & \cdots & typ(p_\mathcal{P}^{m_\mathcal{M}}) \end{bmatrix} \tag{15}$$

$$\begin{gathered} \mathcal{M} \equiv \#\mathbb{M} \qquad \mathcal{P} \equiv \max_{m \in \mathbb{M}}(\#\mathbb{P}^m) \\ \forall_{m \in \mathbb{M}} \forall_{1 \le v \le \mathcal{P}},\ p_v^m \notin \mathbb{P}^m \Rightarrow typ(p_v^m) = \varnothing \end{gathered} \tag{16}$$

The translation matrix is defined for all connected ports: one function for each connection. In all other cases, Θ is undefined.

$$\Theta = \begin{cases} \theta_{i,j}^{m,n} & con(p_i^m, q_j^n) \quad \text{(see def. 6)} \\ \textit{undefined} & \text{otherwise} \end{cases} \tag{17}$$

3. A small example

This example simplifies the model in important ways: all data flowing between ports is represented in XML and all datatypes can be specified either using DTDs or XML Schemas (XSD) (W3C, 2001d). Thus, in principle, all mismatches are due to variations in the XML data type definitions.

$$\forall_{m \in \mathbb{M}} \forall_{p,q \in \mathbb{P}^m}, \check{G}(p) \equiv \check{G}(q), \hat{G}(p) \equiv \hat{G}(q) \tag{18}$$

unless (only keywords are different)

$$\forall_{m \in \mathbb{M}} \forall_{p,q \in \mathbb{P}^m}, typ(p) \neq typ(q) \Rightarrow \Xi(p) \neq \Xi(q) \tag{19}$$

In our example, all datatypes have been described using DTDs and all necessary $\theta_{i,j}^{m,n}$ functions have been specified by Extensible Style Sheet (XSL) (W3C, 2001b) templates. By specifying all DTDs and XSL templates, the application becomes completely defined from the point of view of its data exchange paths.

The rest of this section will particularize further each of these aspects.

3.1. The application

The example application performs syntactic analysis of natural language sentences (fig. 1).

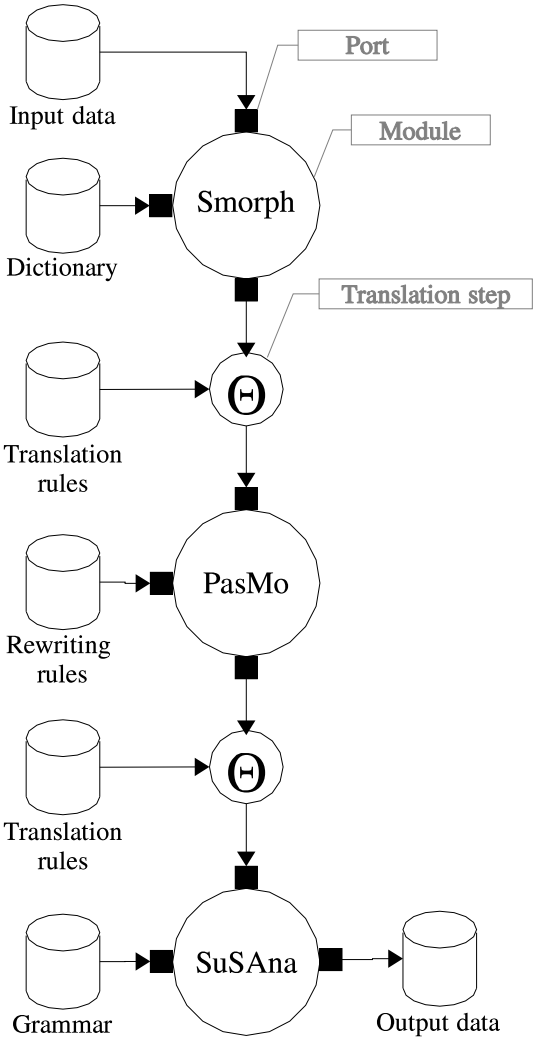

Figure 1: The example application.

The application consists of three modules: Smorph (Aït-Mokhtar, 1998) (morphological analyzer); PAsMo (Paulo, 2001) (rule-based rewriter); and SuSAna (Hagège, 2000; Batista, nd) (syntactic analyzer).

We consider only ports dealing with the data stream to be processed, thus ignoring those used for reading static data (such as dictionaries). Furthermore, in the following we will focus on the connection between Smorph and PAsMo, since the other relevant connection (that between PAsMo and SuSAna) is analogous.

3.2. The application ports

The relevant ports are Smorph's output (s) and PAsMo's input (p). To describe the data flowing through them, we need to specify just $typ(s)$ and $typ(p)$ (eq. 15 and figures 2 and 3). Smorph's output will be translated before being

```
<?xml version="1.0" encoding="iso-8859-15"?>
<!ELEMENT pasmo-in (word)*>
<!ELEMENT word     (class)*>

<!ELEMENT flag EMPTY>
<!ATTLIST flag name  NMTOKEN #REQUIRED>
<!ATTLIST flag value CDATA   #REQUIRED>
```

Figure 3: DTD for Smorph's output port, corresponding to $typ(s)$.

3.3. The translation step

The only relevant transformation, $\theta^{s,p}$, is the one mapping Smorph's output to PAsMo's input. It is implemented as a XSL transformation step and is completely specified by the set of XSL templates (figure 4) that map between data described according to Smorph's DTD and PAsMo's.

```
<?xml version='1.0' encoding='iso-8859-1' ?>
<xsl:stylesheet
  xmlns:xsl="http://www.w3.org/1999/XSL/Transform"
  version="1.0">
<xsl:output method="xml"
  encoding="iso-8859-15"
  doctype-system="pasmo-in.dtd"/>
<xsl:template match="/smorph">
  <pasmo-in>
    <xsl:apply-templates/>
  </pasmo-in>
</xsl:template>
<xsl:template match="item">
  <word text="{@value}">
    <xsl:apply-templates/>
  </word>
</xsl:template>
<xsl:template match="root">
  <class root="{@value}">
    <xsl:apply-templates
      select="class/flags/flag"/>
  </class>
</xsl:template>
<xsl:template match="flag">
  <flag name="{@name}" value="{@value}"/>
</xsl:template>
</xsl:stylesheet>
```

Figure 4: The translation specification in XSL, corresponding to $\theta^{s,p}$.

4. Related work

This work is related with several fields. The first is the field of data modeling, especially in what concerns very high-level modeling, such as the one done using UML (OMG, ndb). Specifications done in UML can be described using the XML Metadata Interchange (XMI) (OMG, 2002) specification that can then be used to specify the XSDs for the data being sent/received on a module's ports. This is useful because it allows us to describe graphically each module and its interconnections and, by extension, an entire application.

Since we plan on evolving in the direction of service specification(see sec. 5.), we have considered work in this area. One such is IBM's Web Services Flow Language (Leymann, 2001) which can be used for specifying multiple aspects of web services. This language is also layered on top of others: Web Services Description Language (WSDL) (W3C, 2001c) and Web Services Endpoint Language (WSEL) (Leymann, 2001). Although this structure closely parallels what we intend in our work, it has a different focus and does not invalidate our proposal.

The third area is that of communication systems, which typically define module interconnection architectures. An example is CORBA. Another, of particular interest for NLP, is the Galaxy Communicator (MIT, 2001; DAR, nd). This architecture is a distributed, message-based, hub-and-spoke infrastructure optimized for constructing spoken dialogue systems. It uses a plug-and-play approach that enables the combination of commercial and research components. It supports the creation of speech-enabled interfaces that scale gracefully across modalities. In this context, our proposal enables easy specification of Galaxy applications. At a different level, our specifications can be gracefully translated into hub scripts and server interface definitions.

In the context of reference architectures, such as the ones proposed by the TIPSTER (TIP, nd) or RAGS (ITRI, nd) projects, our model may prove useful in facilitating integration of external modules into the frameworks defined by those architectures. Note that, unlike most software infrastructures for Language Enginnering research and development, e.g. GATE (Cunningham et al., 1996), our model does not say anything about any module's function or impose any restrictions on their interfaces and is, thus, application- and domain-independent. This is so because the model is exclusively concerned with the data streams flowing between modules and the relations between their semantics at each end and not with the way each stream is used, i.e., the model is not directly concerned with application-related issues. In this sense, the model could be used to describe a kind of "smart glue" for use with other

architectures, e.g. in integration efforts of existing modules into GATE's CREOLE sets, or in datatype management.

Other application-development or intercommunication infrastructures may benefi t from using a high-level specifi - cation such as the one we propose here.

5. Conclusions and future directions

Our approach is useful for application development, since it focuses exclusively on the inputs and outputs of each module, without regard for module internals. This contributes to signifi cant dependency reductions, for the modules can be almost anything and run almost anywhere, as long as a communications channel (according to our restrictions) can be established between them.

We envision various directions for future work.

The fi rst is to provide higher-level service specifi cations on top of port descriptions. This would allow services to be defi ned using the descriptions of its inputs and outputs and, rather than exhaustively describing each port and its data, we would be able, at that higher abstraction level, to simply specify the name of the service. The rest would follow from lower-level descriptions.

Also, along the lines of higher-level abstractions and services, it would be interesting to try and specify automatic translation functions ($\theta_{i,j}^{m,n}$) based on service semantics. Of course, this would mean that semantics would have to be specifi ed in some way as well.

Both these approaches would help to integrate user-developed modules and help integrators to develop transformation steps that cannot be wholly automatically generated.

Another direction worth considering is the construction of module and application servers: modules or pre-built applications would be presented, e.g. via a web browser, enabling users to specify custom applications.

Abstract

The paper suggests some ways to save on software customization when developing a family of NLP applications meeting specific domain and task requirements. The emphasis is made on the application architecture modularity and reusability of system components. A particular focus is set on an easy-to-use environment for linguist developers integrated with the architecture to facilitate the reuse and customization phase.

1 Introduction

In this paper we address the problem of rapid and low cost deployment of NLP systems by suggesting some ways to save on software customization. A wide range of literature can be found in the area of R&D of language processing software, whose goal is to facilitate future development efforts thus reducing customization cost. The issue of customization is closely related to reuse strategies and integration during development process (Prieto-Diaz, 1993; Thomas and Nejmeh, 1992). Constructing general-purpose tools that can be shared by the community is a popular topic of interest nowadays. Such tools are developed both for language acquisition and language processing. To name just a few one can mention GATE, - a tool for locating, loading and initializing components from local and non-local machines (see, e.g. Cunningham, 1999), an abstract model of thesauri and terminology maintenance OO framework (Fischer et al., 1996), grammar development environments integrated with sophisticated text-processing interfaces such as Boas acquisition tool for a quick ramp up of MT systems (see e.g., Sheremetyeva and Nirenburg, 2000), and the Advanced Language Engineering Platform,- a grammar development tool for high-level linguistic processing, (see, e.g. Bredenkamp and Henzte, 1995). It is also recognized that though many increasingly convivial, more widely distributed and hardware-independent applications softwares are currently available it is difficult to find the system that matches exactly the end-user requirements (Degoulet et al., 1994). It seems highly problematic to identify once and forever a particular locus to the dilemma of genericity versus specificity when speaking of genericity "in general" as applied to all kinds of applications. Indeed, the locus can be anything, - the system architecture, the application components, the language resources, etc. If, however, the concept of genericity is considered as applied to a family of applications, i.e., applications interleavingly sharing tasks and domains, one can probably suggest particular approaches to solve the problem. In this paper we attempt just that. The problem of customization can be considered from two perspectives: internal and external. Internal customization is responsible for improvements in a current application and for tailoring this application to the profile of a particular user. External customization refers to the effort and cost to "turn" a current application to a new one. We address these two aspects of customization by describing a cost-effective development of a specific application called AutoPat, - an application for authoring patent claims describing apparatuses in the English Language. A prototype of this application has been developed many years

ago (see, e.g., Sheremetyeva and Nirenburg, 1996) so that we shall not deal with specifications of the application but rather with a re-engineering issue. We focus here on the problem of components reusability and integration of a developer's toolkit into the application architecture. Our objective is

?? to describe a cost-effective migration from the old experimental version of AutoPat, that did not support a lot of functionalities to the AutoPat product;

?? to suggest ways to make improvements (and tailoring) in the current version of the application without extra programming effort;

?? to discuss effectiveness of AutoPat external customization to conceive and realize other specific applications of the same family.

The AutoPat "closest" family includes applications with any combination of the values of the following features:

?? Application type < authoring, machine translation, information retrieval, etc.>

?? Domain < patents with different subject matters <apparatus, method, process, etc.>

?? Document type <patent disclosure, claims>

?? Languages < English, Danish, Swedish, Norwegian, German, French, etc.>

In what follows we first present the context of the AutoPat application and the development environment. Then we shall overview reusable components and detail developers' (customization) tools. Our discussion will mainly address the improvement of the application as well as advantages of distributed environment to develop these kinds of applications.

2 System overview

AutoPat is an NLP application that consists of an interactive technical knowledge elicitation module with a sophisticated but easy-to-use interface at the user end, analysis module and fully automatic text generation module. The architecture of AutoPat with integrated development environment is given in Figure 1.

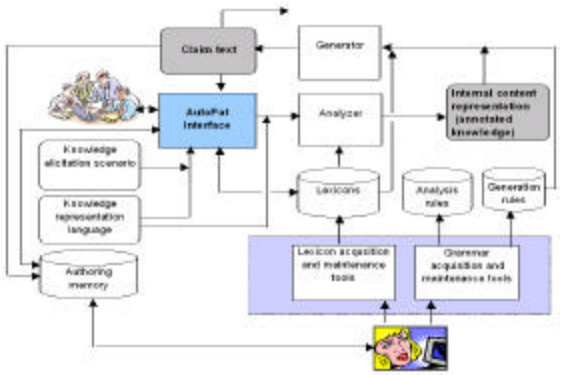

Figure 1. AutoPat overall architecture

Superficially, the architecture of our system conforms to the standard emerged in natural language generation, in that it includes the stages of content specification, text planning and surface generation (realization), as expressed, for instance in Reiter, (1994). However, there are some important differences. Unlike the typical content specification modules, our system relies on an authoring workstation environment equipped with a knowledge elicitation scenario for joint human-computer content specification. The latter starts with the user supplying natural language phrases into the system in the process of computer interview and results in the production of a content representation of a nascent claim.

A wide range of complex problems which are considered to be specific for generation may lead one to believe that generation is completely independent of analysis. This is not, however, the case in practice. The input to generation systems that is fed into the system directly by a user must first be somehow analyzed. This problem becomes especially important in those applications in which input to generation (as it is in our case) is in textual form. The stages of AutoPat processing are not strictly pipelined.The content specification interleaves with interactive semantico-syntactic analysis in that it assigns case-roles status to input phrases and memorizes their boundaries. The values of case-roles is then

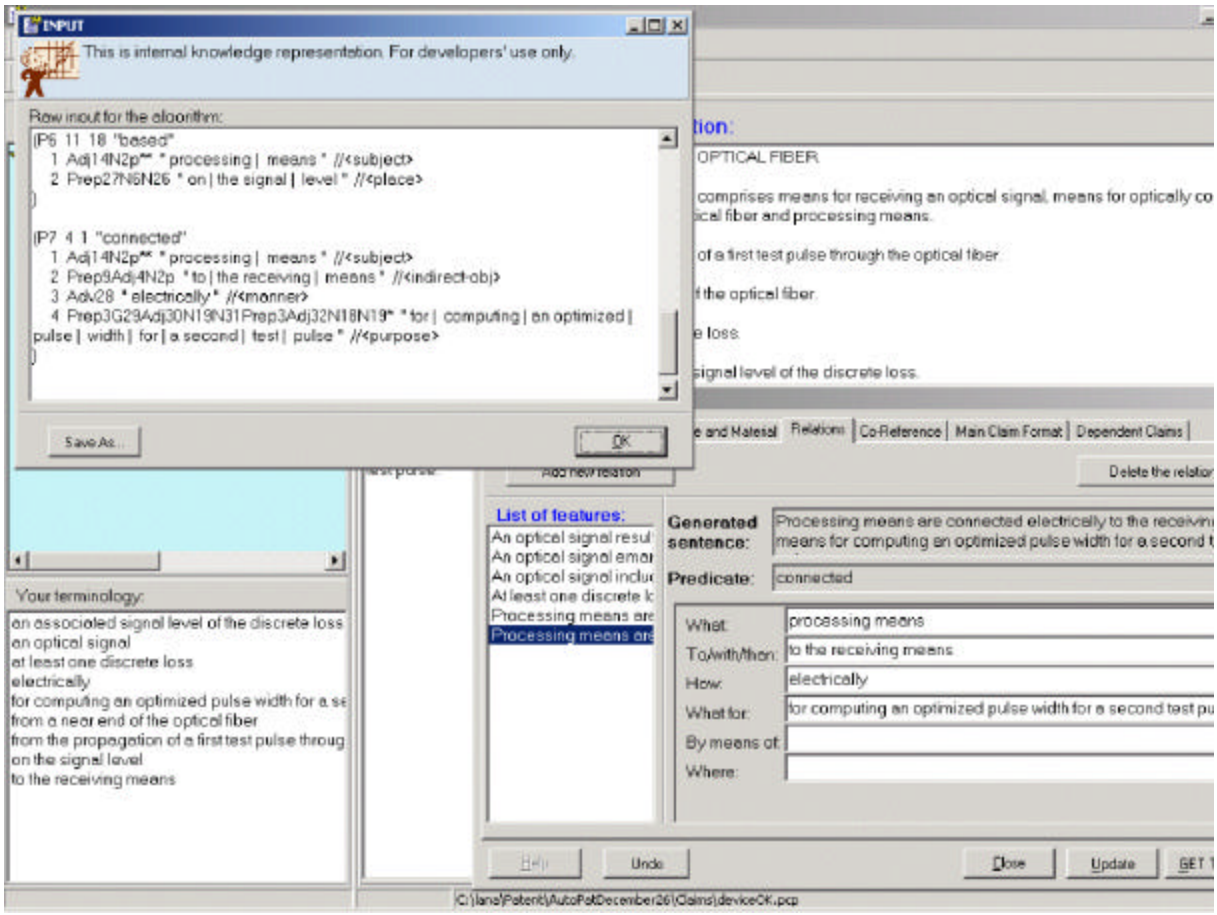

Figure 2. A screenshot of the AutoPat developer's interface window (top left corner) overlapping the user's interface for knowledge elicitation. It displays internal representation of a quantum of knowledge supplied by the user and processed by the application analyzer.

automatically unambiguously POS-tagged, assigned agreement features and interactively marked for coreference thus converting "raw" input into a shallow content representation, a claim draft. The draft is then submitted to an automatic text planner, which outputs a hierarchical structure of templates that is then input into linearizer and grammaticalizer to be converted into a legal claim text.

3 Development process: migration from experimental system to product.

3.1 Design

The first step in developing AutoPat was to define a subset of the experimental model for authoring patent claims that will be the basis of the application and the extension it will need to be turned into a product. The different functionalities of AutoPat application require, besides kernel components (such as the knowledge elicitation scenario, the knowledge representation language, lexicons, grammars and processing algorithms), a user-adaptive interface and linguistic knowledge acquisition tools to fight the well known problem of NLP applications, that of knowledge bottleneck. Developer's tools were integrated into the system architecture to facilitate the customization process and to make it cheaper.

3.2 Reuse and customization of existing components

The second step in the development process is the reuse of already developed components and their customization if they do not fit developer's needs.

3.2.1 Knowledge elicitation scenario

The knowledge elicitation scenario was almost fully reused in AutoPat, only one more step was added that of eliciting knowledge about dependent claims.

3.2.2 Knowledge representation language

Internal knowledge representation language was completely reused.

3.2.3 User Interface

The interface of the old system supported its main functions to model a professional behavior of a patent expert working with an inventor, - a knowledge elicitation interview, and to build internal content representation.

The content of the interview was almost fully reused in AutoPat, only one more step was added that of eliciting knowledge about dependent claims. Major customization dealt with lexicon acquisition functionalities and what might seem minor issues that in reality are very time consuming and thus affect the cost of application. The AutoPat interface is customized so as to support automation of tedious tasks such as typing, revising texts, making sure terminology is consistent, propagating changes through document, spell checking and lexicon acquisition. It has two different acquisition functionalities for predicate lexicon and for lexical units that fill predicate case-roles thus supporting two frames of their description (see Sections 3.2.5 and 4.2). The interface was also customized so as to better suite the user profile in terms of proficiency: the beginner has a chance to work in the Wizard Guide mode. It strictly guides the user through a step-by step procedure of describing essential features of invention and reuses experimental system interview procedure. An experienced user can work in the Professional mode that allows for more speed and flexibility when authoring a claim - the user may freely navigate among the stages of claim composition. Another new functionality allows the user to quit the program at any moment of elicitation session so that next time the user starts it s/he can resume the work where s/he left off.

3.2.3 Analyser

AutoPat reuses the architecture of the old system analyser, which consists of a submodule of interactive semantico-syntactic analysis and a submodule of automatic morphological analysis applied to the case-role fillers. The first analyser submodule is reused.

The submodule of morphological analysis is completely redone, as the old one was just a "toy" for feasibility study. Unfortunately we failed to incorporate to our system any of the described analysers as they proved to be either unavailable or not tuned to our domain. On the one hand, we tried to build our morphological analyser it in the most effort- and time-saving way. On the other hand, in view of other extensions of our AutoPat, such as multilingual generation, machine translation, information retrieval, etc., we decided to develop a reusable, possibly "extendable" morphological tool. As different types of applications need different depth of analysis our morphological submodule of the AutoPat analyzer features flexible sets of tags so that developer could vary the depth of analysis (see Sections 3.2.5 and 4.1). For example, for MT one might think of tags marking semantic information in addition to morphological, which for generation (i.e., for our immediate needs) is only necessary for predicates, but not for case-role fillers. (see Sections 3.2.5, 4.1 and 4.2). The AutoPat morphological analyser applies two levels of disambiguation procedure, one relies on context constraints, and another involves knowledge about case-roles. With one level of disambiguation it can be used as a stand-alone tool for any text from patent domain.

3.2.4 Generator

The upper level generation algorithm is reused. It consists of the same procedures: building a forest of predicate templates, linearization of this forest in a bracketed string of characters, and grammaticalization. The difference between the old version of the system and

AutoPat is that in the latter it is possible to customize algorithms at every generation step to improve the system output without extra programming effort (see Section 4.3).

3.2.5 Lexicons and grammar rules

The AutoPat lexicons are corpus-based and draw heavily on the sublanguage and on the needs of application. They include

a shallow lexicon of lexical units tagged with their class membership, which conveys morphological information (such as POS, number and inflection type) and semantic information, a concept, defining a word membership in a certain semantic class (such as object, process, substance, etc.). For example, the tag Nf shows that a word is a noun in singular (N), means a process (f), and does not end in –*ing*. This tag will be assigned, for example, to such words as *activation* or *alignment.* At present we use 23 tags that are combinations of 1 to 4 features out of a set of 19 semantic, morphological and syntactic features for 14 parts of speech. For example, the feature structure of noun tags is as follows:

```
Tag [ POS[Noun
        [object   [plural, singular]
         process [-ing, other[plural, singular]]
         substance [plural, singular]
         other      [plural, singular]]]]]
```

a deep (information-rich) lexicon of predicates. This lexicon is the main part of the AutoPat static knowledge and covers both the lexical and, crucially for our system, the syntactic and semantic knowledge. The structure of the entries of this lexicon was reused, the vocabulary was greatly enlarged. *Grammar rules* are updated (see section 4.3).

4 AutoPat Development tools

All developer's tools, including lexicon acquisition tools, have interfaces, which, on the one hand prompt acquirers to encode all the necessary features and, on the other hand, do not let them to add anything that is not relevant for the system.

4.1 Shallow lexicon acquisition tools

Shallow lexicon acquisition environment consists of several programs, including *User Interface*, for different stages of lexicon acquisition. *Web Spider* creates lists of words from a particular domain web site (5 million word corpus of US patents, in our case) in text format. *Word Sorter* sorts input wordlists in alphabetical, reverse or frequency order. *Pre-POS-Tagger* creates "dirty" lists of parts-of-speech. The human further cleans these lists. *Word Format Converter* converts lists in .txt formats into a .wdl format, - a special format used by AutoPat programs. *Word List Creator* takes unsorted files, in .wdl format sorts them in any order, merges or subtracts lists of words. *Word List Editor* maintains tagged lists of words allowing for editing, adding, deletion and search of the words. *Tag Editor* edits number and content of tags assigning them to certain groups of lexemes in the final morphological lexicon.

User Interface is used for shallow lexicon acquisition in the course of automatic spell checking. A word typed in by the user is highlighted as misspelled in two cases: when it is really misspelled or when it is not found in the underlying lexicon. The main distinguishing feature of the AutoPat spell checker is that in addition to providing hints to correct a word, it also provides for a pop-up menu of features for a word (in case the user considers it is correct) to be put into the AutoPat shallow lexicon with proper description.

4.2 Predicate lexicon acquisition tools

The main tool for predicate acquisition is graphical Predicate Lexicon Interface. It is directly linked to the main application engine, which relies on linguistic knowledge contained in the lexicon. The interface allows for editing any of lexicon fields, search any word by its prefix or semantic class, propagate changes from one field to another. The interface program has a built-in morphological generator that automatically generates all the word forms of the predicate necessary for generation. The interface has a standing menu of semantic classes and case-roles to select from when acquiring a new word. The acquirer can

customize the menu of semantic classes. Most of the fields of a new predicate entry are automatically filled with default fillers after the semantic class is acquired. The interface is programmed so as to keep acquirer "on the right road" by means of different hints and waning messages. The user can also acquire a predicate through the *User Interface* by simply typing it in a pop-up box and selecting its semantic class in the menu. The grammar forms of a new word are automatically generated in a word box for the user to check and edit if necessary, other information is assigned to a new predicate automatically by default depending upon a semantic class selected by the user. Every new word thus introduced by the user is flagged so that later a linguist could check its entry through the predicate dictionary interface closed for the user.

4.3 Grammar acquisition tools

Grammar acquisition tools include 7 compilers. Compilers 1-4 belong to the AutoPat analyzer, while compilers 5-7 compile rules for the AutoPat generator. All compilers have front-end interfaces providing rule writing help. The formal language for writing rules is very simple and has an IF-THEN-ELSE-ENDIF structure (see Figure 3). Every compiler has another interface to test the rules. Compilers for the analysis rules allow downloading any text files, not necessarily the user's input into AutoPat. That means that these compilers can be used as stand alone programs. In fact the whole morphology analysis module can be used as off-the-shelf-tool separately from AutoPat. *Compiler-1* is used to create tag disambiguation rules, which are applied to the Tagger output. These rules only use context information, which might be a tag or a lexeme within a 5-word window with a tag in question in the middle. The output of this compiler together with the output from the *Tagger* is fed to *Disambiguator* and used for the first disambiguation pass. *Compiler-2* is used to create or edit the second set of tag disambiguation rules that use syntactic knowledge about the case-roles filled by the analyzed strings. *Disambiguator* uses the output of this compiler at the second pass. *Compiler-3* creates rules, which determine whether singular and plural forms of the nouns belong to the same lexeme and can be considered as coreference candidates. *Compiler-4* creates rules for determining agreement features between the predicate and its first case-role. *Compiler-5* is used to write rules for linerazation of the claim plan tree of predicate templates. They specify the order of the words in every predicate template and the location of the templates relative one another in the nascent claim. These rules are more often subject to changes than any other rules. They are fed into *Linearizer* that substitutes the tree of templates with a bracketed string of tags. *Compiler-6* is for writing cohesion rules that delete some of the tagged strings from *Linearizer* output, insert commas and assign morphological features to predicates. Condition part of the rules uses specific knowledge provided by the *Linearizer* and by the predicate lexicon. *Compiler-7* is used for writing rules for inserting determiners before noun phrases in the final claim text. These rules should recognize coreferential phrases, which may be parts of other phrases or worded differently.

In AutoPat three types of rules are not directly linked to any compiler for updating but are "welded in" the programs. They are tagging and semantico-syntactic rules in the analysis module, and text planning rules in the generation module. Tagging rules are very simple and only suggest look-ups in the morphological lexicon. These rules can indirectly be updated through editing tag sets and morphological lexicon. Results of this knowledge update can be displayed in a. special developers' interface. Syntactico-semantic rules rely on interactive knowledge elicitation procedure and consist in looking up a predicate (selected by the user at the knowledge elicitation stage) at the predicate lexicon, presenting the user with a selected predicate template, assigning a case-role status (place, manner, etc.) to every phrase put by the user into a corresponding slot of the template and registering the boundaries of these phrases. Though these types of rules are not editable, the output of syntactico-semantic analyzer can still be checked through the developers

interface built into the users' interface (see Figure 2) and its output can be edited indirectly by editing predicate lexicon. Text planning rules are very complex. They include algorithms of grouping and sorting conceptually close predicate templates into a forest of trees relying on semantic, legal, stylistic and rhetoric domain knowledge built into the system.

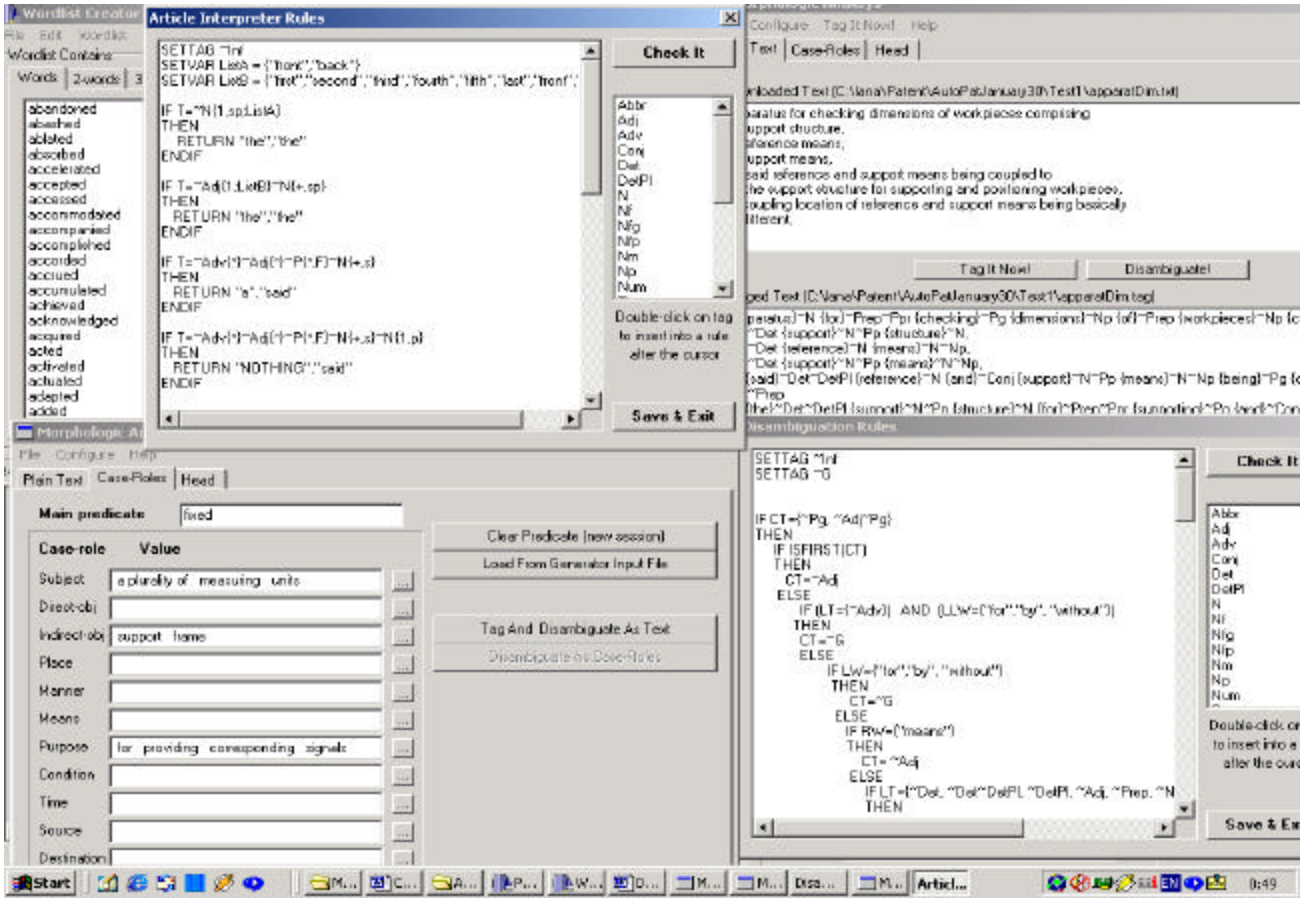

Figure 3. A screen shot of different compilers interfaces

These rules are not editable. But the developer can still update the structure of this tree by updating the predicate lexicon. A special interface was built for the developer to follow the stages of construction of the internal meaning representation and intermediate outputs of every generating procedure. In fact the rules for building a text plan is language independent, they depend only on semantic properties of predicates which could be treated as universal for different languages.

5. Discussion and conclusion

In this paper we addressed the problem of saving on software customization when developing a family of NLP applications sharing domain and task requirements or when updating applications once created. We illustrated the approach on the example of migrating from a prototype system for authoring patent claims to an AutoPat product. The migration was performed in two steps. The first step was the analysis of the aplication, the improvement of old components, such as generator, and the realization of new

components, such as morphological analyzer and a new user interface. The second step of migration which was described in this paper was to create developers tools for customization of application and integrate them into the system.

We were unable to compare the effectiveness of our development tools to other such tools due to their unavailability. Most of developer's tools are components of commercial products and are presented as black boxes, only used internally. This makes them unsuitable for research purposes (see, for example, a similar complain in (Lezius, 1998)).

The application development process described in the paper and targeted at saving on software customization emphasizes reuse and integration. At the level of each component, the AutoPat developer can access specific tools to perform reuse and customization. Integration is about the extent of compatibility of these tools and how seamlessly they can facilitate the development of applications. The development process of AutoPat-product validated the effectiveness of both the tools and their integration into the system. Programmers' work on AutoPat was finished long before the system could be considered a product. After manual acquisition of a training amount of knowledge for programming work the linguist completed the task of creating product-size and -quality knowledge without extra programming effort. We are planning to reuse the same tools for other applications of the same family (see Introduction) including syntax parsing, machine translation and automatic indexing. For example, we have already started the work on machine translation of patent claims where all the English lexicons and tools (e.g. interfaces) for their acquisition will be reused though augmented with new relevant for MT functionalities.

Abstract

In this paper, we describe our experience in reusing and customizing existing tools to meet new information retrieval needs in a corporate setting.
The problem was to supply an authoring aid to handle customers enquiry letters by exploiting a textual case base.
We decided to integrate, and go as far as possible with, a terminology extractor and a context exploration platform. They were previously developed through an academic and industrial collaborative research.
We have found a method to generate an information retrieval hypertext structure on a large collection of homogeneous documents by creating links between noun phrases that are pertinent for navigation. Noun phrases are selected by automatic extraction and filtered on the basis of the linguistic context class where they appear, also determined automatically.
We have tried to point out the peculiar features that made possible the reuse and integration of existing resources, to produce a relatively new solution to a fairly constrained real-world problem.

1. Introduction

Our work is motivated by an novel information retrieval (IR) need formulated in a corporate setting, at *Electricité de France R&D* (EDF R&D, the research and development department of the French national electricity board). The general problem was to supply an authoring aid to help EDF employees handle customers enquiry letters.

Starting from a textual case base and software available, we were invited to study a flexible and cost effective solution that would respect the employees savoir-faire and experience, and add value to existing tools.

Our approach aims at identifying the context where interesting NPs occur in the enquiry letters, in order to enhance the selection of pertinent cross-document links. Context identification is based on spotting linguistic markers of the expression of enquiries and on the exploitation of a structured lexicon that we can extract automatically from the textual case base.

2. The starting point

The initial scenario presented a number of constraints to be respected, concerning both the nature of the IR solution and the technical implementation.

2.1. Two corporate memory corpora

Two corpora were used to carry out a linguistic analysis, train our system for marker identification and test processing performance.

2.1.1. A large corpus of stored letters

A corpus of about 2000 customer letters, in French, was first made available by *EDF R&D*. The collection contains inquiries, intervention requests and complaints. Even when a complaint is not formulated explicitly, generally the writer's intention is to point at some sort of problem that needs fixing.

The corpus is homogenous from the point of view of the general subject matter and purpose of the letters. On the other hand, the variety of speech acts performed by the writers lends a challenging heterogeneity to the texts, interesting but problematic for automatic processing.

The corpus can be introduced in the corporate memory as a case base, and connected to customer profile and commercial strategy databases for global IR about a single customer case.

Unfortunately, letters in this corpus were not associated to the answers they had actually received.

2.1.2. A smaller corpus of letters and related answers

A second corpus of about 200 question-answer pairs is used for testing and discussing evaluation issues. It is a collection of letters that were sent directly to EDF branch managers to solicit special treatment on peculiar issues.

This gives the letters a somewhat special status, which is reflected in their style, vocabulary and structure.

We have used this smaller, more personal collection to put our system to test, point out its limitations, and try to explain them.

2.2. A terminology extraction tool: Lexter

The acquisition and exploitation of a structured lexicon are carried out automatically by the Lexter[1] system (Bourigault *et al.*, 1996), developed at EDF R&D in the framework of a PhD research project. Lexter was designed to extract noun phrases (NPs) from a corpus of texts (in French). Extraction is based on the hypothesis that eligible NPs must exhibit the syntactic pattern of candidate terms, as established by terminology theory. For example : *definite article + noun + preposition + noun* is an observed candidate term pattern. NPs are not extracted by direct pattern matching, but they are isolated by spotting their syntactic boundaries, like, for instance, verbs. The "terminological hypothesis" is not without consequence for our work, as it will be pointed out in the conclusive section.

Extracted NPs are then automatically organized in a structured network of head-expansion relations.

Lexter accounts for morphological variants and head-modifier relations of nouns and NPs, that are grouped into families. It also supplies simple distributional figures, such as frequency of a candidate term in the corpus or candidate term head-modifier productivity within the structured network.

Lexter also stores the whole corpus divided into paragraphs, along with a pointer to the location of each candidate term in the text. This feature was initially designed to supply the terminologist with a linguistic context for validation.

Extraction and corpus-related information is stored in a relational database. We have taken advantage of all Lexter features and results for the generation of hypertext links, as described below.

2.3. A context exploration tool: ContextO

The identification of context classes where candidate terms appear is based on the contextual exploration method (Desclés *et al.*, 1997) implemented in the ContextO platform (Ben Hazez & Minel 2000). The system was designed and is still developed at the LaLICC laboratory (*Langage, Logique, Informatique, Cognition et Communication*) of the Sorbonne University in Paris .

The exploration engine deployed by ContextO is based on the identification of markers of a large number of linguistic functions, as observed in the general language. Markers are acquired through a "manual" linguistic analysis of a corpus of texts, to model the expressions of linguistic functions, depending on the application. They are subsequently organized in semantic classes with object-model relations. Markers are stored in a knowledge base (a relational database, the same as Lexter' s), whichsi accessed by the contextual exploration engine of ContextO, a Java application. Markers are exploited by specialized agents, performing specific tasks. A number of tasks were already available; for example, the identification of static relations (*is-a*, *has*, etc.), causal relations, thematic focus, citations, definitions, etc. For the time being, ContextO exploits markers from French and Spanish, but could easily be adapted to other languages.

The study of our own corpus of letters has helped us find a number of linguistic structures regularly associated to the expression of complaints, justifications or requests. Each letter contains linguistic markers indicating a focus on certain speech acts that help the writer organize argumentative discourse.

For the first tests, the database contained about 200 markers organized into 24 functional classes ("complaint", "demand", "justification", etc.).

3. HyTEC, a new tool born from customization

Hypertext generation based on automatically extracted key-words usually produces an overwhelming number of non-pertinent links. Any NP can actually constitute an anchor for too large a set of heterogeneous links, a serious limitation to the effectiveness of IR.

By exploiting the features of the existing tools, we have designed a system, HyTEC (*Hypertext from TErms in Context*), capable of generating a IR hypertext structure on a large collection of homogeneous documents by selecting only those NPs that are pertinent for navigation.

Our work can be placed in the domain of IR automatic hypertext (Agosti *et al.*, 1997; Allan, 1997), where paragraph (and document) linking is based on IR similarity measures, and is typed.

The specification of our IR hypertext system is based on a real-world application, that is, browsing a large textual case base made of customer enquiry letters, along with the associated reply letters. The aim of the navigation in the document base is to help finding consistent answers to any new incoming letter.

As our document base is liable to frequent updating, we found it interesting that the hypertext structure be generated at each IR session. Therefore, the document base is dynamically indexed by a short content-sample text at the beginning of the session.

A new browsing session is booted by the content of the incoming letter, which supplies content elements to compute a thematic similarity with enquiry letters stored in the corporate memory.

Navigation allows to gather information on similar cases that have already been solved and reuse written material to compose a response to handle the problem.

3.1. Identifying the context of lexical expressions

Textual similarity is computed from what we call the “pragmatic profile” of an input letter. We want to identify the discursive context of NPs in order to select only the most interesting ones and create links to similar NPs appearing in the case base, in comparable discursive contexts.

Our research is based on the articulation of two principles:

1. The exploitation of a lexicon structured by grammatical relations, extracted automatically from the whole text collection;

1 © EDF R&D.

2. The identification of linguistic markers indicating the expression of requests, complaints, justifications and other discourse acts that are relevant in our working context.

These two principles are implemented in the two different NLP systems, that offer complementary functions and results, that we have integrated.

3.2. Computing lexical links between texts

Our hypothesis is that the co-occurrence of a candidate term and a focusing structure selects a portion of text interesting for our similarity search in the case base.

The search for pertinent markers is a means to refine link generation on a number of texts already selected by their lexical components, extracted by Lexter.

In order to reduce the number and, at the same time, to keep only the most pertinent links, we have decided to maintain only the links between NPs. NPs represent a form of mutual contextualization of lexical elements and allow a more precise automatic indexing than simple nouns (Evans & Zhai, 1996). For example, instead of retaining the simple word *electricity*, we will first choose expressions like *electricity bill* or *electricity meter* (as translated from French) as content carriers, because we feel they are thematically more precise.

We have then integrated this domain-specific lexical information, extracted automatically by Lexter, and semantic and pragmatic context information supplied by markers of the general language, identified by ContextO. The lexical information triggers context analysis to create a "signature", a context-tag / NP relation, that is used for indexing and filtering.

Even if the actual language we use is French, the same principle may as well be illustrated with an example in English, like

> Due to *temporary money problems*, I'd be happy if I could *pay the bill* by installments.

Context analysis is triggered by the phrases in italics (*pay the bill* would be a nominal form in French). As markers like *I'd be happy if* (demand) or *Due to* (justification) would be found in a particular context (by context exploration rules), the sentences would be tagged as belonging to a pertinent context class.

Links between portions of texts are computed by matching signatures formed by NPs that are flagged with a semantic tag indicating a context class.

4. Similarity search results

The results obtained by testing the system on three sample entry letter are summarized in Table 1.

The performance of our system on sample texts shows that the simple association of NPs and their conditions of use can effectively improve retrieval precision, when compared to results obtained by generating links between NPs alone.

	Before context analysis		**After context analysis**	
Samples	Initial number of links	Non pertinent	Non pertinent links eliminated	Pertinent links eliminated
1	158	81	71	8
2	93	23	16	11
3	78	32	24	5

Table 1: Results for three sample input letters on the main corpus

For instance, consider the following input text (as translated from French), where extracted NPs are in italics and context markers are in bold:

> Dear Sirs,
>
> Earlier this month, I have received an invoice from you, concerning the **use of gas and electricity**, whose amount *I do not agree* with. As the **big amount** you are asking for apparently concerns only a 2-month period, I have taken down the numbers shown on my **gas meter**. The meter indicated 00613, but your invoice reports 00878. I know this number represents an estimation.
>
> On the other hand, if we consider the **huge difference** between **your estimation** and my **actual gas consumption**, *I refuse* to **pay the amount** you are asking for and *invite you* to send me a **new invoice**, reporting figures closer to reality.

Context identification allowed to retain a target text like :

> Dear Sir,
>
> I am the tenant of the apartment located X Street in TheTown, belonging to Mr and Ms Y. Since I have taken up the place in 1996, I have only received invoices reporting estimations of my electricity consumption.
>
> Before I was here, the place was unoccupied. I'll take the liberty to tell you that at present, the electricity meter indicates 36,637.
>
> ***I'd be grateful if*** you could send me an invoice corresponding to **the actual consumption**.

Notice that the NP *real … consumption* was also included in a focused sentence in the input letter (*On the other hand …, I refuse ...*). Notice also that the target text focuses on the NP *electricity meter* (*I'll take the liberty*

to…), that could also be found in the input letter under the form *gas meter*.

We have found that it is not necessary to carry out context indexing for the input letter to improve precision: it is enough to search the context of NPs in the candidate target texts. On the other hand, to execute a relational indexing (NP + context tag) both for the input and the target texts allows precise link typing, which makes navigation easier.

The same search session as above allowed to eliminate a number of target texts, that had been retrieved be found on the basis of simple NP matching, but were not pertinent, like:

> Sirs ;
>
> I take the liberty to draw your attention to the dangerous situation menacing all the families living in our building.
>
> We experienced important damages due to water overflow last summer. To day, the leakage, which has not been stopped yet, affects the wall bearing our **electricity meters** and wiring.
>
> [*long descriptive text snipped*]
>
> If you consider that there actually is no danger, *I'd be grateful* if you could send us an official written declaration about this, *etc*.

In this target text, there is no co-occurrence of context markers and extracted NPs, as compared to the input letter. Therefore it was not retained by HyTEC, which improves retrieval precision.

Eventually, we are left with 1) non-pertinent targets that have been retained, but also 2) pertinent candidates that have not been retrieved.

In the first case, co-occurrence of markers and NP has been identified in a sentence or paragraph, yet the rest of the letter relates events or circumstances that are different from those found in the input letter. However, the noise caused by uninteresting letters is very low, considering the number of searched texts. In this case, retrieval precision would probably improve if we could rely on a global text model, accounting for lexical and discursive chaining.

In the second case, in spite of global similarity between the input letter and a possible candidate target, content proximity has not been identified. The most frequent cause of this kind of failure is that pertinent markers focus on *synonyms* of extracted NPs. Improved recall rates should be attained cost-effectively by adding a relatively small number (the corpus is homogeneous) of synonymic relations to the NP network. We are planning to test the integration of a tool (SynoTerm) that automatically supplies Lexter with candidate synonyms from general language resources (digital dictionaries) (Hamon, 2000).

5. Generation of a hypertext structure

The results of link computation are presented in the form of a hypertext structure generated on-the-fly, directly exploiting the data structure in Lexter's relational database.

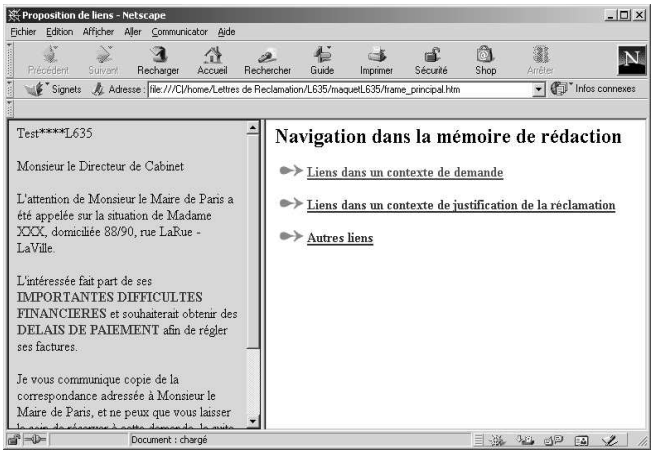

Figure 1: Navigating in context classes

The demonstration window (Figure 1) shows the text of the input letter (left) with salient NPs highlighted and (right) a choice of links to pertinent context classes (complaint formulation, enquiry, justification, etc.).

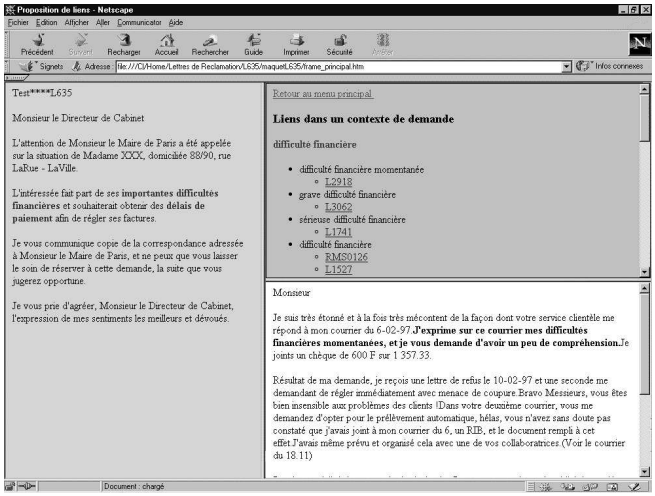

Figure 2: From typed links to target paragraphs

Once a context class has been selected, the links to target texts appear (Figure 2).

6. Evaluating task performance

The results of the first experiments are encouraging in terms of precision/recall ratio (Nava & Garcia, 2001). However, we feel that traditional evaluation measures are not completely adapted to the task, as it is often a delicate matter to decide whether two letters are even loosely connected.

As we are currently testing the system on a more extensive input letter set, a more flexible evaluation protocol is under study. It will possibly include an improved link type taxonomy and link weighing.

7. Methodological issues about customization

In this paper, we have shown how we have reused, customized and integrated two different NLP tools.

Lexter and ContextO belong to two different paradigms, which are, we believe, complementary.

Lexter and ContextO were not designed to be integrated. Lexter is a corpus-based extraction tool, ContextO is a knowledge-rich filtering system. However, we found that their results are complementary, and their coupling has provided benefits that reach beyond the simple application of cascading NLP processes.

In our case, we have observed that facility of integration and customization are related to a number of features, ranging from modularity and separation of linguistic resources and procedures, to implementation by off-the-shelf technology.

7.1. Lexter

We have taken advantage of the following:

1. Corpus-based extraction without domain-specific resources (dictionary, thesaurus, etc.);
2. Shallow morpho-syntactic structuring;
3. Access to the full-text source;
4. Simple distributional data (frequency, head-modifier productivity in the morpho-syntactic network);
5. Extraction results stored and organized in an off-the-shelf relational database (Microsoft Access).

On the other hand, considering our particular application, we have experienced an important limitation due to the fact that Lexter is basically an extractor of candidate terms. This is certainly well suited for technical, domain-specific text processing; but for our collection (customers letters), this constraint is rather restrictive. Given the source, purpose and style of the texts, we would have been happier with additional lexical information, like, for example, verbal phrases (which are generally ignored by the classical terminology theory and applications). In informal writing, an expression like *pay the bill* is often preferred to *bill payment*.

7.2. ContextO

ContextO was *designed* to facilitate the acquisition and reuse of linguistic knowledge, based on the following:

1. Separation of linguistic knowledge and search engine;
2. State-of-the-art object model of text, linguistic data and tasks;
3. Independent specialized agents exploiting the knowledge base;
4. Portable Java engine implementation accessing an off-the-shelf relational database (Microsoft Access).
5. Exploitation of markers related to structures of the general language.

It must be noted, however, that if the marker collection is largely domain-independent, it is sensitive to style and textual genre. Moreover, certain semantic classes (for example, thematic markers) are more generally reusable than others (for example, static relation markers).

Prospective work includes the adaptation of our approach to automatic, corpus-based terminology structuring.

8. Acknowledgements

Our PhD research is financed by *EDF R&D*.

Lexicalized Grammar Specialization for Restricted Applicative Languages

Patrice Lopez, Christine Fay-Varnier, Azim Roussanaly

LORIA, INRIA Lorraine and Universities of Nancy
BP 239, 54506 Vandœuvre-lès-Nancy, France {lopez, fay, azim}@loria.fr

Abstract

In the context of spoken interfaces, we present a practical methodology and an implemented workbench called EGAL (Lexicalized Tree Grammar Extraction) dedicated to design and test restricted languages used in specific task-oriented applications. A complementary methodology is proposed to process the extraction of these applicative languages from a general LTAG grammar and a training corpus. Additional results allow us to estimate the representativeness of the training corpus. An application of the system is presented for the tuning of a LTAG grammar dedicated to a spoken interface on the basis of a Wizard of Oz corpus.

1. Introduction

1.1. Motivations

In the case of a spoken dialogue system, the quality of the human computer interaction largely depends on the ability of the computer to understand spontaneous utterances normaly used by humans. The practical development of a spoken interface for a restricted domains implies that we perform the tunning of existing lexicon and grammar to a particular application. This paper proposes a methodology and an implemented workbench called EGAL (Lexicalized Tree Grammar Extraction) dedicated to design and test restricted natural languages used in specific task-oriented applications. This workbench is a sub-component of a general platform for designing spoken language systems and addresses software designers who are non-experts in natural language processing.

Specializing a grammar for restricted domains supposes at least the two following tasks:

- Cutting down the existing lexicon and grammar.
- Adding new words and new syntactic constructions.

In recent years, the development of large covering lexicalized grammars could be observed. Complementary, studies about the use of this kind of formalism for parsing spoken language have been performed. To address spoken disfluencies and robustness constraints in the context of human computer interaction, additional mechanisms have been proposed which often depend on the application domain. At the lexical and syntactic level, the following adaptations are required:

- Model spoken phenomena that could be considered agrammatical or rare in written language but frequent in spontaneous speech such as ellipsis or interpolated clauses (Price et al., 1989).
- Use robust parsing techniques to take into account the variability of the input.
- Specialize a lexicon and a grammar dedicated to text to a specific kind of dialogue and a specialized domain.

This paper addresses the last point. The specialization of a general hand written grammar to a specific domain is not a trivial task. Probabilistic methods and grammar inference as (Bod, 1995) can be seen as an alternative to this problem. Still a linguistically motivated hand written grammar provides a precise understanding of the occuring phenomena and reusability. In particular, this kind of grammar allows us to take into account the important ambiguity of the syntactic level. This ambiguity is one of the main differences between natural language that we want to process and regular languages which are just an approximation of natural language. Moreover, probabilist methods need very large annotated training corpora. Their development can require the same amount of effort as the writing of a wide-covering grammar.

We present in this paper a methodology and an implemented system called EGAL (Lexicalized Tree Grammar Extraction), able to perform an assisted specialization of a general grammar in order to obtain an applicative sublanguage from a corpus. When the specialized grammar has been obtained, a parsing module allows the evaluation of the grammar on a test corpus and the choice between various parsing algorithms and strategies. The partial and complete derivations can be visualized and compared following different criteria. The methodology also allows us to obtain information about the representativeness of the initial training corpus. Finally, the lexicalized grammar and the parser can be integrated in concrete HCI systems.

The proposed workbench can be applied to various domains. Our main goal is to design generic and portable spoken systems that can process spontaneous language. To illustrate our methodology and system, we have chosen a target application and collected an experimental Wizard of Oz corpus from which we have extracted a lexicon and a specialized grammar. We have finally evaluated the representativeness of the resulting grammar.

1.2. Lexicalized Tree Adjoining Grammars

The lexicalization of a syntactic formalism consists of the association of a set of appropriate syntactic contexts to each entry of the lexicon. Lexicon and grammar are merged in a single entity called *syntactic lexicon*. Lexicalization provides at least two main advantages: First the ability to describe syntactically each specific lexical entry allows us to choose the required complexity of the syntactic structures with flexibility. Even for restricted domains, too much generalization in syntactic descriptions generally results in

unexpected border effects. Secondly the lexicalization allows parsing heuristics since a lot of syntactic ambiguity problems become lexical ambiguities which are easier to process (Abeillé, 1991).

The choice of the formalism is essential for the representation and the understanding of linguistic phenomena. It is also important to consider its applicability for NLP applications. The Lexicalized Tree Adjoining Grammars (LTAG) (Joshi and Schabes, 1992) is interesting for parsing and generation thanks to the lexicalization property and extended domain of locality. Linguistic studies and large-covering grammar developments for example in English and French have shown the practical interest of these properties. Moreover probabilistic models based on LTAG as stochastic TAG (Srinivas, 1997) or supertagging (Srinivas, 1997), allow optimizations for the processing of lexical and syntactic ambiguities on the basis of preferential choices. These properties make the LTAG formalism interesting for spoken utterances understanding (Halber, 1998) and generation in spoken systems (Becker et al., 2000).

Still the lexicalization has some drawbacks, in particular the task of designing of the grammar. Still work in progress, the English grammar of the XTAG system (Doran et al., 1994) already took ten years of development, the French grammar (Abeillé et al., 1994) more than seven years. A large covering grammar can include several thousand of elementary tree patterns called *schemata* (Candito, 1999) and a syntactic database that gives for each lemma the set of corresponding trees or tree families. Considering a given application, the use of the whole general grammar would lead to a prohibitive number of hypotheses. Moreover our goal is to avoid the development of a new grammar for each new application.

Work on the use of LTAG for dialogue systems for both parsing and generation of a sublanguage has been done recently, but the tuning of a general grammar to a specific application and domain remains a problem for the practical application of such a lexicalized formalism. The extraction of sublanguage grammars for LTAG has been discussed in (Doran et al., July 1997). But the proposed solution was based on successive manual approximations by experts. No practical methodology was proposed. No significant features have been identified that could help to perform more efficiently this task or that could lead to a software engineering solution.

2. Collection methodology

2.1. Restricted language

A restricted language can be defined as a set of utterances linked by a restricted domain, used for a particular function and generated by a specific grammar and vocabulary (Deville, 1989). Two factors limit the general language: The kind of discourse or dialogue which is realized and the application domain of the system. A restricted language is not only a subset of the whole language since an application can use technical terms which are only relevant for the domain. Moreover even in limited domains, the size of the vocabulary and the syntactic constructions change as the application evolves. Consequently a system has to propose a methodology to add new words and new syntactic contexts for the structures that would not be covered by a general grammar.

The practical advantages of the restricted language definition are a reduction of the combinatoric complexity of the processing and the ability to use a hand-written grammar (which is for example not realistic for dictation systems).

In the case of spoken dialogue systems, we claim that the systems should not understand words out of the corresponding restricted language because such words do not belong to the competence of the system. The lexicalized grammar defines here the norm of the applicative language, i.e. what is acceptable or not. Since domain restricted applications should not understand every user's request, they eventually have to lead additional dialogues with the user in the case of out of domain words.

2.2. Wizard of Oz experiments

The Wizard of Oz experiments are now widely used as a first step of the design of a spoken dialogue system. This experiment consists in the simulation of a spoken dialogue system in order to get a set of possible user interactions for a given application. The resulting corpus (which has a subjective representativeness) becomes a reference for the linguistic modeling. In other restricted domain applications, such as automatic thematic classification of e-mail in e-commerce, a similar step is necessary.

One of the main problems related to this kind of corpus is its representiveness for the application sublanguage we want to model. If the principle of restricted language is relevant, we can expect that by increasing the size of the training corpus, we will reach a size such that any addition will not result in a significant increase in the vocabulary or the size of the grammar.

Our approach consists first of obtaining a corpus which is classically divided in two parts. The first part is used to design the grammar of the restricted language (*training corpus*). The second one is dedicated to test (*test corpus*).

We have presented the different aspects which are essential for the kind of system we want to build: WoZ Experimental approach in order to obtain a corpus, specialization/designing of a lexicalized grammar dedicated to spoken language understanding, test of the resulting grammar and representativeness evaluation of the training corpus.

We have not found any existing workbench for lexicalized grammar which would combine all these aspects.

3. Presentation of the workbench

The general organization of a lexicalized tree grammar dedicated to parsing relies on three main knowledge sources:

- A morpho-syntactic database which associates an inflected form, a syntactic category and a set of morphological features.
- A syntactic database which associates a given lemma to a set of elementary trees representing the valid syntactic context for this lemma.
- A set of schemata (Candito, 1999).

The grammar designing/tuning module of the system is based on these three kinds of databases (see figure 1).

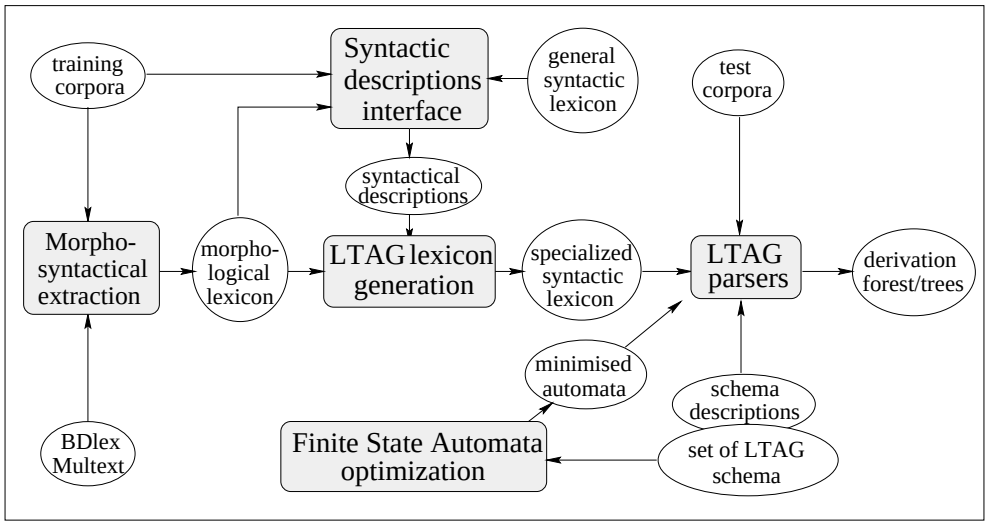

Figure 1: Overall presentation of the EGAL workbench.

3.1. Assisted generation of the lexicons

Morpho-syntactic extraction Given a training corpus, this step just corresponds to the exploitation of existing morpho-syntactic databases, Multext and BDlex (Ide and Véronis, 1994), by extracting the required information for all the words used in the corpus. This process has been implemented with an automaton-based compilation of the morpho-syntactic databases.

Set of schemata We assume that we already have a set of schemata (non-lexicalized elementary trees). For instance this schema can come from an existing hand-written grammar or from an automatic tree generation system as proposed by (Candito, 1999). A graphical editor allows the design of new schemata or the modification of existing ones.

Syntactic descriptions The goal of this module is to identify the syntactic properties associated with a lemma in order to select its correct syntactic structures. This identification is not an automatic process since resources able to enumerate all the possible predicative structures for a given lemma are not available. This result is obtained on the basis of a graphical interface dedicated to non-grammarian users.

The main idea is to associate a term of syntactic features to characterize (i) the various possible syntactic contexts covered by the general grammar (i.e. the various LTAG schemata), (ii) each lemma of a given corpus on the basis of a linguistic test suite illustrated by examples. The unification of these two structures characterizes then the precise subset of the acceptable syntactic constructions for each lemma.

The definition of our syntactic feature set is based on linguistic studies of French (mainly (Abeillé, 1991)). The current system uses nineteen syntactic features for the characterization of a verbal context (for example arity, passive, subject-verb inversion, support verb, equi-verb, reflexive, auxiliary,...) and a frame of possible prepositions. An alternative would be to use the syntactic features corresponding to the metagrammar described in (Candito, 1999) and the corresponding grammar generation system: In this case the description term corresponding to the schema that would be obtained automatically with the generation of the schemata.

For each syntactic feature we create a linguistic test composed by a question labeling the set of possible values and a set of examples. The tests are stored in a declarative way in a XML document. This XML document is then used by a generic test interface that allows a user to fill the frame for each lemma in a friendly way. The result of these tests consists of a feature term which is the syntactic description of the lemma.

For example the two following questions begin the French linguistic tests for verbs:

- Which auxiliary is used with the verb? (one between *être* and *avoir*)
- Can the verb be used in an intransitive/transitive/ditransitive context?

The tests continue until the complete frame of syntactic features and the preposition frame are specified.

The unification of the terms associated to the different schemata and the term obtained for a given lemma gives the correspondence between an entry of the lexicon and the subset of schemata that can be anchored by this entry. For instance on figure 2, the tree schema can be used with the lemma *enlever* since the two syntactic descriptions can be unified. This lexicalization process is uniform with the lexicalization performed on the basis of morphological features (for instance infinite verbs only lexicalize infinitive contexts).

This module can be used in two different ways:

- Completion of the whole list of linguistic tests in order to characterize completely a lemma for all its possible uses.
- Characterization of the syntactic contexts observed in the training corpus.

For the proposed methodology, the second possibility must be chosen. The list of utterances (in the training corpus)

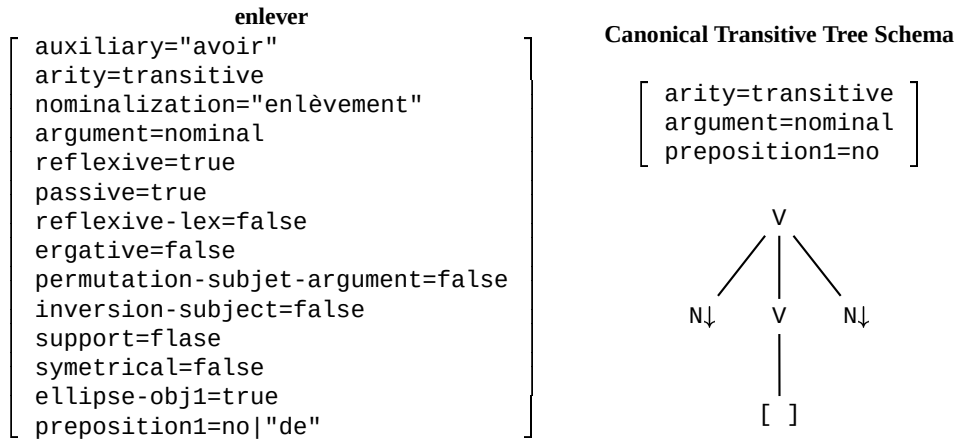

Figure 2: Two examples of syntactic descriptions: one for the French lemma *enlever*, one for a transitive tree schema.

which contain the lemma and the linguistic tests are proposed simultaneously to the user by the graphical description tool. In our methodology, contrary to the classical approach for cutting down the grammar, we specify each entry of the lexicon in terms of its category and also in terms of its correct syntactic contexts. The resulting grammar is really a *lexicalized* subgrammar.

We do not use the principle of tree family used by the XTAG system because of the small size of the lexicon and for reasons of computational efficiency. With tree families, the final selection of trees associated to an entry of the lexicon is obtained dynamically by unification at the time of instantiation. Here the correct trees are already predefined and listed in the syntactic lexicon.

A complementary tool for linguists allows the design of linguistic tests. We note that:

- The descriptions obtained by filling the features frame are independent from the lexicalized formalism. For instance, one could use HPSG lexical types.
- This module allows us to integrate easily new words to a system by characterizing the inflected forms which are not recognized during the morphological extraction. Moreover a very important point is that adding new words with this tool can be done by a non-linguist user if the linguistic tests are correctly written.

Automatic generation of the specialized LTAG syntactic lexicon This step produces the syntactic lexicon by exploiting information from the three databases described before. We add to each entry of the morphological lexicon the list of LTAG schemata which can be lexicalized. This list is obtain by

- The unification of the morphological features of the flexed form with the morphological features of the node to be anchored.
- The unification of the syntactic feature term that describes the corresponding lemma with all the syntactic feature terms of the schemata.

The links to schema are simply noted with external references using the XML links mechanisms. The final anchoring is classically done as a pre-parsing process.

3.2. Parsing test workbench

After the generation of a grammar for an applicative sublanguage given a training corpus, this module aims to test the results on a second test corpus. It allows us:

- To visualize the parsing results (both partial and complete ones).
- To check the generated grammar and possibly change manually some data in the syntactic lexicon or the set of schemata.
- To test and to compare various parsing heuristics and strategies.
- To study out of grammar phenomena.

This workbench implements two chart parsing algorithms and several parsing heuristics:

- A bottom-up connection driven algorithm that delivers extended partial results (Lopez, 23 25 February 2000).
- An implementation of the top-down Earley-like algorithm of (Schabes, 1994).

The bottom-up parser gives complete and partial parses with or without unification of features structures used in Feature Based LTAG. These different kinds of results aim to test the grammar by identifying the step involved in the failure of the parsing.

3.3. Technical choices

The implementation have been made in Java for portability reasons. All the involved data are encoded in the highly portable formalism XML. A specific application of XML dedicated to resources used with LTAG has been developed called TagML (Tree adjoining grammar Markup Language) (Lopez and Roussel, 2000). TagML allows an efficient representation of these data in term of redundancy. For instance it is possible to encode only one time substructures that are redundant in several schemata. Similarly it is also possible to share feature equations occuring in several schemata. All these redundancies imply redundant

computation that could be avoided. This standard representation allows easy resource exchanges with our research partners and allows the sharing and the comparison of tools. The DTD allows us to check the consistency of the whole grammar. Every parser that respects this encoding norm can be integrated to the parsing workbench very easily.

The Java sources, classes and documentation of the parsing test workbench, including editors, are freely available on request. The other modules should also be packaged and available at the time of the conference.

4. Grammar of the GOCAD corpus

4.1. A target application: GOCAD

The GOCAD application aims to model geological surfaces. The protocol and the Wizard of Oz experiment used with this application are presented in (Chapelier et al., 1995). This experiment allowed us to obtain a corpus which has been encoded following the TEI specifications[1]. This corpus of transcribed French spoken utterances is presented in Table 1.

4.2. LTAG for the applicative restricted language

The corpus has been divided in a training corpus (80% of the utterances) and a test corpus (20%). The size of the LTAG grammar obtained with the EGAL system is presented Table 2. The total number of links to schema is a good metric for the whole size of the syntactic lexicon.

Given this specialized lexicalized grammar, the average time for parsing is 167 ms per utterance with an average lenth of utterances of 6.42 words per utterance on Sun Ultra 1. It is difficult to compare with results obtained with the complete French LTAG grammar because first the covering of this complete grammar is really limited for this corpus (124 unknown words). Moreover, for technical reasons, this grammar has been designed for the XTAG system which is very difficult to install (SunOS 4 only for instance) and use. For indication, the parsing of sentences of 10 to 15 words can take more than ten minutes.

4.3. Representativeness of the training corpus

The morphological extraction phase and the generation of the syntactic lexicon for GOCAD are fast (less than one second for the first one, less than ten seconds for the second on an average workstation). Consequently it is possible to realize systematic tests to study the evolution of the generated data. The method consists of first randomly selecting utterances from the whole corpus and then generating the corresponding LTAG grammar. This allows us to study the evolution of the size of the grammar given the number of links to a schema in function of the number of utterances taken into account. A decrease of the slope of the curve indicates an improvement of the coverage. A horizontal asymptote would mean that the coverage of the grammar is perfect for the target sublanguage. The Figure 3 gives the evolution observed for the GOCAD corpus: The number of new structures obtained by considering the last two hundred utterances is very low and we can conclude that the final generated grammar is a good approximation of the GOCAD sublanguage.

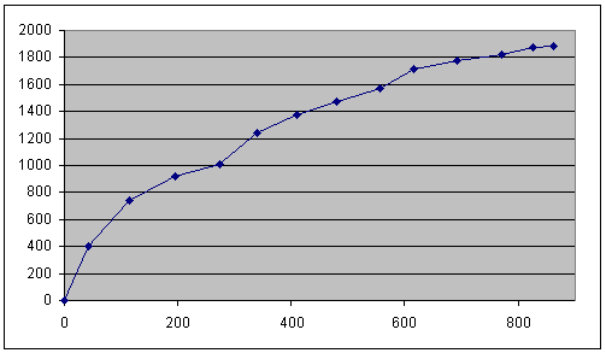

Figure 3: Evolution of the size of the generated LTAG grammar (number of links to schema) as a function of the size of the training corpus (number of utterances)

Such a result can be very useful to estimate the size of the corpus needed to reach a satisfactory covering rate. Covering 100% of the utterances is not our objective since in our approach only utterances corresponding to the competence of the spoken system need to be understood.

5. Future direction

We plan to see how the workbench scales up to other corpora and applications different than spoken interfaces. Our second goal is to extend the specialization workbench to cover multilinguality. One difficulty that arises is that the syntactic features used for the description of tree schemata and lemmas can be different from one language to another. It would mean that only a subset of these features has a real multilingual validity and could be used for parallel specialization of multilingual syntactic ressources. Syntactic features depending on the language might be limited if we only restrict them to pairs of languages, i.e. not considering all the languages at the same time.

A Versatile Knowledge Management Package

Hurskainen Arvi
University of Helsinki, Box 59
FIN-00014 University of Helsinki, Finland
Arvi.Hurskainen@helsinki.fi

Abstract

It is suggested that for the knowledge management system to be accurate, flexible and have wide coverage, the customer should have access to the whole chain of analysis modules, whether general or language-specific. The customer should not be made dependent on pre-coded texts. The analysis package should provide possibilities to perform various levels of encoding, disambiguation, etc. A knowledge management environment, tested with text of 8 million words, is briefly described.

1. Introduction

Sophisticated and powerful systems for knowledge management are not necessarily easy to use, while user-friendly systems are found among such applications that perform fairly simple tasks. Can these expectations be met within one single system? And if not, which of these two should be given preference? There are big differences among end users in the preparedness to use time for learning the system.

I personally, coming from the research community and serving primarily specialised communities outside the academia, am interested in maximizing the usability of a knowledge management package, which consists of language resources as well as of various language-specific and general-purpose applications. I shall discuss a system that analyses the language cumulatively, starting from morphology (Koskenniemi 1983; Hurskainen 1992) and extending to disambiguation (morphological and semantic) and syntactic analysis (Karlsson 1990, 1995a, b; Karlsson et al.; Tapanainen 1996, 1999; Tapanainen and Järvinen 1994; Voutilainen et al. 1992; Voutilainen and Tapanainen 1993). Maximum versatility of the system is achieved by including into the package all components of analysis, so that the user can perform a large number of different tasks within one single system (Hurskainen 1999a). The cumulative language analysis package can be conceived as a chain of phases, where each phase takes the output of the previous phase as input and performs a defined operation. Therefore, each phase of analysis is a potential cutting point, which can be a basis for a customized application. The result of a morphological analyser, for example, is the phase, on which a spelling checker can be built. A further phase in the chain provides a basis for more advanced language proofing tools, such as phrase structure checkers. These are examples of such customisation where the end user has very few choices.

We may, however, conceive of a system where the end user has access to each phase of the analysis chain and to all its intermediate analysis results. Such possibly useful intermediate phases are the list of tokens (tokeniser), morphological analysis with all possible grammatically correct interpretations of each word-form (useful for studying homonymy), heuristic morphological guesser for assigning analysis for unrecognised words, morphological disambiguation (non-ambiguous morphological interpretation of word-forms), semantic disambiguation (non-ambiguous word sense interpretation of word-forms), syntactic analysis (shallow syntactic parsing or full dependency trees [Tapanainen and Järvinen 1997; Järvinen and Tapanainen 1997; Tapanainen 1999]), etc.

If the user has access to the whole package, he or she is able to make maximum use of the power of each of the programs, and can use texts of one's own choice as input. In order to utilize the versatility of the system, the user environment should facilitate processing in pipe, such as found in Unix/Linux environments. Also several general-purpose utilities, filters and programming languages of Unix add to the usefulness of the system. In other words, a comprehensive analysis system working in a powerful environment facilitates the maximum number of applications.

It becomes obvious from the above that this is not a hit-a-button system, and my impression is that really useful systems cannot be made very simple. But they can be made manageable and fairly easy to learn and use, provided that correct and detailed information is given about the properties and function of each module. Below I shall explicate the ideas given above by describing a language-specific knowledge management system applied to Swahili.

2. Components of the system

The knowledge management system has the following components:

(1) A program that cuts and marks the text into suitable pieces for further processing.

(2) Text normaliser that formalises the text suitable for computational analysis.

(3) Tokeniser that identifies each token in text and verticalises the text.

(4) Morphological analyser that gives each token one or more analyses.

(5) Heuristic guesser that utilizes morphological features and assigns an analysis to unrecognised words.

(6) Morphological disambiguator that resolves morphological ambiguity on the basis of context.

(7) Semantic tagger that tags the word-forms semantically with the help of a look-up dictionary.

(8) Semantic disambiguator that resolves semantic ambiguity with the help of (a) context-sensitive rules, and (b) by utilizing the technique of Self-Ordering Map (SOM).

(9) Syntactic analyser. Two versions are provided, one for shallow syntactic parsing (Constraint Grammar), and another one for constructing full syntactic trees (Dependency Grammar).

(10) General lexical database manager for transforming the result suitable for general dictionary compilation.

(11) Domain-specific database manager for preparing domain-specific dictionaries.

(12) Information extraction based on linguistic analysis.

The system is so constructed that each module is built on top of the previous one. For example, the heuristic guesser (5) can be applied only after the phases 1-4 have been processed. Because all modules, except for (1) and (3), are language-specific, access to the whole package has to be provided for the user.

The system has been under development since 1985, and currently it has major components for morphological analysis (Hurskainen 1992), morphological and semantic disambiguation (Hurskainen 1996), as well as for shallow syntactic mapping (Hurskainen 1999a).

3. Where is the bottleneck?

Although it is generally accepted that knowledge-based systems enhance greatly the performance of knowledge management, very few such systems exist. The bottleneck might not be only the lack of sufficiently advanced modules in the system, but rather the fact that the system is necessarily fairly complex, and that rarely the designer(s) of the system have access to the source code of all the components of the system. It often turns out that the developer of a module finds himself struggling with problems that actually should have been solved by the developer of the previous module in the chain. And if the previous module cannot be corrected, the developers are left struggling with problems in the wrong environment. Work with rule-based disambiguation and syntactic parsing is an example of such work, where the developers should have a possibility to correct or change the morphological parser. There are always bugs in the morphological parser, and such bugs are often found in testing disambiguation rules. Also the coding system might need improvement, and it would be best to fix it in the morphological parser and not patch it up after the analysis has already been performed.

4. Shell scripts vs. user-defined processing

The system sketched above makes it possible to construct the processing chain in several ways, depending on needs. As it is well known, command calls of varying complexity may be stored into shell script files. For example, shell scripts for performing various phases in the process may be constructed so that one script performs phases 1-4, another 1-5, another one again 1-6, etc. It is important to note that the system allows the processing of raw text, and with each call the processing is taken that far as is defined in the shell script.

What is defined in shell scripts may be called also directly from the command prompt. Command calls are, however, usually so complex that the use of shell scripts has become a common practice. However, the shell script does not necessarily always give the desired result. For that reason it is often useful to combine shell scripts and command calls as one consequtive chain of commands. What is important is that the user may build one's own working environment by using the possibilities offered by the operating system (Unix/Linux). This does not exclude the possibility that the basic package distributed to the customers contains a model environment for those who do not have interest or time to develop their own more flexible environment.

5. What format should the source text have?

Corpus texts available to the customers are often encoded in some way. If they do not have part-of-speech tagging, or even more sophisticated encoding, they are encoded at least on the level of document structure, by using SGML, TEI, or XML encoding. It depends very much on the application which type of encoding is useful. If, for instance, the application is aimed at retrieving whole documents according to selected criteria, the document structure encoding is useful, and often sufficient. On the other hand, if the application aims at fine-grained knowledge management, the encoding of the document structure provides only a kind of background level, and each token has to be encoded in respect to several levels of linguistic analysis. Let us look in more detail the usefulness of various formats of source text.

(a) SGML, TEI, and XML encoding

One of these encoding systems, increasingly XML, is used in encoding corpora. Although such encoding is not very useful for some applications, it is not harmful either, because it helps in including or excluding sections of the documents in processing.

(b) Corpora with part-of-speech tagging

For a long time corpora tagged with POS codes have been principal sources of corpus-based linguistic investigation. Tagged corpora have the advantage of transparency and fairly good reliability, because the code set as well as the actual encoding of text is visible, and the encoding has been checked. Its disadvantage is that it is a frozen document. Both the text itself and the encoding are in fixed format, and it allows very little calibration.

(c) Corpora with analysis programs

If the aim is to establish an accurate and efficient knowledge management environment, it is hard to see any other possibility than to provide the customer with a package that contains both the source texts and the analysis programs. And in fact the programs are even more important, because they give the user a possibility to use any texts. In order to make the system user-friendly, the analysis system should be able to accept text in the format where texts are usually available.

When the user has access to all programs in the package, it makes it possible to maintain the same texts in various formats. It is obvious that the ordinary text format is useful in retrieving context for keywords. It is also very likely that the user would like to have the text also in some kind of pre-processed format, so that there is no need to process all phases each time when information is searched. At least a tokenised format, or sentence-per-line format, is a useful format to preserve. In that case, proc-

essing could be started from phase 4. The heaviest part of processing is the section composed of phases 5-9, because they contain the actual linguistic analysis and disambiguation. Because this takes some time, depending on the size of the corpus, there is a temptation to analyse the corpus and preserve the analysed version of corpus as a source for further processing. The disadvantage is that the analysed files tend to become fairly large, in Swahili for example 14 times the size of the original file. The disambiguation process downsizes the result by about 50 per cent. However, if the disambiguated text is saved in zipped format, its size is about the same as the original unzipped text. Therefore, there are practical possibilities to maintain even large texts in analysed format.

6. The optimal compromise

It depends on the skills of the user what kinds of use can be made of the language management system. Testing the performance and accuracy of dictionaries (Hurskainen 1994, 1999b) requires much more from the user than the production of concordances, for example. Taking into account the fact that most users value the ease of use, the various phases of analysis described in (2) above can be packed to the following components:

(a) **Tokeniser** includes the phases 1-3
(b) **Morphological** analyser includes the phases 4-5
(c) **Disambiguator** includes the phases 6-8
(d) **Syntactic analyser** includes the phase 9

These components can be compiled as runtime versions, in which case they cannot be modified by the user but their use is easy and fast. This solution includes the most important language analysis components but still leaves the user freedom to process the result of each phase for one's own needs.

7. Summary

A full language analysis package adapted to a suitable platform enhances an accurate, powerful and versatile working environment for a number of applications and user-defined tasks. The system described here relies heavily on language-specific and rule-based components. Although the basic components are generic, domain-specific applications can be built on the basis of features in the analysis. In Appendix are some extracts from text in various formats.

Challenges in MT customization on closed and open text styles

Rémi Zajac
SYSTRAN Software, Inc.
zajac@systransoft.com

Abstract

This paper reports work in progress on two on-going customization projects at Systran. One project targets on-line technical support documentation. This project falls in a domain that has been (and still is) a favorite target for high-quality MT applications. The second project targets open style (on-line) texts on a large set of small domains. We outline and contrast customization issues for these two projects, and present the customization process based on an automated analysis of monolingual corpora.

1. Introduction

Manual versus automatic customization

Customization of MT systems is a problem that has not received much attention. Typically, customization is reduced to the (manual) development of a simple domain-specific dictionary. Complex lexical entries, involving complex subcategorization patterns for example, are excluded; a fortiori, syntactic customization is excluded too.

Most previous work on automated customization make use of a parallel corpus, for example Yamada et als. (1995) and Su et als. (1995, 1999). Of course, example-based systems may be considered fully customized systems (Richardson et als. 2001, Pinkham et als. 2001).

Yamada et als. (1995) present a method to adapt a rule-based MT system to a new domain by using aligned sets of sentences. The method involves the comparison of the MT parse tree (presumably after transfer) with the parse tree of the manually produced translation. A side effect of the comparison is the automatic generation of either bilingual dictionary entries or transfer rules. The interest of the method is not clear since the technical description is rather sketchy and since there is no discussion on the influence of the bilingual corpus on quality improvement. The method seems to be implemented only for simple bilingual lexical equivalences.

Su et als. (1995, 1999) suggest that customizing an MT system can be reduced to learning probabilistic parsing parameters. They use probabilistic learning techniques to select the best parse of a non-deterministic parser. The best parse is the one that gives a translation that is closest to the manually translated sentence (or the one which produces a parse tree that is closest to the parse tree for the manually translated sentence, the paper is unclear on this point). The method does not seem to be implemented.

The best current approaches, providing highest quality results, to fully automatic customization are using example-based techniques built on a substrate of a comprehensive rule-based system as in the MSR-MT project (Richardson et als. 2001, Pinkham et als. 2001). In this approach, there is no distinction between lexical and syntactic customization. What is learned is, in essence, a set of lexicalized transfer rules that may cover entire sentences.

Customization projects at Systran

Systran has recently started several customization projects, for example for on-line technical support documentation as in the Autodesk project (Senellart et als. 2001b). In all these projects, there is no bilingual corpus available. An essential part of the effort is the development of an automated methodology and tools to speed-up customization and to lower costs. A parallel effort that also supports customization projects is directed at the restructuration of the MT architecture towards better modularity and declarativity, and improved performances (Senellart 2001a).

The paper is organized as follows. The next section gives an overview of two on-going customization projects at Systran and outlines specific customization issues. One project falls in a domain that has been (and still is) a favorite target for high-quality MT applications: (on-line) technical support documentation. The second project targets open style (on-line) texts on a large set of small domains. The next two sections present the customization process. Section 3 describes the assessment of customization needs for a given application. This assessment translated into a customization plan, and the customization process itself is described in Section 4. We conclude on several open issues.

2. Two customization projects at Systran

MT applications have been traditionally divided into dissemination and assimilation applications. An

assimilation scenario is an analyst working of foreign documents in open domains and open styles (technical documents as well as web postings and email). These kinds of applications use a generic MT engine with a very large lexical coverage and implementing a non-specific language model that will succeed in providing an average quality on most texts and fail to provide a high quality on most texts. Dissemination applications target the translation of technical documents, typically technical user manuals, for publication. Technical documents cover closed domains and closed styles. Dissemination applications use specific MT engines with targeted lexical coverage and implementing a tailored language model that succeeds in providing a good quality on most texts.

It should be clear that, at present, manual customization could only be envisaged in the dissemination scenario, on a closed domain and a closed text style. For this kind of scenario, some rule-based MT systems have demonstrated high-quality translations. However, no system has ever been able to provide high-quality translation on open domains and open style documents. The consensus in the MT community seems to be that on these kinds of texts, MT can only be used for assimilation scenarios. However, this consensus is based on past experience with rule-based systems: it is still an open question whether example-based or statistical-based systems may achieve high-quality on open domains and open style.

Scenario 1: on-line technical support documentation

The source corpus for this project is medium size (tens of thousands documents, about 2M words). The document style is technical and homogeneous and documents are written by technical writers following specific style guidelines and using an in-house glossary. Sub-types of documents are well defined, for example, FAQs and procedures. The domain is homogeneous covering a single family of products, but very complex, with a high number of concepts and a high number of relationships between concepts. The corpus evolves slowly over time as new documents are added for new versions of existing products. There may be completely new products (still within the same product family) with new concepts and new terminology to cover. Therefore, a continuous monitoring of the document database is necessary to keep track of the emergence of new concepts and terms. At that point, a focalized customization effort is needed for these new documents.

This type of application has been a favorite target for high-quality MT in the past and still remains a favorite (See e.g., Richarson et als. 2001, Pinkham et als. 2001). Translation problems may be reduced to some extend by using a writing style guide. For example, the lexicon can be limited to common words (new words for new concepts only). Grammar and style variation can also limited by the use of technical writing guidelines. Such guidelines could be implemented in a controlled language checker. The idea is the same as for other controlled languages, but with a more modest aim: not solving all MT problems but limiting MT problems to a narrower range.

The main challenge is how to describe the terminology of a large and complex domain: the ontology of the domain is narrow but deep, complex and very specific. For this project, we use a mix of terminology extraction tools (see e.g., Jacquemin 2001). Another issue will be tracking emergence of new concepts as the document database changes over time, and update the terminology accordingly.

Scenario 2: fast changing on-line postings

This customization project blurs the distinction between MT for assimilation and MT for dissemination. In this project, the corpus is very large, millions of postings, with several thousands of new postings every day. The style is very relaxed and makes use of a large range of colorful expressions, with plenty of misspellings and grammar errors, highly variable punctuation usage, as well as uncommon abbreviations. The corpus can be divided into a large number of unrelated sub-domains. Within each domain, the terminology is relatively restricted with a limited number of concepts and a limited number of relationships between concepts. However, there is a very large number of proper names referring to specific products and entities.

In a posting, we can identify several sections that can be categorized into different styles. For example, a description of an object, contractual sections dealing e.g., with payment options or shipping, etc. However, there are always sections that cannot be fitted into any well-defined slot and must be considered free open text. These sections are the most challenging since they are typically argumentative in nature, conveying opinions and trying to convince the reader to adhere to these opinions. These sections are also the ones exhibiting free informal syntax and creative use of language. A specific issue here is to automatically segment a posting into sections that correspond to homogeneous styles and select most appropriate translation parameters for each style.

Each posting addresses a specific domain, and each domain is shallow and relatively simple. Each domain can be managed using simple thesaurus-like management tools à la Wordnet. There are however two main challenges. One is the number of domains (hundreds). Another is the novelty factor that requires constant tracking and customization to match changes in language. In particular, we need to track the emergence of new words (neologisms as well as new names and abbreviations) and new expressions.

3. Evaluation of Customization Needs

Customization assumes a base MT system. The first step in a customization project is to measure the gap between

the quality of this base system and the quality of the targeted customized system in order to evaluate as precisely as possible the customization needs, and to develop a customization plan.

If a bilingual corpus is available, the customization needs could be estimated by evaluating the performance of the base system against the corpus. The translation of the source corpus produces a baseline translation that can be compared and evaluated against the manual translation (target side of the bilingual corpus). An in-depth evaluation of mismatches provides a detailed catalog of customization requirements for both lexical customization and grammatical customization. This evaluation can also assign mismatches to specific sub-grammars of the MT system: NP analysis, verb transfer, relative clause generation, etc. This of course can only be done manually on a small set of documents only.

An indirect but more economical way of evaluating the customization needs is to:

- Measure the performance of the system on a known source baseline corpus, and to
- Evaluate the distance between the baseline corpus and the source corpus.

By using a set of quantitative linguistic indicators, it is possible to estimate the amount of customization needed to achieve a pre-set quality target. The following paragraphs give an overview of an automated customization evaluation process that includes the establishment of a baseline and the construction of a terminological (domain) profile, a lexical profile and a syntactic profile for the source corpus. These profiles are compared to the baseline in order to provide a quantitative estimate of the customization needs (Underwood & Longejan 1999).

A terminological profile of a corpus provides an estimate of the closure of the vocabulary of the corpus as well as the complexity of the domain. The vocabulary closure is measured by counting the number of new terms that appear when a new text is seen (term growth curve). If this curve flattens out rapidly (few new terms appear in newly seen documents), the vocabulary is essentially closed. In such a case, the customized system will probably require little lexical maintenance after delivery.

The complexity of the domain is estimated using the number of technical terms belonging to the domain and the number of interconnections between these terms. The number of interconnections between terms can be estimated by counting the number of syntactic relations between technical terms occurring in the same sentence: predicate-arguments relationships (predicate-object, but also predicate-subjects), and head-modifiers relationships.

New usages of existing words can be detected only as a failure in parsing or translation: parsing and translation failures are collected and sorted by shared lexical units: any lexical unit that occurs in several parsing or translation failures is a potential source of failure and should be investigated.

The syntactic profile of a corpus provides an estimate of the customization work needed on grammars for parsing, transfer and generation. The base system is evaluated on a standardized test suite where test items are categorized by linguistic classes of phenomena. This evaluation provides a detailed account of the strengths and weaknesses of the base system in terms of linguistic categories. We then run the system on the source corpus and extract a frequency profile of morphosyntactic phenomena. This frequency profile is matched to the baseline profile in order to build a customization plan, and to estimate the level of quality that can be achieved for a given level of effort.

4. Customization Process

The customization loop

The source corpus is segmented into translation units (sentences) and the translation units are translated, sorted and stored in the development database. Customization then proceeds along two parallel lines: one customization for terminology and lexical elements, and another for grammar and style. Customization plans are directly derived from terminological, lexical and syntactic profiles. Since any change in a component of the system may have unforeseen impact on other components, and in order to ensure constant progress and test for regression, testing is done continuously and in parallel to development. Continuous testing uses the development database, allows to focus on the main customization issues, to deal rapidly with any potential regression, and to measure progress.

Words that are not in the system dictionaries are extracted during the initial assessment. This initial step also produces a list of lexical units that may be sources of parsing or translation failures, and are therefore candidates for revision. Terminology lists are built using terminology extraction tools. Initial customization proceeds using these lists. As the systems dictionaries are updated, the test database is translated with the updated dictionaries, and new translations are compared with the initial ones. Any translation that shows a difference is added into the review set.

The initial assessment produces a frequency list of morphosyntactic structures that appear in the source corpus. Given that the baseline evaluation identifies the weak areas of the system, this list is converted into a customization plan where the most frequent weak areas are dealt with first (modulo dependencies between grammar modules).

Testing

Testers review new translations as the system is updated. Two different kinds of testing are done, one for terminological and lexical customization, and another for grammar and style. New translations are sorted according to various criteria, including coverage of terminology and difference in translation. For example, new terms added in the dictionaries should be matched and translated for all translation units containing these terms. Two lists are built: one containing matched terms (for simple checking) and one containing unmatched terms (to identify potential dictionary coding problems). A similar testing process is used for structural customization. For example, after working on relative clauses, all sentences containing relative clauses are extracted and divided into a list of changed translations and a list of unchanged translations.

When a translation is changed, it should show an improvement in quality: progress is tracked for any changed translation and quality of new translations is evaluated and recorded. Tracking the quality improvement rate allows us to estimate the cost-effectiveness of the customization effort.

5. Conclusion

The customization method presented in this paper is directly challenged by fully automatic methods using example-based techniques, including for example MSR methods (Richardson et als. 2001, Pinkham et als. 2001). Although manual customization is obviously feasible and can reach acceptable quality, one important issue is the cost-effectiveness of the method: a manual method should be cheaper than using automated customization with a bilingual corpus. Therefore, it should be cheaper or equivalent to the cost of translating a bilingual training corpus (this obviously depends on the minimal size required by the training algorithm). We assume that it may be cheaper when there are multiple target languages as the initial work of analyzing the source corpus and extracting terminology and other specific linguistic pattern can be shared among all target languages. Another important issue is the evolution of the source document database: we need to develop specific methods for tracking changes in language and for updating the language resources at a minimal cost.

To evaluate the accuracy of the estimates of customization effort, and to evaluate the speed and cost-effectiveness of the customization methodology, we are recording a set of quantitative indicators to help us provide accurate estimations. During a customization project, we are tracking cost of creating/customizing lexical entries together with the quality impact of these new of customized entries on the whole corpus. We do the same for grammar customization. Finally, the quality of the MT system is evaluated before customization, and a post-customization evaluation provides a measure of the improvement in quality that has been achieved. Experience over several projects should help us find the most relevant indicators, and obtain accurate estimates from detailed corpus analyses.

Abstract

We describe the background and motivation for an e-learning project—*IT-based Collaborative Learning in Grammar*—where NLP resource reuse has become an important issue. The resources are of several kinds: POS-tagged and syntactically annotated corpora (treebanks), parsing systems and grammar writer's workbenches, and visulization and manipulation tools for linguistically annotated corpora. Our experience thus far has been that although there are a number of such resources available e.g. on the Web, as a rule, numerous incompatibilities and lack of standardization at all levels—markup formats, linguistic annotation schemes, grammatical framework, software APIs, etc.—make the reuse of these resources into a non-trivial endeavor.

0. Preamble: the Setting

It is generally acknowledged that the goal of teaching grammar—especially at the university level—should not primarily be that students memorize definitions of concepts and grammatical constructions, but rather that they understand and learn to recognize different structural patterns. This can hardly be achieved without giving students practical training in the skill of grammatical analysis. Research has shown that hands-on problem-solving is more stimulating and thought-provoking than when the information and results are handed down to the pupils during lectures. Further, our experience has been that students learn about grammatical constructions and phenomena more actively when these constructions are discussed by comparing the system found in their native language with that of another language. An added factor contributing to an active student participation is the choice of the material forming the basis for exercises and group activities, which should preferably be as natural as possible.

With these pedagogical considerations in mind, we formulated a project for realizing a new format for teaching courses in grammar in Linguistics and Computational Linguistics (the ability to reason about grammar and to carry out grammatical analyses of language utterances being necessary prerequisites for all linguistic studies of language and thereby part of the core curriculum of these subjects). In the proposed format interactive practical training and corpus-based exercises comprise an integral part of the students' learning process, giving them the opportunity and incentive to participate more actively in their own learning process. Using IT as a tool for collaborative work allows the students to choose the problem-solving strategy which suits them best, as well as the time and place to work on the problem. A corpus of natural language material for grammatical analysis contributes to a more active participation, as it not only presents the grammatical constructions in their context, but also gives students a greater freedom to approach the material and conduct the investigation from a perspective which suits their individual learning styles. A text corpus consists of naturally occurring language in its natural physical context, since it is made up of complete texts or large text fragments, as opposed to the made-up or isolated single sentences or phrases often used to illustrate grammatical points in linguistics textbooks. This accompanying physical context makes it possible to investigate the textual, discourse-level, functions of the grammatical phenomena.

An outline of the proposed training material is presented below. It has a modular architecture, composed of four types of modules (see Figure 1, below):

1. 'Encyclopedia' module, containing descriptions of grammatical concepts and constructions. Its content will be attuned to the contents of the course and the interactive exercises (as, in their turn, the exercises will be adapted to the 'encyclopedia' contents), and at appropriate places, there will be hyperlinks to interactive exercises dealing with the current topic.

2. 'Text corpus' module, containing at least (a) POS-tagged and syntactically annotated corpora of Swedish, and (b) an annotated corpus of a foreign language. For (a), we will use the SUC and Talbanken annotated Swedish corpora (see below); for (b), we will use a corpus of Kinnauri (a Tibeto-Burman language spoken in India) narratives available on the web (`http://www.ling.uu.se/anjusaxena/corpus.html`; see figure 2), which is hyperlinked to a morpheme dictionary. Further, with the help of a graphic interface students will be able to see a 'map' of how and where one particular morpheme or a word occurs in the corpus (see Olsson and Borin (2000)), providing support in their work on the functions of grammar. The students will work with the

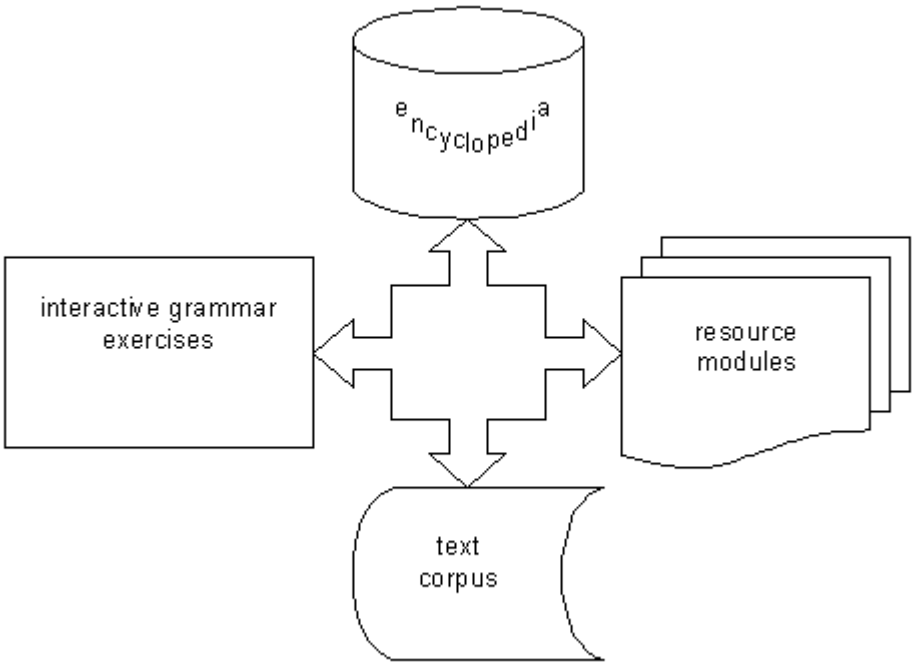

Figure 1: Organization of the proposed IT-supported grammar training application

same corpus as part of their group activities and as part of their examination.

3. 'Interactive exercise' module. Our aim here will be to provide students with a set of exercises, with basic tools for computer-mediated student cooperation in virtual work- groups (a 'spreadsheet' for problem-solving; optional 'step-by-step questions' for the grammatical topic covered; grammar rule writing exercises to be discussed in more detail below), with hyperlinks to the 'encyclopedia', to the 'resources' (see below) and to the annotated corpus of a foreign language (which, in turn, will be hyperlinked to the dictionary; see Saxena (2000)). As part of each theme, students will first discuss the construction during the lecture session, then again while examining the construction in the corpus, and finally also while comparing the results of the corpus-based analysis with the Swedish system and then discussing it in the group. This learning method where the same construction is examined from a number of mutually reinforcing practical and theoretical viewpoints will, hopefully, provide the students with support and incentive in their learning process. Further, the same corpus will be used in grammar courses in first and second semesters, providing grounds for deeper analyses in the second semester than would have been the case.

4. 'Resource' modules will provide a pool of resources for further reading and relevant links to other sites.

The architectural organization of the software proposed here has several advantages, the two most significant ones being extensibility and 'conceptual decentralization'. Extensibility means that new functions can be easily integrated in the application. 'Conceptual decentralization' is especially significant as it allows the possibility of adjusting to individual learning styles. For example, if the student prefers to start out with the 'encyclopedia' material and go from there to the appropriate exercises, when she feels the need to do so, she has that choice. At the same time, the application allows the possibility of starting out at other entry points, e.g., 'interactive exercises', with the option of calling up the relevant 'encyclopedia' material at each instant.

1. The NLP Resource Customization Problem

NLP resource customization has become an issue in this project mainly in connection with module 3 (interactive grammar exercises). It has been our aim from the conception of the project to rely mostly on standard WWW and open-source software—i.e., software which is generally free and where the source code is freely available and modifiable by the user—for implementing the modules. This design philosophy has the advantage of making the application maximally platform-independent, as well as providing a familiar interface—a standard web browser—for students and faculty.

One of the exercises that we have planned for module 3 builds upon a combination of a syntactically annotated corpus (a treebank) and a grammar writer's workbench. The basic premise of the exercises is a further refinement of the idea presented by Borin and Dahllöf (1999). We propose to use grammar rules written by students (using an existing grammar development tool) as search expressions in the

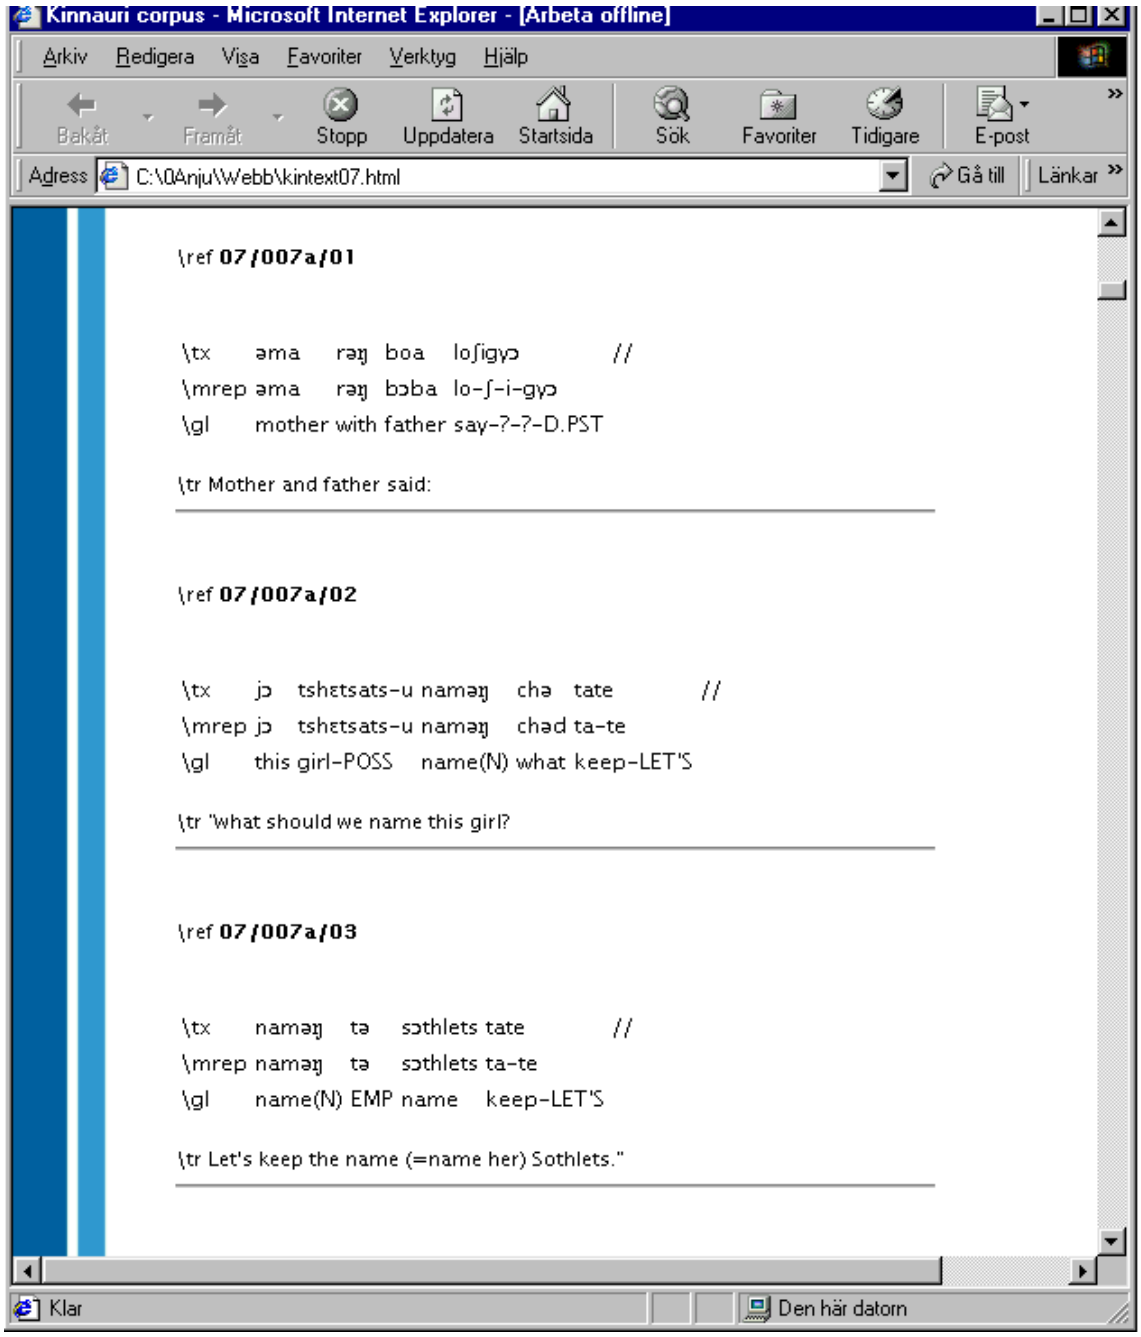

Figure 2: The Kinnauri corpus – Web format

treebank. In its simplest form, the result of the search would be expressed as precision and recall. Given an NP rule formulated by a student, we could automatically tell how many of the (maximal) treebank POS sequences matching the rule actually make up NPs, how many are not NPs, and how many NPs in the treebank are not described by the rule. There are all kinds of conceivable elaborations of this basic scheme, which could be seen as a more linguistically sophisticated parallel to the use of (unannotated) text corpora and concordancing software in so-called data-driven language learning (Flowerdew, 1996).[1] For the Computational Linguistics students, there is the additional advantage of being able to work from the very beginning of their studies with the same kind of tools and resources that they will be using 'for real' after graduating, in their professional life.

What we have found already in this beginning stage of the project, however, is that there are some serious obstacles to using available NLP resources.[2] Mostly, the issues that have arisen in this connection concern (lack of) compatibility and standardization of NLP resources. Some of

[1]The basic idea here is similar to the ICECUP FTF (Fuzzy Tree Fragment) grammatical query system for parsed corpora (Wallis and Nelson, 2000), but with a diffent use and target audience in mind.

[2]Here, we use "NLP resources" as a cover term for both *language resources* and *processing resources* in the terminology adopted by Cunningham (2002).

Figure 3: Alternative SUC annotation formats

the issues are:

- Differences in fundamental storage and text markup formats. The three corpora that we are considering for use in the project have three different storage formats: (1) The basic format of Saxena's Kinnauri narrative corpus is as a Shoebox database (Buseman and Buseman, 1998) (see figure 4), from which a web version in HTML hyperlinked to a morpheme lexicon was semiautomatically derived (see figure 2); (2) The Stockholm Umeå Corpus (SUC; Ejerhed and Källgren (1997)) comes in an SGML corpus format as specified by the Text Encoding Initiative (TEI; `http://www.tei-c.org/`), and further, there are two different grammatical annotation formats, Parole/EAGLES format (see Monachini and Calzolari (1996)) and SUC format (see figure 3); (3) The Talbanken syntactically annotated corpus of Swedish (Einarsson, 1976a; Einarsson, 1976b; Teleman, 1974) is in an 80-column punch card format with only capital letters (see figure 5).

```

Figure 4: The Kinnauri corpus – Shoebox format

- Differences in POS tagging and syntactic annotations between corpora. The SUC and Talbanken Swedish corpora, although both are POS tagged, use different tagsets, with e.g. SUC having two and Talbanken three subclasses of nouns, and SUC, but not Talbanken, marking number in nouns, etc. Tagset incompatibilities, even within a language is a problem that has been noted in the literature (e.g. by Atwell et al. (2000)), and there has been some work on tools for automatic tagset mapping (e.g. Teufel (1995)). The problems are compounded when several languages are involved,[3] which would be desirable in our setting, where the linguistic subdisciplines of Contrastive Linguistics and Language Typology rely on explicit comparisons between languages at various linguistic levels. As stated above, we know from experience that students learn about grammatical constructions and phenomena more actively when these constructions are discussed by comparing the system found in their native language with that of another language. Preferably, the other language should be one that the students do not know already, as they then will be better able to concentrate on the analysis of 'pure' form. This is why we intend to use the Swedish and Kinnauri corpora together in our first application.
- Differences in POS categories, syntactic categories and grammatical framework between the corpora on

[3]The problem of crosslinguistic mapping of part-of-speech tags has not been extensively discussed in the computational linguistics literature (see Borin (2000); Borin (Forthcoming 2002); Borin and Prütz (2001)), but in general linguistics, there is an extensive literature on the issue of crosslinguistic properties of part-of-speech systems and the universality of proposed parts of speech, which is very relevant in this context (e.g., Anward et al. (1996); Itkonen (2001); Pawley (1993)).

Figure 5: The annotation format in the Talbanken treebank

the one hand and the grammar writing tools and parsers on the other. Thus, the Talbanken corpus uses a fairly traditional Swedish functional grammatical framework, where e.g. NPs are not directly recoverable, but only indirectly, through a combination of syntactic function and lexical category of the head word, while it seems that many, perhaps the majority, of the grammar writing tools freely available on the Web presuppose a phrase structure framework.

- Differences in implementation language, storage model, API, documentation and source code availability, etc. of potentially suitable software. For an excellent overview of these issues, see Olsson (2002).

Thus, we have been forced from the outset to discuss seriously how we are to integrate existing NLP resources in our application, as well as how to make the application itself extensible, so that e.g. new language corpora or new annotations can be added.[4]

2. Taking Stock and Looking Ahead

We are attempting to reuse NLP resources originally meant for NLP research—both *language resources* (notably annotated text corpora) and *processing resources* (the most important being parsers and grammar writing tools)—in an e-learning application for IT-based collaborative learning in grammar courses for Linguistics and Computational Linguistics university students. At the moment, we are locating and evaluating[5] NLP resources, mainly on the web, for the corpus-based interactive grammar exercises. As the corpora are in place already, we are now evaluating tools for the manipulation and visualization of corpus data, parsing systems, and grammar writing environments (workbenches), which raises a number of compatibility/standardization issues that need to be resolved. These compatibility/standardization issues point in two directions simultaneously, as it were:

1. backwards: How can we integrate in our application, with the least amount of effort, existing NLP resources of the kind that we need?

2. forwards: How can we ensure that we ourselves, as well as others, will be able in the future to modify the existing NLP resources, or add new ones, in the framework that we define?

The preliminary answers to these two questions are as follows.

There does not seem to be a simple answer to the first question. Generally, we think that it is more desirable to be able to reuse existing language resources—i.e., texts and corpora, lexicons, and the like—than processing

[4]Courses in Hindi and Turkish at Uppsala University will be used as testbeds during the third year of the project, based on relevant Hindi and Turkish corpus resources.

[5]The evaluation is to be mainly pedagogical, i.e. we will ask ourselves whether a particular resource will be suitable for the pedagogical framework that we have adopted for teaching grammar. However, usability—as the term is used in Human–Computer Interaction research—will also be an important evaluation criterion, as well as the the estimated effort needed to adapt the resource for our needs. See Hammarström (Forthcoming 2002) for details.

resources—in our case first and foremost grammar writing and processing environments—for the pragmatic reasons that

- constructing an annotated corpus from scratch is likely to be a much larger effort than building a grammar writing environment;
- standardization efforts have progressed further particularly in the realm of POS tagged language corpus resources than in the case of language processing resources (Monachini and Calzolari, 1996; Bird et al., 2000; Ide et al., 2000; Cotton and Bird, 2002) (and treebank formats; see Atwell et al. (2000)), although, as a rule, their use in computer-assisted language learning applications has not been considered in this connection (Borin, 2002).

Hence, we aim at being able to handle at least POS-tagged corpora using the EAGLES/Parole tag scheme and marked-up according to the TEI/CES SGML or TEI/XCES XML language corpus formats (thus recognizing, e.g., the SUC Parole format without special preprocessing).

As for the second question, it too, is easier to answer for language resources. Here, we will harmonize the underlying corpus formats with other ongoing projects in our departments,[6] while simultaneously endeavoring to conform to standards that are being worked out in the NLP community. This means that we will undertake the conversion of the Kinnauri and Talbanken corpora into this format, and that in due course we plan to make the corpora generally available in the new format.

As far as 'grammar writer's workbenches' are concerned, we have not yet been able to find a ready-made environment user-friendly enough (for our Linguistics students) and bug-free enough to be immediately useful for our purposes. Thus, it seems likely that we will have to put in some development effort in this area. If this turns out to be the case, the most likely kind of workbench that we will modify or build, will be one within the general paradigm of unification-based feature structure grammar. The evaluation of these systems is still ongoing, however (Hammarström, Forthcoming 2002).

3. Acknowledgements

The work described here forms part of the project *IT-based Collaborative Learning in Grammar*, a collaboration between the universities in Uppsala and Stockholm, funded by the Swedish Agency for Distance Education (DISTUM), for the three years 2002–2004. Anju Saxena is the principal investigator for the project. See also `http://www.ling.uu.se/anjusaxena/distum.html`.

[6] We will strive to be compatible with the corpus format developed in the CROSSCHECK (`http://www.nada.kth.se/theory/projects/xcheck/`), SVANTE (`http://www.ling.uu.se/lars/SVANTE/`) and *ASU availability* projects, in all of which formats and tools for Swedish *learner corpora* (see Granger (1998)) are being developed. The basic corpus format will adhere closely to XCES, with 'standoff' linguistic annotation (Ide et al., 2000).

Preface

Effective question answering is crucial for proper human-system interaction, and systems that can answer questions help to realise the artificial intelligence dream of a machine as a collaborative agent. Question answering draws on many capabilities including information retrieval, language processing, and human computer interaction. Effective question interpretation and answer generation require technologies that index, retrieve, transcribe, extract, translate, and summarize. Question answering can occur in multilingual, multimedia, and multiparty environments. The applicability of question answering ranges across all domains and tasks including learning, playing and conducting business.

Topics in the call for papers, listed in its entirety at www.lrec-conf.org/lrec2002/lrec/wksh/QuestionAnswering.html, included but were not limited to:

- Roadmaps for question answering language resources (LR) and scientific algorithm developments
- Existing question answering language resources
- Guidelines, standards, specifications, models and best practices for question answering LR
- Methods, tools, and procedures for the acquisition, creation, management, access, distribution, and use of question answering LR
- LR and evaluation and benchmarking of question answering systems and algorithms for tasks including:
  - Advanced question analysis
  - Answer discovery and integration
  - Answer explanation and presentation generation
  - Interactive question answering
- LR and evaluation methods for advanced question answering challenges, including but not limited to:
  - Question answering from heterogeneous (structure, unstructured, semi-structured) sources.
  - Multimedia (e.g., text, graphics, audio, video) and Multimodal (i.e., auditory, visual) question answering
  - Multilingual question answering
  - Answering questions from multiple perspectives (e.g, political/economic/legal, local/national/international)
- Question answering components, architectures or instrumentation that facilities evaluation

This one day workshop aims to refine a roadmap (www-nlpir.nist.gov/projects/duc/papers/qa.Roadmap-paper_v2.doc) for question answering applications and the methods for the creation and evaluation of resources for the next decade in support of these systems. The workshop will draw upon research in the TREC Q&A track, the AQUAINT program, and efforts planned for the ARDA Northeast Regional Research Center (NRRC). Participants will help formulate grand challenge problems, discuss possible data sets and/or evaluation metrics/methods, articulate the role of and necessary advances in resources and evaluation to solve these challenges, as well as strategize jointly about the most effective and efficient path forward. Possible joint products arising from the workshop include:

- A list of existing resources and ones under development (with planned release dates)
- Joint formulation of a Q&A roadmap, motivated by ARDA's roadmap (www-nlpir.nist.gov/projects/duc/papers/qa.Roadmap-paper_v2.doc)
- List of evaluation methods and benchmarks of question answering systems
- List of unresolved research problems and/or areas in question answering
- Shared knowledge of research groups and efforts

Table 1 below lists the papers included in the workshop, the primary focus of the article, question answering issues addressed in the papers, and the kinds of sources focussed on.

TABLE 1. Overview of Contributions

Primary Focus	Title	Technical Issues Addressed	Sources	Author(s)
Evaluation	The Evaluation of Question Answering Systems: Lessons Learned from the TREC QA Track	Evaluation, benchmarking, TREC, existing resources	Newspapers	Ellen Voorhees
Evaluation	Why are People Asking these Questions? A Call for Bringing Situation into Question-Answering System Evaluation	Evaluation, Application	Statistical tables; Mechanical Engineering Papers; Web Sites	Elizabeth Liddy
Evaluation	A Curriculum-based Approach to a QA Roadmap	Question answering, roadmap, evaluation, resources, computational linguistics	documents	John Prager
Evaluation	Evaluating QA Systems on Multiple Dimensions	Ambiguity resolution, evaluation methodology	TREC QA track corpora (Future: Chinese and Japanese newswire)	Eric Nyberg, Teruko Mitamura
Inference	Inference in Question Answering	Inference, question-answering, test suites	documents	Bonnie Webber, Claire Gardent, Johan Bos
Applications	The Challenge of Technical Text	Question Answering, Technical Domains, Technical Terminology, XML	Technical Manuals	Michael Hess, James Dowdall, Fabio Rinaldi
Applications	Question Answering in the Infosphere: Semantic Interoperability and Lexicon Development	question answering systems, query optimization, semantic interoperability, lexicons, connectivistic databases	Sensors (Plans to address documents)	Steven Lulich, Paul Thompson
Multiperspective and Temporal	Multiple Perspective and Temporal Question Answering	question answering systems, multiperspectives, temporal expressions, events	Newspapers	James Pustejovsky, Jan Wiebe, Mark Maybury
Multilingual	Summarization Based Japanese Question and Answering System for Newspaper Articles	Japanese Q A System, summarization technique, information fusion from multiple newspaper articles	Newspapers	Yohe Seki, Ken'ichi Harada
Multilingual	Question Answering system for POLISH (POLINT) and its language resources	question answering, language resources, grammars, dialogue corpora, Polish language	Question-answer corpus	Zygmunt Vetulani

Any international workshop demands the selfless contributions of many individuals. We first thank the authors and participants for their important contributions. We next thank the Organizing Committee for their time and effort in providing detailed and high quality reviews and counsel. And we thank Paula MacDonald at MITRE for her tireless and excellent administrative workshop support.

What's the Next Big Thing in Question Answering?

John B. Lowe*
UC Berkeley / LACITO Paris / Formerly of Ask Jeeves, Inc. and W3C AC

Question answering as a computational craft has been around just long enough to have a colorful history and a track record of successes and failures. This checkered past provides object lessons and touchstones in the quest for an effective roadmap for further research.

Early attempts to answer questions by computer -- valiant, creative, and ambitious -- enjoyed limited success due to a number of constraints both foreseen and unforeseen. The importance of certain now well-understood principles governing conversation (e.g. Austin 1962, Grice 1957, 1969, Searle 1969, Dreyfus 1972, 1979) and indeed linguistics generally (Harris 1995, Lakoff 1989) were only dimly appreciated three or four decades ago. Computational resources, both hard and soft, were scarce -- NLP and IR accessories (tokenizers, POS taggers, and parsers, for example) which today are taken for granted often did not exist or had to be re-invented in each instance. While the early research program did not always realize its ambitious goals, a large number of approaches were tried and to some extent evaluated. Much was learned.

The advent of the web and other technological developments of the mid- to late-nineties injected new vigor into the question-answering field. For the first time in a long time commercial and intellectual opportunity was seen in open-domain question answering and a number of companies, both startups and established firms, rushed into the fray.

Yet another wave of twenty-first century technology promises to both enable and challenge future QA systems. The first of these is the so-called Semantic Web. A gleam in the eye of the web inventor Tim Berners-Lee and others for some time now (Dertouzos 2001), the Semantic Web is to be partially enabled by Web Services, another initiative which is now the subject of a turf war between major players in information services.

If the mark of a mature research programme is a group of focused researchers working together within an accepted paradigm judged on the basis of impartial evaluation criteria then the question answering field is mature. Nevertheless, even the best systems today handle only a few classes of the known range. Furthermore, the prospects for general solutions are anxiously dependent on developments in other fields as disparate as linguistic semantics, sociolinguistics, and knowledge representation (KR).

The roadmap presented as part of this workshop demonstrates the maturity of the field. It also indicates that question answering is at a crossroads and how important it is to pick the right path. As part of my talk, I will critique some of the major points and suggestions made therein, with an eye to clarifying their achievability and the consequences of success.

The Evaluation of Question Answering Systems: Lessons Learned from the TREC QA Track

Ellen M. Voorhees

National Institute of Standards and Technology

Gaithersburg, MD 20899-8940
ellen.voorhees@nist.gov

Abstract

The TREC question answering (QA) track was the first large-scale evaluation of open-domain question answering systems. In addition to successfully fostering research on the QA task, the track has also been used to investigate appropriate evaluation methodologies for question answering systems. This paper gives a brief history of the TREC QA track, motivating the decisions made in its implementation and summarizing the results. The lessons learned from the track will be used to evolve new QA evaluations for both the track and the ARDA AQUAINT program.

1. The TREC QA Task

TREC is a workshop series designed to provide the infrastructure required for large-scale evaluation of text retrieval and related technologies (National Institute of Standards and Technology, 2002). A "track" for the investigation of question answering systems was introduced into TREC-8 in 1999, and has been run each year since then for a total of three times to date.

The original motivation for the track was to foster research that would move retrieval systems closer to *information* retrieval systems rather than *document* retrieval systems. Document retrieval systems' ability to work in any domain was considered an important feature to maintain. At the same time, the technology that had been developed by the information extraction community appeared ready to exploit. Thus the task for the TREC-8 QA track was defined such that both the information retrieval and the information extraction communities could work on a common problem. The task was very similar to that used in the MURAX system (Kupiec, 1993), which used an on-line encyclopedia as a source of answers for closed-class questions, except that the answers were to be found in a large corpus of documents rather than an encyclopedia. Since the documents consisted mostly of newswire and newspaper articles, the domain was essentially unconstrained. However, only closed-class questions were used, so answers were generally entities familiar to information extraction systems.

Participants were given a document collection and a test set of questions. The questions were fact-based, short-answer questions such as *How many calories are there in a Big Mac?* and *Where is the Taj Mahal?*. Each question was guaranteed to have at least one document in the collection that answered it. For each question, participants returned a ranked list of five [*document-id*, *answer-string*] pairs such that each answer string was believed to contain an answer to the question. Answer strings were limited to either 50 or 250 bytes depending on the run type. Human assessors read each string and made a decision as to whether or not the string contained an answer to the question in the context provided by the document. Individual questions received a score equal to the reciprocal of the rank at which the first correct response was returned (or 0 if none of the five responses contained a correct answer). The score for a run was the mean of the individual questions' reciprocal ranks.

2. Evaluation

The TREC QA evaluations have been based on the assumption that different people will have different ideas of what constitutes a correct answer. This assumption was demonstrated to be true during the TREC-8 evaluation. For TREC-8, each question was independently judged by three different assessors. The separate judgments were combined into a single judgment set through adjudication for the official track evaluation, but the individual judgments were used to measure the effect of differences in judgments on systems' scores. Assessors had legitimate differences of opinion as to what constituted an acceptable answer even for the deliberately constrained questions used in the track. Two prime examples of where such differences arise are the completeness of names and the granularity of dates and locations.

Fortunately, as with document retrieval evaluation, the relative scores between QA systems remain stable despite differences in the judgments used to evaluate them (Voorhees and Tice, 2000). The lack of a definitive answer key does mean that evaluation scores are only meaningful in relation to other scores on the same data set. Absolute scores *do* change if you use a different set of judges, or a different set of questions. However, this is an unavoidable characteristic of QA evaluation. Since assessors' opinions of correctness differ, the eventual end users of the QA systems will have similar differences of opinion, and an evaluation of the technology must accommodate these differences.

A [*document-id*, *answer-string*] pair was judged correct if, in the opinion of the NIST assessor, the answer-string contained an answer to the question, the answer-string was responsive to the question, and the document supported the answer. If the answer-string was responsive and contained a correct answer, but the document did not support that answer, the pair was judged "Not supported" (except in TREC-8 where it was marked correct). Otherwise, the

pair was judged incorrect. Requiring that the answer string be responsive to the question addressed a variety of issues. Answer strings that contained multiple entities of the same semantic category as the correct answer but did not indicate which of those entities was the actual answer (e.g., a list of names in response to a who question) were judged as incorrect. Certain punctuation and units were also required. Thus "5 5 billion" was not an acceptable substitute for "5.5 billion", nor was "500" acceptable when the correct answer was "$500". Finally, unless the question specifically stated otherwise, correct responses for questions about a famous entity had to refer to *the* famous entity and not to imitations, copies, etc. For example, two TREC-8 questions asked for the height of the Matterhorn (i.e., the Alp) and the replica of the Matterhorn at Disneyland. Correct responses for one of these questions were incorrect for the other.

One of the problems of judging entire strings for correctness is that the resulting judgments do not create a reusable test collection. The primary way TREC has been successful in improving document retrieval performance is by creating appropriate test collections for researchers to use when developing their systems. While creating a large collection can be time-consuming and expensive, once it is created researchers can automatically evaluate the effectiveness of a retrieval run. Unfortunately, different QA runs very seldom return exactly the same answer strings, and it is quite difficult to determine automatically whether the difference between a new string and a judged string is significant with respect to the correctness of the answer. Word recall (Breck et al., 2000) and answer patterns (Voorhees and Tice, 2000) have been suggested as ways of approximating a reusable test collection. These approximations have been well-correlated with human judgments in tests to date, but they mis-judge broad classes of responses. Since the mis-judged classes are frequently the cases that are difficult for the original systems being evaluated, the approximations are likely to be less useful as QA systems continue to improve. Nonetheless, they are currently helpful for providing quick feedback as to the relative quality of alternate question answering techniques.

3. Retrieval Results

The most accurate of the TREC-8 systems were able to answer more than 2/3 of the questions. When an answer was found at all, it was likely to be highly ranked. Not surprisingly, allowing 250 bytes in a response is an easier task than limiting responses to 50 bytes. Indeed, traditional passage retrieval techniques are effective when a response as long as 250 bytes is acceptable (Singhal et al., 2000).

Most participants used a version of the following general approach to the question answering problem. The system first attempted to classify a question according to the type of its answer as suggested by its question word. For example, a question that begins with "who" implies a person or an organization is being sought, and a question beginning with "when" implies a time designation is needed. Next, the system retrieved a small portion of the document collection using standard text retrieval technology and the question as the query. The system performed a shallow parse of the returned documents to detect entities of the same type as the answer. If an entity of the required type was found sufficiently close to the question's words, the system returned that entity as the response. If no appropriate answer type was found, the system fell back to best-matching-passage techniques.

The absolute value of the scores for TREC-9 systems was lower than for TREC-8, but in fact the systems were significantly improved (the TREC-9 task was much more difficult as described below). The improvement in QA systems came from refinements to the individual steps of the general strategy described above rather than an entirely new approach. TREC-9 systems were better at classifying questions as to the expected answer type, and used a wider variety of methods for finding the entailed answer types in retrieved passages. Many systems used WordNet (Fellbaum, 1998) as a source of related words for the initial query and as a means of determining whether an entity extracted from a passage matched the required answer type.

Many systems continued to refine this approach in the TREC 2001 track. However, the TREC 2001 track also saw a resurgence of approaches that relied on simpler pattern matching methods using very large corpora (generally the web) rather than sophisticated language processing. The idea exploited in the massive data approach is the fact that in a large enough data source a correct answer will usually be repeated often enough to distinguish it from the noise that happens to occasionally match simple patterns.

4. Creating a Question Set

The manner in which the test set of questions was assembled has had a big effect on the results of the QA evaluations. In TREC-8, the majority of the questions were created expressly for the track, and thus tended to be back-formulations of a statement in a document. In TREC-9, the questions were selected from an Encarta log that contained actual questions, and a raw Excite log. Since the raw Excite log did not contain many grammatically well-formed questions, NIST staff used the Excite log as a source of ideas for actual questions. All the questions were created without looking at any documents. The resulting test set of questions was much more difficult than the TREC-8 set, mainly because the TREC-9 set contained many more high-level questions such as *Who is Colin Powell?*. For the TREC 2001 track, the source of the questions was again web logs, this time from Microsoft and AskJeeves who automatically filtered their raw logs to select queries containing question words. NIST did additional human filtering of the logs, selecting a final set of 500 questions. Except for some tweaking of the spelling and punctuation, the questions were as they appeared in the log.

NIST has made no attempt to control the relative number of different types of questions in the test set from year to year. Instead, the distribution of question types in the final test set has reflected the distribution in the source of questions. The TREC 2001 test set contained a dramatically greater proportion of definition questions than the previous years. While a large fraction of definition questions is "real" in that the filtered MSNSearch and AskJeeves logs contain many definition questions, there are easier ways to find the definitions of terms than searching for a concise

definition in a corpus of news articles. As a result, NIST intends to exert somewhat more control over the distribution of question types in future tracks.

5. Other Tasks

Each of the TREC QA tracks have differed slightly from one another in ways other than the manner in which the test set of questions was assembled. To investigate whether QA systems are robust to the variety of different ways a question can be phrased, the TREC-9 question set contained 500 questions drawn from the logs, plus an additional 193 questions that were syntactic variants of an original question. For example, the test set contained four variants for the question *What is the tallest mountain?*: *What is the world's highest peak?*, *What is the highest mountain in the world?*, *Name the highest mountain.*, and *What is the name of the tallest mountain in the world?*. Systems that parsed questions into a common representation generally had fewer differences in their responses to question variants than did systems that relied on templates to classify questions by answer types. Overall, however, most variant sets showed little variability in the average score obtained by the different participants, indicating that the difficulty of obtaining the underlying information being sought dominated the results. For the few variant sets that did have a wide range of average scores, the difference was usually caused by different word choices in the variants. For example, the original question *Where was Poe born?* had a much higher average score than any of the variants that all asked for Poe's birthplace.

The TREC 2001 track contained three tasks, the main task, the list task, and the context task. The main task was similar to the previous tracks except questions were not guaranteed to have an answer in the document collection. Recognizing that there is no answer is a challenging task, but it is an important ability for operational systems to possess since returning an incorrect answer is usually worse than not returning an answer at all. The majority of the systems did not attempt to do no-answer processing.

The list task was designed to require systems to assemble an answer from information located in multiple documents. Such questions are harder to answer than the questions used in the main task since information duplicated in the documents must be detected and reported only once. The test set of questions consisted of 25 questions constructed by NIST assessors, each of which specified a target number of instances of a particular kind of information to be retrieved. For example, *What are 9 novels written by John Updike?* was one of the question used in the task. Systems returned an unordered list of [*document-id*, *answer-string*] pairs where each pair represented a single instance. The list could contain no more than the target number of instances. Each individual instance was judged as in the main task. The evaluation metric used was average accuracy, where the accuracy for a single question was the number of distinct correct instances retrieved divided by the target number of instances. The best performing system had an average accuracy of 76%, suggesting that the list task as defined is feasible with current technology.

The context task was intended to test systems' ability to track discourse objects (context) through a short series of questions. However, system performance was so dominated by whether the system could answer the particular type of question posed that differences in ability to track context were not detectable. More research is needed to create an evaluation that actually measures a system's ability to track context.

6. Future Evaluations

The TREC QA track has stimulated research on open-domain question answering and has created a foundation on which future evaluations can build. The data used in the TREC tracks, including questions, answer patterns, sentences containing answers, and evaluation scripts are available on the TREC web site (National Institute of Standards and Technology, 2002).

To date, the TREC QA track has used only factoid questions. This allows the evaluation of the answers to be judged using a binary decision of correct/incorrect. While assessors' opinions as to correctness differ even for this basic question type, evaluation is at least stable in that the relative quality of different QA systems is not materially affected by such differences in opinion. Answers to other types of questions require a more fined-grained scoring procedure: answers that are explanations or summaries or biographies or comparative evaluations cannot be meaningfully rated as simply right or wrong. The appropriate dimensions along which such answers should be judged, scoring mechanisms that reflect quality in those dimensions, and the stability of evaluations using those scoring mechanisms all need to be investigated.

The impact the way in which the test set of questions was assembled has had on system effectiveness in TREC illustrates the balancing of tensions required to create an effective test. One the one hand, careful selection of questions allows specific features of QA systems to be tested, enabling crisper conclusions to be drawn. On the other hand, such selection generally reduces the realism of the test. Designed tests usually lack the diversity of subject matter, vocabulary, and sentence constructions that are represented in large samples of naturally occurring questions. Such diversity can be particularly important to include in initial evaluations when the features that affect performance on the task are not well understood.

The TREC track will continue, with the goal of increasing the kinds and difficulty of the questions that systems can answer. The main task in the TREC 2002 will focus on having systems retrieve the *exact* answer. In past tracks, responses could contain extraneous information and still be judged correct provided the extraneous information was not distracting. Such fuzziness in the definition of correct was used in the first track when it was unclear what the systems' abilities were, and it has remained. However, the fuzziness is masking true differences in systems in the final scores. Forcing system to be precise will not only allow scores to better distinguish among technologies, but also improve QA technology.

An evaluation effort related to the TREC QA track is the new AQUAINT (Advanced QUestion and Answering for INTelligence) program sponsored by ARDA (Ad-

vanced Research and Development Activity), a research center within the U.S. Department of Defense (see `http://www.ic-arda.org/`). The main focus of AQUAINT is to move beyond factoid questions, including the investigation of scoring mechanisms for complex answer types. Within the first year of AQUAINT (2002), AQUAINT contractors and NIST will run pilot studies to experiment with different measures.

Introduction

I believe that in order for the field of Question-Answering (QA) to evolve to the stage where it will provide maximum utility, the environment in which a QA system is to be used should become a parameter in the evaluation of QA systems. That is, the current evaluation paradigm is becoming restrictive and may well push development in a single direction that will not produce systems that will prove useful in multiple environments. Even a quick review of the potential scenarios in which QA can be utilized suggests two key facts: 1) what is considered *'a useful answer'* in one context might not be useful in another, and; 2) currently permissible methods that systems can utilize to determine correct answers are not feasible in many real world QA environments. This paper will advance this position and suggest a range of situational dimensions that should be considered for inclusion in the QA evaluation roadmap.

QA Evaluation

While there was significant early research in Question Answering in the fields of logic and linguistics (Belnap, 1963; Belnap & Steel, 1976), automatic QA was first focused on in a large-scale evaluation framework in the TREC Conferences, beginning with TREC-8 in 1999 (Voorhees & Tice, 1999). The paradigm established in TREC-8 and continued in the next two TREC Conference QA tracks is simple fact-based, short-answer questions. Initially, answer strings were limited to either 50 or 250 bytes depending on the run type. In TREC-10, the 250 byte condition was eliminated and the list task was added. The list task consisted of 25 questions which specified the number of unique responses to be retrieved, e.g., *"What four countries are the top producers of wheat in the world?"* All other parameters of the main QA task remained the same (Voorhees, 2001).

Discussion at the TREC 2001 Workshop on QA intimated that the QA track in TREC 2002 will accept as correct only fragments which contain the minimal answer to the question. Any explanatory text, even if within the 50 byte limit, will cause the answer to be marked as incorrect. Additionally, the practice introduced in TREC 2001 of a system first determining the most frequent potential answer by searching the web, and then finding a document in the TREC collection which contained that answer fragment will continue to be allowed.

Potential Problems

The need for a more refined evaluation of answer strings was evident from some sample answers shown at the Workshop as they contained text that was non-contributory to the answer and just happened to contain the correct answer that had been provided to the relevance assessors. However, this was not always true. In some instances, the additional text can be argued to have provided useful supportive or confirmatory information. The potential problem I see in the

requirement of a minimal answer is that this evaluation paradigm, which does not permit the inclusion of supporting information that might be useful in some QA scenarios, will foster the development of systems which will be useful in only a subset of the contexts in which QA systems are truly needed.

Furthermore, the decision to allow systems to utilize redundancy on the web to select answers (Brill et al, 2001) will also foster methods that may not be useable in many QA environments. It is highly unlikely that the redundancy approach will transfer to QA systems that are developed for specialized resource environments. While the simple factoid questions for which multiple instances of responses can be found on the web have been the norm in the QA track, this is not typical in other environments for which QA systems provide great utility.

While the existing QA evaluation scenario has utilized very simple questions, has focused on a narrow definition of length of useful answer to the exclusion of other issues, and has permitted the use of a method of determining an answer which will not work in other than the simple query environment, some QA system builders have begun to call for an evaluation paradigm that considers dimensions above and beyond correctness (Breck et al, 2000). We strongly agree with this view and encourage the discussion of a broader evaluation paradigm for the QA Roadmap that will take into account the wide range of environments in which QA is already providing an essential service.

Range of Possible QA Environments

Consider the three following real-life environments for which we have developed QA systems. In each of these environments, the collection, the type of queries, how the system determines answers, and what constitutes an acceptable answer formulation for the user vary dramatically.

1. Scientific Questions from Undergraduate Students

We have developed a QA system (Liddy, 2001) with funding from NASA and AT&T for use within a collaborative learning environment for undergraduate students from two universities majoring in aeronautical engineering who are taking courses that are taught within the AIDE (Advanced Interactive Discovery Environment for Engineering Education). The students are able to ask questions and quickly get answers in the midst of their hands-on collaborations within the AIDE. The collection against which the questions are searched consists of textbooks, technical papers, and websites that have been pre-selected for their relevance and pedagogical value. We are currently working towards the addition of transcripts of class lectures and accompanying power point slides. The students questions are not typically simple factoid questions, but tend more towards '*Why*' and '*How*' questions and require more than bare answers, such as:

? *How do ablating materials minimize energy conducted into a RLV?*
? *What are the changes made to the design of the Shuttle SRM since the Challenger Accident?*
? *How are malfunctions detected for the pitch and yaw gimbal actuators of the space shuttle OMS engines?*

Answers are provided in increasing window sizes, allowing the student to gradually expand the amount of text by mouse-clicking from 'answer-providing passage', to paragraph (s) containing the 'answer-providing passage' to full document(s) containing the 'answer-providing passage'. The system is currently undergoing user testing. The U S Army has funded us to create a similar capability for the students in the Army's intel training programs. They share NASA's vision that

work in the future will consist largely of virtual collaborative situations in which questions that arise will need to be answered electronically from selected sources.

2. Citizens' Search for Statistical Information

Naïve users need to access statistical information, but frequently do not have the sophisticated understanding required in order to translate their information needs into structured database queries using the controlled vocabulary which are currently required. However, these users can articulate quite straightforwardly in their own terms what they are looking for. One approach to satisfying the masses of citizens with needs for statistical information is to automatically map their natural language expressions of their information needs into the metadata structure and terminology that defines and describes the content of statistical tables. To accomplish this goal, under funding from NSF's Digital Government Initiative (http://istweb.syr.edu/~tables/), we undertook an analysis of 1,000 user email queries seeking statistical information from federal agencies which provide internet access to their statistical tables. Our goal was to understand the dimensions of interest in naïve users' typical statistical queries, as well as the linguistic regularities that could be captured in a statistical-query sublanguage grammar. We developed an ontology of query dimensions using this data-up analysis of the queries and extended the ontology where necessary with values from actual tables. We proceeded to develop an NLP statistical-query sublanguage grammar that enabled the system to semantically parse users' queries and produce a template-based internal query representation which was then mapped to the tables' metadata, in order to retrieve relevant tables which were displayed to users with the relevant cell's value highlighted (Liddy & Liddy, 2001). Typical queries were:

? *I am trying to find the percentage of women in the workforce from the years 1900 to 1998*.
? *I want to know how many people worked for small businesses last year.*
? *What was the average amount of time women spent on housework per week in 1900; 1950; 1995?*

This project made it eminently clear that the situation predicts the nature of the questions, the resources searched, and the acceptable answer formulation.

3. Speech-based Inquiries in Travel and Tourism

In an exciting project in the commercial world, we worked with a speech understanding technology company to provide answers to travelers who were planning Caribbean vacations via interaction with a voice-activated system. While the business idea was well-researched, the current status of speech-understanding technology was not, and the corporation failed to pull off the application. However, I mention it here because it introduces a third and very different set of users, answer-providing resources, and answer formulation in which appropriate supporting detail is essential.

? *We're looking for a family resort in the Caribbean with baby sitting, other activities for a family with a one and three year old. Any suggestions?*
? *My fiancee and I were wondering if there was anywhere we could go in October that would not be extremely crowded, yet more secluded?*
? *When is the best time to go on a Caribbean Cruise - and do you recommend bring our 16 year-old so? He is very bright.*

Again this situation points out that evaluation needs to reflect an environment – we do not foresee that all questions will be ones that can be satisfied with short answers which are found redundantly present on the web. Requirements in this particular situation contradict the TREC QA evaluation requirement that evidence supporting the answer should not be provided.

Conclusion

We have found that the collection of documents that will be available for querying, the nature of queries generated by real users, as well as the breadth vs. narrowness of what constitutes a useful answer in each of these instances is not the same. Therefore, it would only seem appropriate that an evaluation should fully specify the user, the purpose for which they are asking their question, and the nature of an acceptable answer. These should be parameters that can be varied in QA evaluations. It is essential that the situational aspects be known so that the criteria provided to the human relevance assessors truly reflect what users in that particular context would require. Evaluations should be designed that simulate as closely as possible the dimensions of the context in which users will be posing their questions. Clearly the use of multiple scenarios would enhance the possibility that evaluation would lead to a range of QA systems, each defined by the parameters of the situation in which they are to be used.

Abstract

The QA community is beginning to understand the core problems in the field, and they largely coincide with those of Natural Language Understanding. The difficulty of answering a question by a current QA system is a function of the match or lack of it between the question or its expression and the resources used to answer it, not how difficult it is for a human to answer it. A prominent factor in making a question hard now is not so much in finding an answer but in validating whether a candidate answer is correct. The problem in many ways parallels that of reading comprehension for children, which suggests a graduated approach to developing and evaluating the field. The difficulties faced by QA systems include long-standing issues in computational linguistics, such as anaphora resolution, metonymy etc.; logic-oriented issues such as scope and quantification as introduced by adverbs and articles; structural problems where the answer must be assembled from many sources, as well as reasoning about space, time and numbers. These problem areas are largely orthogonal, and can be introduced progressively with at each step accepted criteria for success.

Introduction

The approach TREC has been taking to Question Answering has been rather like asking fourth-graders to read and understand *Hamlet*, and when they show even some rudimentary success, moving them on to *War and Peace* and then *Finnegan's Wake*. While it is very understandable that members of the community - or indeed several communities: academic, government, military and web-users - wish to push the state of the art as far and as fast as possible, it is inescapable that complete success at QA requires mastering all of the core problems of NLP. This has not been done over the last fifty years and is not going to be achieved anytime soon.

Approximately two years ago, a first QA Roadmap was drafted on behalf of ARDA (ARDA, 2000), based on input from many key researchers in the field (including the present author). That document developed the question taxonomy previously proposed by researchers at SMU (Moldovan et al., 2000). That taxonomy lists a series of increasingly difficult questions, characterizing them by the kind of questioner who would ask them. The taxonomy is very well intentioned but, in hindsight, unfortunately wrong in some of its details or its emphasis and difficult to work with because of two inherent assumptions that appear to have been made, or at least not rejected.

The problematic assumptions are (1) that it is possible to grade the difficulty of questions by semantics independent of the corpus and/or other resources that will be used to answer them, and (2) that what is difficult for a human will also be difficult for a computer. As for the first point, we observe that understanding the question is indeed part of the QA process, but it is only a part. Understanding the corpus (plus ontologies and other kinds of data) is equally important, as is being able to match these resources to the question. Sometimes such a match is trivial, sometimes it requires considerable linguistic processing and/or reasoning: which is the case cannot be determined from the question alone.

For example, consider the question:

> When was Queen Victoria born?.

It is very easy to answer if there is a text passage of the form:

> … Queen Victoria was born in 1819…,

and only a little trickier if the text reads

> … Queen Victoria (1819-1901) ….

However, if the text contains no such statements, but instead just the indirect reference

> … King George III's only granddaughter to survive infancy was born in 1819 …,

along with text (possibly elsewhere) that states

> … Victoria was the only daughter of Edward, Duke of Kent,

along with more text (possibly yet elsewhere) that states

> … George III's fourth son Edward became Duke of Kent …

the question becomes considerably harder to answer.

By contrast, the seemingly difficult question

> Should the Fed raise interest rates?

becomes much simpler to answer in the presence of a news article quoting Alan Greenspan as saying

> All of the current leading economic indicators point in the direction of the Federal Reserve Bank raising interest rates at next week's meeting.

On a lighter level, even the perennial

> What is the meaning of life?

is a cinch to answer if one consults *The Hitchhiker's Guide to the Galaxy* (Adams, 1982)[1].

If one accepts that questions by themselves cannot be arranged in order of difficulty, the very notion of a Roadmap might seem to be called into question. However, it is the thesis of this paper that a systematic approach mirroring somewhat an academic curriculum can achieve the desired goals. A basic method of the classical Western educational system is the incremental dissemination of new information and skills, building on previous knowledge (as opposed to, say, the immersion approach to language learning). Evaluation is performed continually, with testing materials crafted either to examine as closely as possible just the new material, or a combination of new and old, as the teacher sees fit.

Going beyond TREC

The problem with the current TREC-style evaluation using real user's questions and real news articles is that every question can potentially test a different variety and combination of system skills and knowledge, so a system's performance can vary widely from question set to question set. A given system can fare remarkably differently on seemingly isomorphic questions because of idiosyncrasies of the data resources. Granted, using large enough question sets it becomes possible to rank order QA systems, as TREC does (Voorhees & Tice, 2000), but the current setup does not enable one to easily assert exactly what is being tested in a system (except QA in a holistic way), or what, if anything, a system is good at. Amongst other things, this makes it difficult to predict performance when a QA system is to be deployed in a new domain, or how it will behave with different user groups.

Three trends in TREC QA, from the first instance in TREC8 to the proposed TREC2002, have had and are having the benefit of forcing systems to "know" what they are doing. These are: (1) the trend from 250-byte answers to 50-bytes to "exact answer", (2) from 5 submitted answers to a single answer, and (3) the (as yet largely unexploited) possibility of "no answer". These refinements of the track are fine and do a great service in that they greatly reduce the chances that systems get the right answer "by accident", but they represent the end of the line in this particular kind of evaluation development. It should be mentioned, though, that while these improvements are necessary for the evolution of QA systems whose output will in turn be used by other automatic systems, they are not so necessary when the consumers of the output are real users, who can tolerate a set of candidate answers and who will generally be pleased to see the answers in the context of text passages. Having said that, it is true that if a system can do well in the more constrained context it can only benefit its performance in the less constrained one.

The essential difficulty with question answering stems from the fact that textual material is in natural language, and that to consistently answer questions posed against text corpora requires understanding the text. Since these texts were written with human readers in mind, they make copious use of all of the linguistic and stylistic devices that make reading pleasurable and computer understanding difficult: anaphora, definite noun phrases, synonyms, subsumption, metonyms, paraphrases, nonce words, not to mention idioms, figures of speech and poetic or other stylistic variations. For example, in answer to "How did Socrates die", we find from the TREC corpus:

> His chapter on wifely nagging traces nagging back to the late Cretaceous period and notes that one of the all-time nags was Socrates' spouse, Xanthippe. Hemlock was a pleasure by comparison.

and

> We also meet snake root, which is toxic, and poison hemlock, which for over two thousand years has been famous for curing Socrates of life.

In fact, all of the other mentions of Socrates and hemlock together in this corpus happen to be indirect, thus making this simple sounding question particularly difficult. Usually, though, in a large corpus such as TREC uses there are multiple mentions of facts interesting enough to be the subject of questions, and for every obscure reference there are often several plain ones.

Following the train of the argument in this paper, it would seem that by far the easiest way to provide a Roadmap for QA would be to mimic the progression of reading comprehension tests in school, by using texts written for progressively higher grade-levels. These would start with texts employing only short sentences using simple syntax and little imagery, and progress to adult-level texts such as news articles and beyond. The difficulty here, though, is that these elementary texts do not exist in sufficient quantity, especially online, to provide a meaningful-sized corpus (the current TREC QA corpus is 3GB). If we cannot fix the corpora, then at least we can fix the questions. [We should mention here a recent posting by Karen Spark-Jones to the TREC web site (Spark-Jones, 2001). The posting lists a set of questions, and for each one a

[1] The answer is 42.

large number of candidate answer sentences that address some aspect of the questioner's concern, but may or may not answer the question itself. This is in the same spirit as the theme of this paper, as it finesses the issue of finding such sentences, but allows one to concentrate on the problems of question-answer match.]

Impedance match

Using as background the earlier argument that multiple mentions of interesting facts should generally reduce problems of text complexity, we can again advance the suggestion that sets of increasingly difficult questions be developed. The measure of difficulty, though, will be quite different from that espoused in the first QA Roadmap. The notion is to identify components of the QA task that are difficult for a machine to perform, rather than difficult for a human. In some cases, the difficulty will ensue from the absence of a direct answer in the resources used, as discussed above. In other cases, the difficulty will derive from the linguistic and/or logical structure of the question, rather than its semantics (that is, the semantics of the individual content words). Take for example the question "What is the population of France's capital?". Assuming that there is no text that directly restates the question, the task is to first find the capital of France (Paris), and then to find the population of Paris; these two steps may well be performed using different documents or different knowledge bases or databases. The level of difficulty of the question does not stem from the fact that two resources must be searched. Given the problem breakdown, it is straightforward to construct the two necessary queries. The difficulty comes from the question's structure: the system must know that the phrase "France's capital" is a reference to an entity that must itself be found before the outer question can be answered.

The structure of the problem in general ensues from not only the structure of the question but also the availability of *knowledge sources*: both the information resources and the kinds of processing needed to make use of them. The question "What is the largest city in France?" can be answered in a variety of ways: from a direct statement in text; from a table listing French cities and their sizes; from discovering that Lyon is the second largest French city, and that Paris is larger than Lyon; from an enumeration of separately discovered pairs of {city, size} (making assumptions of completeness), and others. The difficulty of the task can be varied by making available or unavailable any of the pertinent knowledge sources. To summarize, the measure of difficulty of the questions mentioned so far in this paper stems from what might be called the *impedance match* (or *mismatch*) between question and knowledge sources. Moving on, we can orthogonally mine the linguistic dimension for incremental difficulty.

The Linguistic Dimension

In what follows we present an unordered and non-exhaustive list of the kinds of linguistic capabilities that a full-fledged QA system should have. These capabilities can be expressed and evaluated by question sets that require that particular competence for successful performance. We have already seen some examples of questions that derive their difficulty from the absence of a direct and straightforward representation of the answer in the available resources. The remaining examples are for the most part easy for humans to address, but illustrate difficulties that computers have with NLP.

Consider the following two questions:

> Name a US state where automobiles are manufactured

and

> Name a US state where automobiles are not manufactured

The vast majority of present-day QA systems will pay no attention to the *not*, although it is critical for correct behaviour. Likewise, other adverbial modifiers such as *just* and *only* can play havoc with the system's performance. Sometimes the presence of a single such modifier can require large amounts of real-world knowledge. Consider

> Name an astronaut who made it to the moon

versus

> Name an astronaut who nearly made it to the moon

One can easily come up with half-a-dozen reasonable interpretations of *nearly* here, each giving different sets of correct answers.

In a similar vein, articles play an important role in question interpretation. The TREC community has been arguing for years whether Atlantic City is a correct answer to "Where is the Taj Mahal?". Making the article indefinite would generate much less of a dispute whether casinos, hotels and restaurants were allowable answers; having a computer understand the difference, though, would be a challenge. Interesting questions arise when articles are absent and the end-user is unknown. Is the question:

> What is mold?

really a hurried form of

> What is a mold?

What if the end user is the native speaker of a language that doesn't use articles? One can imagine an exercise where the system is given a set of questions to be answered in the context of each of a set of user-profiles. These profiles may be no more than simple age/profession/nationality descriptors, but sufficient to elicit different maximum-likelihood interpretations for each question in the set.

An important area where difficulty can be introduced in an orthogonal manner is in that of ungrammatical ques-

tions. Although NIST has tried to make the TREC QA questions immune from this problem, by the author's count about two percent contain one or more misspellings, incorrect capitalizations, incorrect compoundings, or syntax errors. Observing the first such errors in TREC8 has had the unintended beneficial consequence of causing some groups to develop and deploy spell-checkers and other fault-tolerant mechanisms. Raw questions from real users undoubtedly contain a much higher percentage of such errors than in TREC; keyword-based queries, so common on the Web, can be considered to be degenerate cases of ungrammatical sentences.

A common cause of problems, not only in QA but also in basic Information Retrieval, is the lack of lexical match between two equivalent or ontologically-related concepts. Question sets that specifically test subsumption, synonymy, meronymy and other relationships can easily be generated, in the obvious way.

QA systems today don't do well with numbers. "How many"-type questions are easy to answer if the sought figure is discussed in text, but not so if the system has to enumerate instances. Ability to convert between units is largely absent. Ability to evaluate reasonable magnitudes is also missing.

QA systems are currently monolingual. It is clearly desirable to be able to query in one language texts in another, but there is scope for awareness of other languages that falls far short of full CLIR, or maybe that should be CLQA. Even simple questions like "What does ciao mean?", bearing no explicit indication of foreign language presence, can benefit greatly from systems having some notion of what is English.

Summary

Developing a Roadmap for QA entails developing a series of tasks which, when mastered, would result in an extremely capable system. The current TREC approach of requiring QA systems to do everything in the first year, and just be better at it in subsequent years, does not provide the right kind of incremental basis. Instead, rather like in a modular school curriculum, technical areas to be addressed should be identified and codified in question-sets that require the requisite capability to answer. The question-sets may be accompanied by restrictions on resources that may be used. Such "learning modules" can be either orthogonal or incremental, or even some combination. Developing them will not be as easy as generating the TREC question-sets, since, in many cases, knowledge by the question-set compiler of the resources available (text corpora, ontologies, databases) will be necessary to judge how and where a given question is appropriate, just as a textbook author must know the subject matter in order to set appropriate questions for each chapter.

Evaluating QA Systems on Multiple Dimensions

Eric Nyberg & Teruko Mitamura

Language Technologies Institute
Carnegie Mellon University
5000 Forbes Ave., Pittsburgh PA 15213 USA
{ehn,teruko}@cs.cmu.edu

Abstract

Question-answering systems are expanding beyond information retrieval and information extraction, to become full-fledged, complex NLP applications. In this paper we discuss the evaluation of question-answering systems as complex NLP systems, and suggest three different dimensions for evaluation: objective or information-based evaluation; subjective evaluation; and architectural evaluation. We also discuss the role of ambiguity resolution in QA systems, and how ambiguity resolution might be evaluated.

1. Introduction

The recent QA Roadmap (Burger et al., 2001) expanded the scope of question answering along several dimensions, including: multiple question types, multiple answer types, multiple media, multiple languages; interactive dialog with the user to refine/guide the QA process; multiple answer perspectives; and ultimately, answers which provide an evaluation or judgment based on retrieved data. QA systems are expanding beyond information retrieval and information extraction, to become full-fledged, complex NLP applications.

We present three different types of evaluation: a) *information-based evaluation*, which (like the TREC QA track) focuses on the completeness and correctness of the answers given; b) *utility-based evaluation*, which focuses on the usability of the QA system for the end-user; and c) *architectural evaluation*, which focuses on the characteristics of the software architecture used to implement the QA system. For each type of evaluation, we discuss possible ways to define test data and carry out an evaluation.

These three types of evaluation are relevant for next-generation QA systems such as JAVELIN (Nyberg et al., 2001). The ideas presented here draw upon our experience with the evaluation of other complex NLP systems (e.g. Machine Translation (Mitamura et al., 1999), Integrated Information Management (Nyberg & Daume, 2001)) that are directly relevant to advanced QA.

2. Extending Information-based Evaluation: Ambiguity Resolution

At the core of current QA evaluation methods is the objective evaluation used in the TREC QA track. Objective evaluation requires the creation of questions and correct answers for each question, given a corpus and some pre-defined criteria for judging "correctness". The QA Roadmap describes the evolving capabilities of QA systems, which will require new objective measures (i.e. new TREC QA tasks). Although objective evaluation is extremely useful and easy to carry out once the data sets have been created, it is probably not feasible to create a single suite of questions that adequately tests all dimensions of a QA system in an objective manner. For example, different suites might evaluate system's performance on various question types, answer types, document sets, etc. More global capabilities, such as ambiguity resolution, cut across all of the question and answer types and should be evaluated separately. In the remainder of this section we discuss the specific challenges of creating an objective evaluation for ambiguity resolution.

Starting with TREC 2002, the QA evaluation track will include question ambiguities. In general terms, an ambiguous question is one that has more than one meaning or interpretation. In a QA system, question ambiguity is significant when the different meanings imply different answers. If there is a high degree of ambiguity (many different meanings), or the ambiguity implies a much greater degree of information processing (many more texts to be searched), the system should attempt to resolve the ambiguity.

Ambiguity in natural language has been studied in detail in the fields of computational linguistics and machine translation, and all of the classic forms of ambiguity can affect a QA system (lexical ambiguity, syntactic ambiguity, pronominal anaphora, scope ambiguity, etc.). When designing a QA system, it is important to consider a) whether (and how) to detect a particular type of ambiguity; b) whether (and

how) to resolve the ambiguity before searching for an answer; c) whether (and how) to resolve ambiguity as part of composing the answer. The diagram in Figure 1 illustrates the difference between approaches b) and c). In either case, the system can resolve the ambiguity automatically, or interact with the user to resolve the ambiguity.

In the following subsections, we discuss three specific types of automatic disambiguation that can be evaluated in an advanced QA system: context disambiguation, structural attachment disambiguation, and word sense disambiguation.

2.1. Context Disambiguation

Context can be disambiguated automatically by using the analyst profile or past session memory. The context category (e.g. economy, politics, geography, etc.) can be used for disambiguation. Questions might include words that can belong to different domains; for example, the words "line, defense, conference", may indicate an academic context or a sports context.

Questions that refer to attributes of objects may also be ambiguous in different contexts. As noted in the QA Roadmap (Burger et al., 2001), the same attribute name might imply different answer types. For example, the general notion of "dimension" as queried in questions like *How big is New York*? or *How big is the Pacific Ocean?* implies different possible answer types (e.g. a population count, a geographical area in square miles, etc.). In each case, the QA system must select more specific query terms that are appropriate to the particular meaning intended. For example, *How old is Koizumi?* can be answered by searching for a birth date, where a question like *How old is Siemens?* requires searching for events like *incorporated*, *founded*, etc. The strategy depends on knowing whether the question refers to a person or an organization, in this case.

It is a large task to address this type of ambiguity for unrestricted English text, since this presupposes a well-defined semantic model with broad coverage ("world knowledge"). A more feasible method for developing test data and evaluations might be to construct an model of the most relevant contextual ambiguities for intelligence gathering tasks. For the most relevant query object and answer types associated with a particular corpus (e.g. person, organization, location, country), it should be possible to determine the set of salient attributes of each type (e.g. age, location, size), along with the potentially ambiguous question terms that are typically used to refer to those attributes. This type of empirical data gathering presupposes that a set of sample questions are available for analysis. Once all of the attributes and their source language query terms have been identified, a set of questions could be constructed to evaluate a system's ability to search for the correct attribute given an ambiguous query.

Although this discussion has focused on single attributes, realistic questions will also include nested attributes, such as *How big is support for Koizumi?* For this question, it is important to know that a) Koizumi is a person in the political arena, b) *support* in this context implies public opinion concerning job performance, and c) big is a relative measure of public opinion, perhaps based on the results of a public opinion poll. Handling this type of nested ambiguity will require not only the disambiguation of nouns such as *Koizumi* and *support*, but also an understanding of syntactic structure and the relationships represented by prepositions like *for*.

2.2. Structural Disambiguation

One of the challenges for phrase level analysis is the resolution of structural attachment ambiguity (e.g. prepositional phrase attachment). In building the JAVELIN system, we plan to extend the automatic structural attachment heuristics developed for the KANT system (Mitamura et al., 1999) to handle structural disambiguation in question analysis. If the system cannot automatically resolve structural ambiguity, then it will ask the analyst for clarification.

In our work on machine translation, we have developed two fundamental ways to evaluate ambiguity resolution: a) by testing analysis results (meaning interpretations) against a pre-defined "gold standard", and b) by checking the correctness of the translation results (Mitamura et al., 2002). Interestingly, an incorrect ambiguity resolution sometimes has no impact on the quality of the translation result, because the input sentence can be translated correctly in spite of the mistake. The analogy for QA systems is that there will be ambiguous questions that can be answered correctly using simple methods without ambiguity resolution, e.g. simple query term search without reformulation. An adequate test suite for ambiguity is one where the probability of getting the correct answer is significantly increased if some form of ambiguity resolution takes place.

Another type of structural ambiguity is seen in the phrase *domination of China*, which could be interpreted as *someone is dominated by China*, or as *China is dominated by X* If we think of *dominate* as a binary predicate accepting

two organizations or countries as arguments, then the nominal form *domination of X* will be a common way to ask questions about *dominate* events when one party is unknown. The ambiguity arises when the pattern $V_{nominal}$ *of N* can be interpreted such that N is either the subject or the object of *V*.

For both types of ambiguity, designing test suites depends on analyzing a set of representative questions to determine what kinds of structural ambiguity arise in realistic scenarios. Since solving the general problem of ambiguity resolution in English is a large, difficult problem, QA evaluations should narrow their focus initially to the types of structural ambiguity that are relevant for QA systems. Once a set of ambiguous constructions is identified (e.g. the *of* case illustrated above), a variety of test cases should be constructed with respect to the evaluation corpus. Effective test cases will be those where more than one potential answer exists, depending on the interpretation of the question, and getting the right answer involves some form of disambiguation.

We also note that there are structural ambiguities that should always be resolved automatically, because only one structural interpretation is semantically valid.

2.3. Word Sense Disambiguation:

During question analysis, word sense disambiguation may follow from identification of the question context (as mentioned above). When there is more than one word sense for a particular term that is not resolved automatically, the system will ask the analyst to choose a term definition from a given list. Evaluating word sense disambiguation can be broken down into two parts: a) does the system represent all of the possible meanings for ambiguous terms in the corpus, and b) can the system correctly select the appropriate meaning in a given sentence (in the absence of contextual or structural cues). For nouns, this involves assigning all possible object types (person, organization, location); for verbs, it involves assigning all possible event meanings.

Once a set of common ambiguous words are identified, based on an analysis of realistic scenarios, a variety of test cases should be constructed with respect to the evaluation corpus. Effective test cases will be those where more than one potential answer exists, depending on word sense disambiguation, and getting the right answer involves correct choice of word meaning. There may also be cases where only a single answer exists, and all but one sense of a particular word are invalid in the domain context.

2.4. Discussion

For objective evaluation, the question is "*How well does System X resolve ambiguity type Y*?"[1]. Ambiguity resolution is important if resolving the ambiguity significantly enhances the system's probability of getting the right answer. Conversely, when constructing a test suite, it is useful to select questions where the probability of getting the right answer is significantly lower if the system does not resolve the ambiguity. For each of the ambiguity phenomena, an effective test suite will contain questions that have multiple answers. The TREC answer format (regular expressions) can be utilized. The real challenge is in crafting questions that differentiate between systems that disambiguate and those that do not, since the probability of getting the right answer is also influenced by the specific documents in the corpora and the degree of evidence for alternative answers.

Contextual ambiguity has important considerations for question answering systems. When a single, isolated question is asked, the context is unconstrained and the question can be assigned any meaning that is valid in the scope of the entire corpus. When a question is asked in the context of a question answering dialog, the context may be constrained to the particular topic of that session. Note that a continuation question may include ambiguous references (e.g. pronominal anaphora) that refer to concepts originally introduced in either a prior question or an answer. The QA system should automatically resolve ambiguities by referring to the existing context whenever possible.

For information-based evaluation, it is essential to construct test questions and answers that address the purpose of the evaluation. This is true not only for ambiguity resolution, but also the other QA phenomena that can be evaluated objectively (e.g., answer justification, answer completeness, multilingual QA, etc.).

---

[1] Note that objective evaluation does not consider the processing time used by the system. A system that resolves ambiguity during question analysis might in general be faster than a system that resolves ambiguity during answer generation, since it prunes the search space earlier.

3. Utility-Based Evaluation – How Good is the Tool?

As QA systems move beyond the laboratory to real-world applications, objective information-based evaluations must be supplemented by utility-based evaluations that evaluate the effectiveness of the software for real tasks. End-to-end system evaluations must focus on realistic analyst scenarios, and characterize the overall system's performance under different operating conditions. We envision at least three ways to evaluate end-to-end performance, described in the following subsections.

3.1. Percentage of Task Completion

The most important functional metric is whether or not the system can retrieve the desired information. Of course, a comprehensive test suite for task completion should exercise all of the question types and answer types to be covered by the system. But it is also necessary to consider other dimensions, such as the specificity or "vagueness" of the user's question.

If a question is precise and unambiguous (e.g., When was Enron incorporated?), then the system should retrieve the desired information quickly, with no further interaction with the user. On the other hand, if the question is vague (e.g., Where is Enron?), the evaluation could focus on at least two different outcomes: a) the system finds all possible answers (place of business, global markets, etc.), or b) the system refines the question interactively to focus on the "correct" answer (e.g., *Where is Enron's headquarters located?*).

Once a set of reference questions and answers should is created to exercise all of the possible question types and answer types, the test set should be expanded to include various "vague" reformulations of each question, to test task completion under varying levels of initial specificity.

3.2. Efficiency of Task Completion

This efficiency metric will measure how easy it is to get the desired information using the system. This dimension is crucial for a realistic evaluation; since JAVELIN will support interactive planning with the user, it will be necessary to strike a balance between accuracy (task completion) and automaticity (how much burden is placed on the analyst during the resolution of ambiguity, clarification, etc.). We can measure the overall time elapsed (how long the analyst has to wait for the answer), the amount of time spent by the analyst in responding to clarifications, and the total number of clarifications per question.

When evaluating the efficiency of machine translation systems, we often compare the time required for a complete manual translation to the time required for a machine translation plus human post-editing. To make an analogous comparison in QA evaluation, we should compare the time required by an unaided human (using only a search engine) to retrieve an answer with the time required by a human plus QA system. If a given task takes less time when using the QA system (despite the need for user interaction, refinement, etc.), then the QA system is more efficient than a human using a search engine.

3.3. N-Point Subjective Measure

Researchers in human factors have noted that the fastest system is not always the "best" - users may prefer a system that is up to slower than another, if it provides better feedback regarding its progress. In open-domain QA, it will be important to measure the user's perception of various subjective measures, e.g., *How well do you understand what the system is doing?*; *Does the system provide you with adequate feedback?*; *Is the system easy to use?*; *Does the system ask you too many questions?*, etc. Such measures are important in that they help to determine what the user considers a "usable" system - note that a system which performs no clarifications may not inspire confidence in an analyst who expects to spend a certain amount of time guiding the search.

In our work with machine translation systems, we have observed two important phenomena with respect to subjective evaluation: a) there is a definite threshold regarding interactivity – if the system asks too many questions on a particular task, the user will lose patience and select the default response, especially when under time pressure; and b) if the content of or motivation for a clarification question is not apparent to the user, they will lose confidence in the system. The subjective evaluation of QA systems should attempt to determine whether these two phenomena are also relevant for information-seeking tasks.

4. Architectural Evaluation

An objective "black-box" evaluation focuses on only those characteristics that are important to the end user, who cannot "see inside" the actual system as it is working. But it is also important to consider glass-box evaluation, which has two important benefits: a) the ability to evaluate the performance of individual system modules can

help developers to rapidly locate and address problems in functionality, performance, etc.; b) an understanding of how easy it is to tune, extend and maintain the system. Therefore architectural evaluation is primarily for the system developer and the system client, who are concerned with the global characteristics of the QA system as a product of software engineering.

Architectural evaluation can be performed in the context of a design review (Pressman, 2000), which focuses on the architectural design and system documentation rather than an information-based evaluation. Although QA systems are designed and implemented using a variety of paradigms and techniques, a global set of design criteria that can be evaluated in a more or less subjective manner for each QA system. The requirements for an ideal QA architecture are similar to those summarized by the TIPSTER II architecture working group (Grishman, 1996):

? **Standardization**. Does the system specify a standard set of functions and interfaces for information services? Is it possible to mix and match different modules in a straightforward manner? In the IIM system (Nyberg & Daume, 2001) we specified a set of standard interfaces for system components that allow the end-user to perform unlimited customization without recompilation of the main system.

? **Rapid Deployment**. How easy is it to create new applications from existing components? A system with an inherently modular design is easier to reconfigure for new applications.

? **Maintainability**. Is it possible to update one module in the system without affecting the others? One key for rapid progress in QA research is the ability to work on the different aspects of the problem (question analysis, retrieval, answer formulation, etc.) in parallel, with frequent system-level testing.

? **Flexibility**. How easy is it to alter the performance of the system by allowing novel combinations of existing components?

? **Evaluation**. Is it possible to isolate and test specific modules (or versions of modules) side-by-side in the same application? If a system incorporates multiple strategies or "loops" (Harabagiu, et al., 2000), how can we evaluate the contributions made by each strategy or algorithm to the overall utility of the system?

Complex QA systems incorporate several different algorithms, modules, processing loops, etc. Effective glass-box evaluation requires a certain degree of instrumentation inside the software, so that various measurements, logging, etc. may be done before, during and after key processing steps (Nyberg & Daume, 2001). This allows the developers to identify component-specific effects and perform ablation studies that clearly evaluate the contribution of a particular component to the system's overall performance.

If a QA research effort is focused purely on initial discovery of new algorithms, then perhaps architectural evaluation is of secondary importance. However, for longer-term efforts aimed at building a reusable technology base for ongoing development, we argue that architectural evaluation and attention to software engineering are of paramount importance. The JAVELIN project is intended to produce a general, extensible architecture, and we intend to evaluate the JAVELIN system design along dimensions such as reusability (of components, operators, etc.) and external extensibility (e.g., by ARDA's chosen third-party integrator).

5. Conclusion

Ongoing research is expanding the scope of question-answering systems beyond information retrieval and information extraction to include complex NLP techniques. In this paper, we advanced the idea that the evaluation of advanced QA systems can and should be carried out on three different levels: information-based (objective) evaluation, utility-based (subjective) evaluation, and architectural evaluation. As the field moves beyond its focus on information-based (TREC-style) evaluation, we must develop new test suites and test methods to improve the quality of QA systems along all three dimensions.

Abstract

One can only exploit inference in Question-Answering (QA) and assess its contribution systematically, if one knows what inference is contributing to. Thus we identify a set of tasks specific to QA and discuss what inference could contribute to their achievement. We conclude with a proposal for *graduated test suites* as a tool for assessing the performance and impact of inference.

1. Introduction

Our point in this position statement is that, to use inference in Question-Answering (QA) in a way that will support what Barr and Klavans (2001) call *component performance evaluation* – assessing the performance of system components and determining their impact on overall system performance – one must identify specific *question-answering tasks* that can potentially gain by exploiting inference. In the first generation of QA systems (i.e., those designed to answer questions in terms of information in structured databases), only a few QA tasks were seen to need inference. In all cases, inference complemented the extensional process of relational (SQL) database querying, through reasoning on the concepts involved:

- Stallard (1986) used terminological reasoning (in a description logic) for the task of mapping from the logical form (LF) representation of a user's query and the concepts it was couched in, into the concepts and relations that formed the *data model* for the database.

- In the context of QA from multiple databases, inference was used in (Hendrix et al., 1978) in the task of developing plans for what databases to access for concept extensions, which would then be combined to produce an answer.

- Kaplan (1982) used inference on the query and its presuppositions for the task of generating a response to a question whose direct answer was not deemed useful.

- Pollack (1986) used inference on the query and an enhanced *data model* for the task of identifying and correcting user misconceptions that underlay otherwise unanswerable (or not usefully answerable) questions.

- In (Mays, 1984; Mays et al., 1982), when a question couldn't be usefully answered at the time it was asked, inference in the form of a temporal tableaux reasoner was used to generate a response to a question whose direct answer was not deemed useful. Specifically, it was used to identify whether the situation described in the question could occur in the future. If so, the QA system could offer to monitor for its occurrance, at which time the question could be answered.

Not all of these QA tasks are relevant to today's (or even tomorrow's) Open-Domain QA systems, which are designed to answer questions on the basis of *unstructured data* (i.e., free text). Nevertheless, it is still the case that there are places where inference can enhance the capabilities of Open-Doman QA systems (Burger et al., 2000; Hirschmann and Gaizauskas, 2001) and/or improve the quality and/or accuracy of their answers. As already noted, our point in this position statement is that, to use inference to these ends, one must identify specific *question-answering tasks* that will drive inference. This will then allow development of the kinds of *graduated test suites* with respect to which *evaluation* can be carried out on both the QA system and the inference engines themselves.

Note that the position we are taking here is very similar to that in (Hobbs et al., 1993), where the authors identify a set of *discourse tasks* that need to be solved in order to explain why the sentences of a text, in combination, would be true. These *discourse tasks* include (but are not limited to): interpreting compound nominals; resolving definite referring expressions; further specifying vague predicates; identifying how predicates apply to their arguments; disambiguating the arguments to predicates; determining coherence relations between adjacent segments of text; and detecting relation of an utterance to the speaker's overall plan. These, in turn, may depend on solving lower-level tasks such as resolving attachment and/or word sense ambiguities, resolving anaphora, and filling in missing (semantic) arguments. But by first specifying the discourse tasks, the authors can show exactly how inference (in their case, *weighted abduction*) can potentially – with efficient search and sufficient background knowledge – be used to solve them. (Note that weighted abduction is not a technique for *forward reasoning*. So any discourse task that requires determining the additional conclusions that can be drawn from a text may require another form of reasoning.)

In the first part of this statement, we identify a set of *question-answering tasks* in which inference could allow enhanced or extended QA services. Our goal is not to comment on what has or has not already been done in using inference in Open-Domain QA systems, but rather to lay out general areas where inference can contribute. We conclude by saying a bit more about *graduated test suites.*

2. QA Tasks

For this short position paper, we restrict the label *QA tasks* to ones that follow from a *functional role* of question or answer, rather than as text *per se*. That is, it is well known that inference can support discourse processing: texts can be parsed using *deduction* – it is what DCGs are all about – and (theoretically) they can be assigned a consistent explanatory interpretation using a combination of *weighted abduction* (Hobbs et al., 1993) and *consistency checking* (Blackburn and Bos, forthcoming). While this kind of interpretation can knit together elements of a text and supply missing (implicit) elements of its fabric, and thereby be critical for deriving answers to particular questions or even particular classes of questions, discussing the role that inference can play in discourse understanding requires its own paper, which we or other people should write.

Similarly, QA interactions are *dialogues*, and work done by Perrault, Cohen, Allen, Litman, Pollack, Walker and others has clearly shown that inference is needed to support dialogue processing – e.g., to decide what a question is really asking for. But this too is a large enough area to require its own paper.

Our focus in this paper then is on the significant set of tasks that remain after both discourse and dialogue understanding are, for the moment, put aside. Among these, we can identify several where inference could provide enhanced or extended QA services.

2.1. Expanding the search criteria for *potential* answers

It is standard procedure in QA to establish search criteria based on the question that has been posed. These search criteria make up the formal *query*, which is used to find *potential* answers in the form of candidate documents that may provide evidence for or contain a *proper* answer.

To increase the yield of potential answers, alternative terms can be added to the query. While this does not intrinsically require inference, what inference can do is expand queries with truth-functionally or defeasibly equivalent *global* reformulations of the original question. These can be used to augment the query with terms that could not have been identified using essentially *local* translation of individual words that ignores their context and functor-arguments dependencies, including implicit (semantic) arguments. For example, abductive reasoning on the question

(1) What do penguins eat?

(solving the implicit argument of *when* the eating event takes place – the same generic "in general" as the generic subject penguins) might produce a defeasibly equivalent version in terms of their *staple diet*. This term would not be added for a question like

(2) What did the characters eat in the seduction scence from the film "Tom Jones"?

which has its (optional) event argument instantiated.

Inference can also expand a query with one-way *entailments* of the original question. For example, being *awarded a degree in Computer Science* (CS) entails being *enrolled for a CS degree*. Given the question

(3) How many students were enrolled in Computer Science at Cambridge last year?

computing its one-way entailments would allow the query to be expanded with *award*$\wedge$*degree*.

Finally, inference can expand queries through subconcepts that form a *partition* (i.e., disjoint cover) of a concept in the original query; a distinct sub-query can be formed for each one. In this way for instance, the query

(4) How many people work for IBM?

could be decomposed into a set of sub-queries such as e.g., *How many men work for IBM? How many women work for IBM* or *How many white collar workers does IBM have? How many blue collar workers does IBM have?*.

Although we have discussed these expansion techniques in terms of constructing a query (either initial or follow-up, in case the initial query does not produce sufficient results), the same techniques could benefit the *ranking* of potential answers with respect to the question, if *recall* on the original query is felt to be sufficient.

2.2. Determining *proper* answers from *potential* answers

A proper answer to a wh-question may be found within a single clause, or it may be distributed through the potential answer (*answer locality*). Moreover, a proper answer may be explicit in the text (i.e., derivable simply by pattern matching), or it may require inference or other method of information fusion (*answer derivability*).

Even where an answer appears to be *explicit* in a text, inference can help determine whether it is a *proper* answer (Bos and Gabsdil, 2000), as with the following potential answers to:

(5) Q: Who invented the electric guitar?
A1: Mr. Fender did not invent the electric guitar.
A2: The electric banjo, cousin of the electric guitar, was invented by Bela Fleck.

A proper answer to this question must entail either (1) that there is someone who invented the electric guitar, or (2) that there is no such person, or (3) that it is true of everyone. All of these are logical relations between a potential answer and a representation of the question in terms of its question domain D (here, persons) and its body B (here, inventing the electric guitar). As such, inference can be used to determine whether any of these relations hold.

Inference can also help when *proper answers* are only implicit in *potential answers*. In (Hobbs et al., 1993), Hobbs et al. show that *weighted abduction* can be used to solve a variety of *discourse tasks*, thereby making explicit information that is implicit in a text. This can be applied to potential answers. For example, a potential answer to the question

(6) Where do condors live?

might contain the compound nominal *the California condor*. As in resolving "the Boston office" (Hobbs et al., 1993), this can be (abductively) resolved to condors whose location is California. That this is a matter of abductive inference rather than simple pattern matching, can be seen by not wanting to draw similar conclusions in determining proper answers to the similar question

(7) Where do terriers live?

Here, compound nominals such as "Yorkshire terrier", "Boston terrier", "West Highland terrier", etc. in potential answers would yield such incorrect proper answers as Yorkshire, Boston, etc.

There is much more to be explored here. Nevertheless, it is clear that inference can be used to support more than one aspect of this task.

2.3. Comparing *proper* answers to wh-questions

The way in which answers are sought in open-domain QA means that one cannot avoid the problem of determining whether proper answers derived from different potential answers (candidate documents) are the same (i.e., mutually entail one another) or different. In the latter case, one may also not be able to avoid the problem of determining whether (i) one answer is more specific than another (i.e., the more specific answer entailing the more general one, but not vice versa); (ii) two answers are mutually consistent but not entailing in either direction; or (iii) two answers are inconsistent. Determining such relations among proper answers becomes a QA task for Open Domain QA, where it was not one for database QA because the underlying relational DB query system was able to recognize and remove all duplicates.

The outcome of such determination depends on whether the original question is taken to have a single answer (a unique individual or property or set) or alternative answers, the set of which is of unknown cardinality. Whatever the reason, these are problems that inference can help solve.

- Answers determined to be equivalent (mutually entailing) can be replaced by a single member of the equivalence class;
- Answers that differ in specificity (one-way entailing) can be replaced by either the most specific one (as with the answer to *When was the Bastille taken?*, where *14 July 1789* is preferred over the less specific *14 July* and *1789*) or by a conjunction of the most specific answers (as with answers to *Who is Noam Chomsky?*, where *MIT linguist*$\wedge$*left-wing activist* is the preferred way to combine the answers in the set *MIT linguist, linguist, MIT academic, political activist* and *left-wing activist*);
- Answers that are mutually consistent but not entailing can be replaced by their conjunction (as with *MIT linguist* and *left-wing activist* above);

- Answers that are inconsistent are the only true alternatives. In the case of questions with unique answers, only one of them can be correct. In the case of questions with alternative answers such as *Where do penguins live?*, all the alternatives may be distinct proper answers.

2.4. Comparing questions

Where efficiency is a goal of QA, it can be supported by determining whether a new question is one that has previously been answered (Harabagiu et al., 2001) or is related in a systematic way to one that has previously been answered. (This is the reason that FAQ-lists exist.) Inference is a valid way of computing both *equivalence* relations between questions and *subsumption* – i.e., whether one question is more specific than another one. The latter allows two different forms of answer re-use. Consider the questions

(8) Where can I go skiing in the Northern Hemisphere in June?

(9) Where can I go for winter sports in the Northern Hemisphere in June?

If one has cached the answer to (8), then one has a partial answer to question (9), which subsumes it. Conversely, if one has already cached the answer to the subsuming question (9), that answer may contain or provide a basis for an answer to question (8). That is, if (9) has been answered by answering the set of questions that follow from each possible way of instantiating the general term "winter sports", then one already has an answer to (8). On the other hand, if question (9) has been answered in general, then (much as with the "linked" questions in TREC-10) sources for that answer might prove a good place to start looking for an answer (8), rather than posing it against a completely open domain.

2.5. Determining *proper* answers to yes/no questions

One may take the set of proper answers to a yes/no question to comprise simply *yes* and *no*, or one may take it more broadly to include temporal and/or modal qualifiers as well – eg. *possibly, sometimes, it depends*, etc. In the first case, determining a proper answer requires identifying what support exists for a positive answer (*yes*); what support exists for a negative answer (*no*); and on which side the support is stronger. Practically, this could involve separate queries – one seeking evidence for the positive assertion, the other, for the negative assertion. These queries could differ because lexical items can have distinct negative-polarity counterparts. For example, given the question

(10) Does Anacin contain any stimulants?

a query seeking evidence for the positive statement might contain the terms ANACIN, CONTAIN and STIMULANT, while the query seeking evidence for the negative statement might contain the terms ANACIN, LACK and STIMULANT. But because *potential answers* retrieved in response to such questions may themselves contain explicit negation (i.e., *no* or *not*), deciding what they support requires determining the scope of negation. Here, inference can determine which of the readings are consistent. Inference can also be used as discussed in Section 2.2. to determine whether two pieces of *evidence* are the same or different, so that instances of the same evidence or instances of stronger and weaker evidence aren't multiply counted.

In general, it is easier to find positive evidence than negative evidence, as what does not hold is most often conveyed implicitly, by the lack of evidence for it (i.e., the *closed-world assumption*). But for certain yes/no questions, evidence for a negative answer may be easier to come by than for a positive one. For example, in a question with a universal quantifier such as

(11) Did Larsson score in every game he played for Celtic?

a single piece of negative evidence (e.g., "Larsson failed to score in Tuesday's game") is needed to justify a negative answer, while a positive answer requires either a potential answer that itself contains a universal quantifier or a set of potential answers that cover the entire set of games. The latter is essentially (extensional) database question-answering, with the *closed-world assumption* that the database covers all positive instances.

2.6. Generating responses in lieu of or support of a direct answer

Unlike in TREC-9, TREC-10 systems were asked to identify when they couldn't answer a question. In database QA, finding no answer to a question was not an uncommon occurence. One reason for this occurring was failure of a presupposition in the question. For example, the question

(12) Have any women been awarded a Pulizer prize for sports journalism?

may have the direct answer *None* because the existential presupposition that there is a Pulizer prize for sports journalism is false. Hence, techniques were developed (Kaplan, 1982) for recognising presupposition failure and for generating responses such as *There is no Pulizer prize for sports journalism.* But as shown

in (Blackburn and Bos, forthcoming), verifying presuppositions involves inference in order to check their consistency and informativity in context.

Another reason for not being able to answer a question is that *positive* information is lacking. Here, a partial response can be formulated if *negative* information can be found that *excludes* something from the set of proper answers. For example, given the question

(13) Which French cities did Reagan like?

information to the effect *Reagan disliked Paris* provides a useful partial response. Inference can be used to recognize that an individual is excluded from the set of proper answers.

A third situation motivating a response is the case of negative answers to extensional yes/no questions, which are rarely very informative – e.g.

(14) Q: Did Hearts played a home game against Celtic in January?
A: No.

In such cases, the answer to a "weaker" question – one that can be computed from the original one by subsumption reasoning, may provide the basis for a useful response – e.g. *Did Hearts play a game against Celtic in January?* or *Did Hearts play a home game against Celtic?* or *Did Hearts play a home game in January?*. More complex questions, such as ones containing quantification and/or negation, may require more complex subsumption reasoning to establish weaker questions that are worth posing.

Note that weakening the question only makes sense for questions answered extensionally, not ones answered through inference or pattern matching such as

(15) Do penguins migrate?[1]

Other situations in which responses are useful in lieu or support of a direct answer, many of which require forms of inference, are described in (Webber, 1986).

3. Graduated Test Suites

While TREC evaluation of QA systems has focussed on the full end-to-end task, some systems have also carried out what Barr and Klavans (Barr and Klavans, 2001) call *component performance evaluation* – assessing the performance of system components and determining their impact on overall system performance. The components of interest here are those that use inference. We see *graduated test suites* as a tool for assessing their performance and impact, allowing: (1) comparison against similar components that do not use inference; (2) comparison of components that differ in what inference tools they use; and (3) assessment of the impact of improvements in inferential ability. We also see graduated test suites as a way of evaluating automated reasoning tools on the inference problems raised by QA.[2]

We now discuss two of the above QA tasks, making explicit what one would expect to see in a distinct test suite for each. As in TREC, developing the test suites would involve carefully crafting a set of examples to the correct level of difficulty, fixing evaluation criteria and delimiting in a more precise way the linguistic task involved.

Expanding the query. Section 2.1. identifies four ways of expanding the query: through equivalence, through entailment, through multiple sub-queries and through abduction. For each of these tasks, inference can be involved as follows.

When expanding the query with semantically equivalent reformulations, inference can be used in at least one of two ways: First, given a subsumption based hierarchy KB encoding relations between word meanings, inference can be used to *find* the set of (structured) concepts which are logically equivalent to the structured concept representing the initial query. Alternatively, for reformulations produced by some other mechanism (e.g, parsing the query and then generating paraphrases from the resulting semantic representation(s)), inference can be used to *check* that they are indeed semantically equivalent.

Similarly, when expanding the query with more specific variants, inference can be used either to *find* within a hierarchy, the set of most specific concepts subsumed by the concept representing the query, or, for potential variants found by other means, simply to *check* that each indeed stands in some kind of entailment relation to the initial query.

Thirdly, when expanding concepts (and/or sets of concepts) in the query into *partitions* (i.e., disjoint covers) of more specific sub-concepts, the task for automated reasoners would be to check that the conjunction of queries $Q_1, \ldots, Q_n$ obtained by replacing a concept in the original query Q by a partition of its immediate sub-concepts is equivalent to the original query.

Finally, queries can be expanded by making implicit information explicit. This requires some kind

[1] Many types of penguin migrate, swimming north each autumn in the Southern Hemisphere and south each spring.

[2] Automated reasoners have been optimised for their performance on problems from mathematics and logic. As this is not necessarily optimal for NL problems, we need to drive their optimisation in this direction. That is the reason for having test suites for both QA components and automated reasoners.

of abduction – e.g, weighted abduction (Hobbs et al., 1993) or model building (Gardent and Konrad, 2000a; Gardent and Konrad, 2000b). With the first, the reasoner is given a semantic representation of the query, along with relevant world, domain and/or lexical knowledge and returns the cheapest explanation (proof) of the query, making explicit the hypotheses (either abduced or assumed) that support it. Similarly, model building will produce a (minimal) model satisfying the formula which encodes the explicit and implicit information expressed by the query.

In all cases, the information (facts in model or logical formulae) resulting from query expansion can be converted to a form appropriate to the query. If queries are Boolean combinations of key words and/or phrases, NL Generation techniques can be applied to each semantic component to produce a parse tree whose leaves constitute a string of lexical *lemmas*, from which key words and phrases can be identified and added to the query.

Determining proper answers. For **wh-questions with a single answer**, the problem of determining a proper answer from a potential answer depends on (i) the *expected answer type* (positive, negative, unknown); (ii) the *answer locality* (whether the answer is contained in a single clause or distributed over the text), and (iii) the *derivability* of the answer (whether it is explicit in the text and derivable simply by pattern matching, or it requires inference or other method of information fusion).

Test-suite examples could therefore be divided into 12 classes, of different complexity, depending on the values of these factors. For example, consider *expected answer type*. Formulated in first-order logic, with ϕ_A representing the meaning of the potential answer A, D the domain of the question and B its body, (1) if the expected answer type is positive, there is at least one object having the properties set by the question. So the inference task is simply: **Prove** $\models \phi_A \rightarrow \exists x(D(x) \wedge B(x))$**.** (2) Alternatively, if the expected answer type is negative, there is no object having the properties set by the question. So the inference task is: **Prove** $\models \phi_A \rightarrow \neg\exists x(D(x) \wedge B(x))$**.** (3) Finally, if the expected answer type is unknown, then *both* the above inference tasks are required.

For **questions with multiple answers**, we can only comment now on the use of inference for questions that can be expanded into a set of more specific subqueries with known cardinality, such as

(16) What is the longest river on each continent?

which can be expanded into *What is the longest river in Europe? What is the longest river in Asia? ....* Once expanded in this way, each sub-query is a simple wh-question with a single answer. This is then the case discussed earlier.

4. Summary

There is no question that QA would not also be enhanced through the use of inference in *discourse tasks* involved in finer-grained examination of the texts retrieved in response to user-queries. It would likewise be enhanced by the use of inference in *dialogue tasks* involved in understanding the user's current utterance with respect to the current QA dialogue. Here we have focussed solely on the use of inference in *QA tasks* – tasks that follow from the *functional role* of a question or an answer – and how it could contribute to achieving these tasks, over and beyond methods that don't use inference.

When considering the development of *graduated test suites* to assess system performance on QA tasks and its impact on overall system performace (and also the performance of automated reasoning tools), it makes sense to consider the use of previous TREC questions and the set of passages (potential answers) that the retrieval components of TREC QA systems have returned in response. The usefulness of doing so is most obvious in the case of two of the tasks discussed here: determining proper answers from potential answers and comparing proper answers to wh-questions. What now requires discussion is what to do next.

The Challenge of Technical Text

Michael Hess, James Dowdall, Fabio Rinaldi

{hess,dowdall,rinaldi}@ifi.unizh.ch

Abstract

When evaluating and comparing Answer Extraction and Question Answering systems one can distinguish between scenarios for different information needs such as the "Fact Finding", the "Problem Solving", and the "Generic Information" scenarios. For each scenario, specific types of questions and specific types of texts have to be taken into account, each one causing specific problems. We argue that comparative evaluations of such systems should not be limited to a single type of information need and one specific text type. We use the example of technical manuals and a working Answer Extraction system, "ExtrAns", to show that other, and important, problems will be encountered in the other cases. We also argue that the quality of the individual answers could be determined automatically through the parameters of correctness and succinctness, i.e. measures for recall and precision on the level of unifying predicates, against a (hand-crafted) gold standard of "ideal answers".

1. Introduction

The classical type of *information need* satisfied by existing IR systems can be described with the scenario of "Essay Writing": If you have to write an essay on a given topic you need to locate as much backup material dealing with this topic as possible, i.e. preferably whole documents[1].

Increasingly, more specific types of information needs become important. *First*, one need not catered for by the "Essay Writing" scenario is a determination to locate factual knowledge about individually identifiable entities, concerning their location in time or space, their properties, or their identity with other entities. This could be called the "Fact Finding" scenario, and it is the situation assumed by the QA Track of TREC. The questions are factual questions ("where is/who is XYZ"). One source of such information is, of course, news items but also includes encyclopedias, text books, and fact sheets.

A *second*, equally important, information need beyond the "Essay Writing" scenario arises in situations where concrete problems require explicit solution(s) from a collection of documents. This could be called a "Problem Solving" scenario, and the questions asked are procedural ("how do I do XYZ"). A typical, real world, example is that of an airplane maintenance technician who needs to repair a defective component. He must locate in the massive maintenance manual of the aircraft the exact description of the specific repair procedure. Other text types that contain procedural information are "case data bases" used for trouble shooting purposes, operational handbooks, and some types of scientific articles (e.g. diagnostic and therapeutic reports in medicine).

Third is the situation where you need to find information about principles and regulations, i.e. what one might call the "Generic Information" scenario. The typical questions are definitional ("what is"), and the typical texts consulted in this situation are on-line encyclopedias, but also technical standards publications. Many technical manuals also contain numerous definitions of concepts or devices. It can also be argued that deontic texts (laws etc.) also fall under this heading, and they are extremely important in society.

What users need in the "Fact Finding", "Problem Solving", and "Generic Information" scenarios are systems capable of finding those exact (parts of) sentences in document collections that constitute the answer to their question. Depending on the type of question ("where is/who is", "how do I", "what is") different problems will be prominent to different degrees. Thus, named entities are important for answering factual questions but less so for problem solving and definitional questions. There is also evidence that for the latter two types of questions a deeper (syntactic and semantic) analysis of questions is needed than for the factual ones. In order to define standards for comparative evaluations that are not biased towards one particular type of information need, examples of queries and texts of different types should be used from the very beginning.

In the present position statement we will briefly describe ongoing research in the related fields of Question Answering (QA) and Answer Extraction (AE), primarily in the dual context of the TREC QA track (section 2.) and of our own work on the first text type mentioned above, i.e. technical manuals (section 3.). Later we will present some of the problems that are specific to different text types (section 4.), briefly consider the difficulties of evaluating AE systems (section 5.), and finally mention the resources used in our work (section 6.). As relative 'outsiders' we explicitly aim at providing a critical and, in some respects, dissenting voice, giving the view of somebody approaching Question Answering from a perspective different from that defined (and circumscribed) by the TREC QA track.

2. Results from TREC

Results from the two first TREC Question Answering Tracks (Voorhees, 2000; Voorhees and Harman, 2001) seemed to show that standard, keyword based, IR techniques are not sufficient for satisfactory Answer Extraction. When the answer is restricted to a very small window of text (50 bytes), systems that relied only on those techniques fared significantly worse for the kind of questions used in

[1] It has been often observed that Information Retrieval should rather be called "Document Retrieval".

the QA track than systems that employed some kind of language processing.

More successful approaches employ special treatment for some terms (Ferrett et al., 2001) and named entity recognition (Humphreys et al., 2001), or a taxonomy of questions (Hovy et al., 2001). Interestingly, some sort of convergence appears to be emerging towards a common base architecture which is centered around four core components (Abney et al., 2000; Pasca and Harabagiu, 2001). Passage Retrieval (Clarke et al., 2001) is used to identify paragraphs (or text windows) that show some general similarity to the question (according to some system specific metric), a Question Classification module is used to detect possible answer types (Hermjakob, 2001), an Entity Extraction module analyzes the passages and extracts all the entities that are potential answers, and finally a Scoring module (Breck et al., 2001) ranks these entities against the question type, thus leading to the selection of the answer(s).

The results of this general design are promising for the kind of factual questions that make sense in the context of news messages. Since such questions ask mostly about properties of individually identifiable entities, good named entity recognition can go a long way towards finding informative text passages. However, for other types of questions (procedural and definitional) we need to be able to analyze other types of constructions, and pinpoint answers more precisely. This means that the choice of a single type of text for the purpose of comparative evaluation creates the risk of "over-fitting" in that all competitors converge on the techniques used by the most successful system for this particular type of text. This effect tends to stifle innovation rather than foster it, and we think that a wider range of texts should be used in comparative evaluation from the beginning to counteract this danger.

It appears that, partly, the problem has already begun to emerge in the latest TREC QA track (TREC10). On one hand, many systems are converging towards the 'generic AE system design' described above, on the other hand, the system that did best (Soubbotin and Soubbotin, 2001) made massive use of heuristics and patterns, that might have limited portability to other domains and other types of applications.

3. ExtrAns

Over the past few years our research group has developed an Answer Extraction system (ExtrAns) (Rinaldi et al., 2002; Mollá et al., 2000) that is mainly geared towards procedural and definitional questions over technical texts.

Two real world applications have so far been implemented with the same underlying technology. The original ExtrAns system is used to extract answers to arbitrary user queries over the Unix documentation files ("man pages"). A set of 500+ unedited man pages has been used for this application. An on-line demo of ExtrAns can be found at the project web page.[2]

More recently we tackled a different domain, the Airplane Maintenance Manuals (AMM) of the Airbus A320. The combined challenges of an SGML-based format and the more technical nature of the text and a larger size (120MB)[3] have been met using the original basic architecture (Fig.1), plus a specialized XML based tokenizer and a new CSS-based display utility.

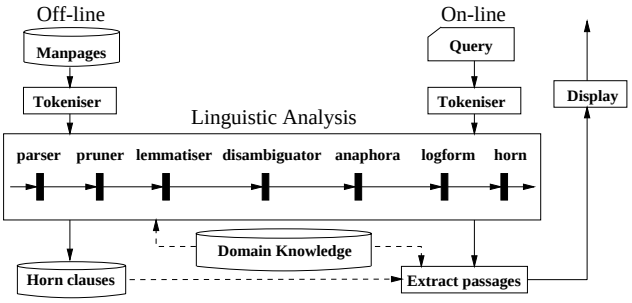

Figure 1: Architecture of the ExtrAns system

Essentially, ExtrAns extracts answers from documents by semantically comparing queries against document sentences. This is achieved by deriving, from documents and queries, the basic semantic relationships of each sentence and representing them as Minimal Logical Forms (MLF). These are representations that use selected reification and underspecification to keep them open to dynamic, incremental and non-destructive extension, depending on requirements. Answers are derived from these logical forms by deductive proof. This representation is both expressive enough to allow non-trivial comparison and computationally "light" enough for real world applications. True, this approach requires expensive deep linguistic analysis of questions and documents, involving syntax, semantics and consideration of lexical alternations (synonyms and hyponyms) but it returns, in exchange, the exact answer sentences (ideally) and often manages to even determine the individual parts of sentences constituting the exact answer(s) to user questions.

The general design of the system is fairly standard. A (very powerful) tokenizer identifies word and sentence boundaries as well as domain specific multi-word terms. Once tokenized, sentences are parsed using Link Grammar (LG) (Sleator and Temperley, 1993). Link Grammar's ability to predict the syntactic requirements of unknown words ensures that an analysis of all sentences is returned. So ExtrAns always produces MLFs, possibly extended with special predicates that mark any unprocessed tokens as "keywords". Multi-word terms (to be extracted independently and beforehand) are parsed as single syntactic units. Relieving LG of the need to compute the internal structure of such terms reduces the time and space involved for parsing technical text by almost 50%.

A corpus-based approach (Brill and Resnik, 1994) then disambiguates prepositional phrase attachments as well as gerund and infinitive constructions. An anaphora resolution algorithm (Lappin and Leass, 1994) resolves sentence-internal pronouns. The same algorithm can also be applied

[2] http://www.ifi.unizh.ch/cl/ExtrAns/

[3] Still considerably smaller than the size of the document collections used for TREC.

to sentence-external pronouns but this is not (yet) done in ExtrAns.

From the resulting disambiguated linkage, semantic relations between verbs and arguments as well as modifiers and adjuncts are expressed as a MLF. Strict underspecification ensures this only involves objects, eventualities and properties. These predicates are conjoined, and all variables are existentially bound with maximal scope. By way of an example, (1) represents the sentence, *"A coax cable connects the external antenna to the ANT connection"*:

```
(1) holds(o1),
    object(coax_cable,o2,[v3]),
    object(external_antenna,o3,[v4]),
    object(ANT_connection,o4,[v5]),
    evt(connect,o1,[v3,v4]),
    prop(to,p1,[o1,v5]).
```

ExtrAns identifies three multi-word terms, translated into (1) as the objects: `v3`, a coax_cable, `v4` an external_antenna and `v5` an ANT_connection. The entity `o1` represents the fact of a 'connect' eventuality involving two objects, the coax_cable and the external_antenna. This reified argument, `o1`, is used again in the final clause to assert the eventuality happens '*to*' v5 (the ANT_connection).

The utility of reification, yielding the additional arguments `o1`, `o2`, `o3` and `o4` as hooks to the abstract entities they denote is that the expression (1) can now be modified by monotonically adding constraints over these entities without destructively rewriting the original expression (Schneider et al., 1999). So the sentence *"A coax cable **securely** connects the external antenna to the ANT connection"* changes nothing in the original MLF, but additionally asserts (2) that `o1` (i.e. the fact that the coax cable and the external antenna are connected) is *secure*:

```
(2) prop(secure,p8,o1).
```

This MLF only needs to refer to the reification of an **eventuality** for further modification but other, more complex, sentences will need to refer to the reifications of **objects** (e.g. for non-intersective adjectives) or of **properties** (e.g. for adjective modifying adverbs).

ExtrAns extracts the answers to questions by forming the MLF of the question and running Prolog's theorem prover to find the MLFs from which the question can be derived. So,

"How is the external antenna connected ?'

becomes:

```
(3) holds(V1),
    object(external_antenna,O2,[V5]),
    evt(connect,V1,[V4,V5]),
    object(anonymous_object,V3,[V4]).
```

If a sentence in the text used as a knowledge base asserts that the *external antenna* is connected to or by *something*, the query will succeed. This *something* is the anonymous object of the query. If there are no answers (or too few) ExtrAns relaxes the proof criteria by introducing hyponymy related tokens as part of the MLF. Additionally, a sentence identifier indicates from which tokens the predicate is derived (not shown in the example above). This information is used to highlight the (relevant parts of the) answer in the context of the document (see Fig. 2).

This kind of very parsimonious representation could appear too "semantically weak" for general QA. This may be true but it is optimized for the task at hand (AE) and can be extended, at will, for more demanding tasks (such as full QA). The MLFs can also be used to ensure that sentences are retrieved that are, in strictly logical terms, not correct answers, but they are useful nevertheless. Thus (4i-ii) are useful (albeit not logically correct) answers, in addition to the correct answers (4iii-iv).

(4)
i. The external antenna must not be directly connected to the control panel.
ii. Do not connect the external antenna before it is grounded.
iii. The external antenna is connected, with a coax cable, to the ANT connection on the ELT transmitter.
iv. To connect the external antenna use a coax cable.

4. Text Types, Question Types, and Problem Types

At present, discussions in the TREC community around the further development of Answer Extraction and Question Answering (e.g. in the "Roadmap" document (Burger et al., 2001)) address a very large number of problem and question types, many of them very thorny. However, they do so almost exclusively against the background of *one specific document type*, viz. newspaper texts.

We feel, on the basis of six years' of development and experimentation with Answer Extraction systems, that this exclusive focus on a single, very specific, type of document is not ideal, and that other document types should be considered from the beginning. There are three reasons for this:

1. Processing Strategies developed for newspaper texts become less relevant to users accessing increasing volumes of technical data.
2. Some important problems of AE/QA hardly occur in newspaper texts.
3. Some of the problems that are quite fundamental to any kind of AE/QA can be found in a more isolated, "pure", form in other types of text.

Concerning the *first* point, it is our experience that better access to archived newspaper texts and similar documents is low on the list of priorities for most potential users of QA/AE-Systems in industry, administration, and academia. One exception may be intelligence agencies with interests in monitoring news streams. However, systems that allow high-precision access to the information stored in texts covering narrower, more technical, domains would be welcomed by many organisations in business, administration, and research. Cases in point are (among others):

- Technical manuals of complex systems (any large technical system comes with massive manuals, most often in machine-readable form)
- On-line help systems (for software or other complicated products, such as some financial products)
- Customer queries (systems that process and answer e-mails and/or Web inquiries)
- Access to abstracts and full texts of scientific articles (such as Medline).

Concerning the *second* point, there are some important problems *not* given sufficient weight in the Roadmap document, due to the fairly specific characteristics of newspaper texts:

- **Domain specific terminology:** It is generally recognized that the compilation and use of terminologies is a top priority for the automatic processing of texts in technical applications. The *use* of a (reliable) terminology for a given domain makes the processing of texts vastly simpler, faster, and more useful than without (the quality of Machine Translation systems, for instance, remains dismal without terminology). However, the automatic *compilation* of terminologies ("term extraction") is basically an unsolved problem (none of the available methods produce really useful results). More work is needed in this field but the problem is very peripheral in the Roadmap document.
- **Procedural Questions:** In many of the applications mentioned above (apart from natural language interfaces to technical manuals also on-line help systems and customer e-mail processing systems) the procedural questions of the type *"How do I do X?"* ("How do I convert Apple files to UNIX text format?", "How can I move funds from checking to savings?") are of paramount importance. However, this type of question makes little sense in the framework of newspaper texts, and is therefore given too little attention in the Roadmap document.
- **Generic Questions:** In the documents used for the above-mentioned types of applications (but also in on-line encyclopedias etc.) many sentences are *generic* (timeless rules). Typical questions directed at such texts are *"How do you stop a Diesel engine?"* or *"What is a typhoon?"*. These, too, are relatively rare in newspaper texts (which normally describe individual, time-bound facts), and they are consequently not mentioned in the Roadmap document [4]. Although generic sentences are admittedly a thorny problem they must not be ignored, due to their general importance.

[4] A small number of definitional questions were included in TREC9. In TREC10 their number was significantly higher, due to the different source of the questions. It has however been observed that a corpus of newspaper articles is not the best place to search for answers to that type of questions (Voorhees, 2001).

Concerning the *third* point, there is a number of problems that are fundamental to any kind of AE/QA system, and that do occur in newspapers texts, but which are "drowned" by the numerous other difficulties resulting from the characteristics of newspaper texts. Among them are:

- **Intensional constructions**: Contrary to (almost) common belief, intensional constructions are fairly common in perfectly normal language, and not treating them properly results in wrong answers. Cases in point are "higher order verbs" (as in "pack **attempts** to store the specified files in a packed form" - it may not succeed) and intensional uses of adjectives (as in "Only the super-user can allocate **new** files" - they don't exist yet).
- **Anaphoric references:** Although it has been argued that anaphoric reference (by means of pronouns or definite noun phrases) is irrelevant for document retrieval purposes (or even damaging) the situation is definitely different for AE/QA. Crucial information is often contained in sentences that refer to entities *only* by anaphoric references. Moreover, information is often given in technical manuals just once, so even one missed pronominal reference may seriously impair retrieval performance. Even for the relatively simple task of named entity recognition we must often have recourse to some of the techniques needed for reference resolution ("Bill Gates of Microsoft" &... "Gates" ... "the Gates company" etc.).
- **Pluralities**: Reference to groups of objects (be it through plurals ["dogs"] or through conjunctions ["Fido and Rover"]) is a well-known headache, in particular due to the different possible readings of plural noun phrases (collective/distributive/cumulative: "Fido and Rover fought/barked/ate up the food"). While in many cases it is possible to leave underspecified the exact number of objects introduced by pluralities this is no option when we want to get exact numbers from textual documents (e.g. via "how many"-questions).

The specific characteristics of newspaper texts that somehow overshadow these problems are:

1. **Range of topics:** Due to the vast range of topics covered by newspapers the topic of *sense ambiguity* becomes a top priority problem (cf. "Where is the Taj Mahal?"). In more restricted domains we can usually get away with little or no sense disambiguation (and if we have to perform it, it is much simpler than in open domains). Since sense disambiguation is a very thorny problem, domains where it is not of primary importance would be most useful.

   The wide range of topics also creates the rather ill-understood problem of the type "original vs. copy" ("What is the height of the Statue of Liberty?" - only the original, no models thereof).

2. **Time-dependence of information:** The things described by newspapers are mostly time-dependent

("When was Yemen reunified?" or *"Who is the president of Ghana?")*. Keeping track of stages (i.e. the changes that the world is undergoing) is difficult (not least as we can, of course, refer to past states of affairs, and would therefore be able to process the various ways in which natural language encodes such information [the whole tense system!]).

3. **Volume of information:** The sheer volume of information in newspapers archives puts such a heavy burden on processing systems that a strong bias towards shallow analysis is created. One case in point is SRI's TACITUS which was replaced by FASTUS for the MUC competitions, for reasons of speed alone, although TACITUS is a much more powerful system.

Naturally, all these problems will have to be solved sooner or later but, in our opinion, the far more fundamental problems mentioned above could be approached best when kept somewhat sheltered from these minefields.

We certainly do not argue against the use of very large, TREC-like, collections of newspaper texts in the development and evaluation of AE/QA systems but argue for the early inclusion of more moderate volumes of technical texts representative of other, very important, types of documents.

5. Evaluation of AE/QA Systems

As experience gained in the past QA tracks has shown the question of how AE and QA systems shold be evaluated consists of at least two components:

1. What should the answer sets look like?
2. How should the quality of an answer be determined?

The *first* question concerns, among other things, the question of the size of the answer string and, connected with it, that of answer justifications. There is agreement that a fixed-length string that happens to contain the correct answer but in a wrong document context should not be counted as correct (e.g. the answer string "Bush" taken from a document written when George Bush was president but dealing exclusively with shrubs). However, this requirement forces assessors to consult the original document and determine whether the answer string is justified. Clearly a considerable element of uncertainty is entered into the evaluation that way (Is the justification allowed to be implicit in, and/or distributed over, the document? When is an answer justified?)[5].

For a pure AE system, i.e. one *retrieving* explicit answers rather than *computing* answers from possibly distributed, possibly implicit, information (as done by true QA systems) this problem can be contained somewhat by requiring systems to retrieve not fixed-length strings but (not necessarily contiguous) fragments of sentences of potentially unlimited length that, when concatenated, constitute the complete answer, ideally as a well-formed sentence, as seen in Fig. 2. That this is a sensible requirement becomes particularly obvious in technical domains. Consider, for instance, the question:

> **Do I need write permissions to remove a symbolic link?**

A 50-byte answer window may retrieve from the Unix manual, among others, the string:

```
" need write permission to remove a
symbolic link, "
```

Checking the document sentence will reveal that this string is a completely wrong answer as the sentence from which it was taken is:

> **Users do not need write permission to remove a symbolic link, provided they have write permissions in the directory.**

The arbitrary limit of 50 bytes just happened to cut off the crucial negation. However, requiring the AE system to return a complete, ideally well-formed, sentence will result in the justification to be part of the answer itself (in this case, the entire document sentence should be returned).

Another aspect of the first question concerns the *test queries*. Clearly, it is always better to use real world queries than queries that were artificially constructed to match a portion of text. By using, as we suggest, manuals of real world systems, it is possible to tap the interaction of real users with this system as a source of real questions (we do this by logging the questions submitted to our system over the Web). Another way of finding queries is to consult the FAQ lists concerning a given system available on the Web. By combining those two sources we compiled a list of 524 questions about the Unix domain. However, a large proportion of them is problematic as they have no answers in the document collection or are clearly beyond the scope of an automatic system (for example, if the inferences needed to answer a query are too complex even for a human judge). Nevertheless they are a useful starting point for a set of test queries in this domain.

Concerning the *second* issue, that of answer quality, the standard measures of Precision and Recall are not ideal for an Answer Extraction system, when applied to individual answer sentences. It can, in particular, be argued that Recall is significantly less important than Precision, as the aim of such a system is to provide (at least) one correct answer, rather than all the possible answers in a given collection. The user needs to find one good answer to a question and they are not interested in repeatedly finding the same answer.

In the Question Answering track of TREC a measure of precision is therefore used that takes this into account, viz. the Mean Reciprocal Rank (MRR). The Rank of a given result is the position in which the first correct answer is found in the output list of the system. Over a given set of answers the MRR is computed as the mean of the reciprocals of the ranks for all the answers.

The problem with this approach is that the underlying assumption, that an answer returned by an AE system is either completely correct or completely wrong, is not entirely realistic. Quite often we get a series of answers

[5] for the latter see:
http://www.isi.edu/natural-language/projects/webclopedia/controv-trec10-eval.html

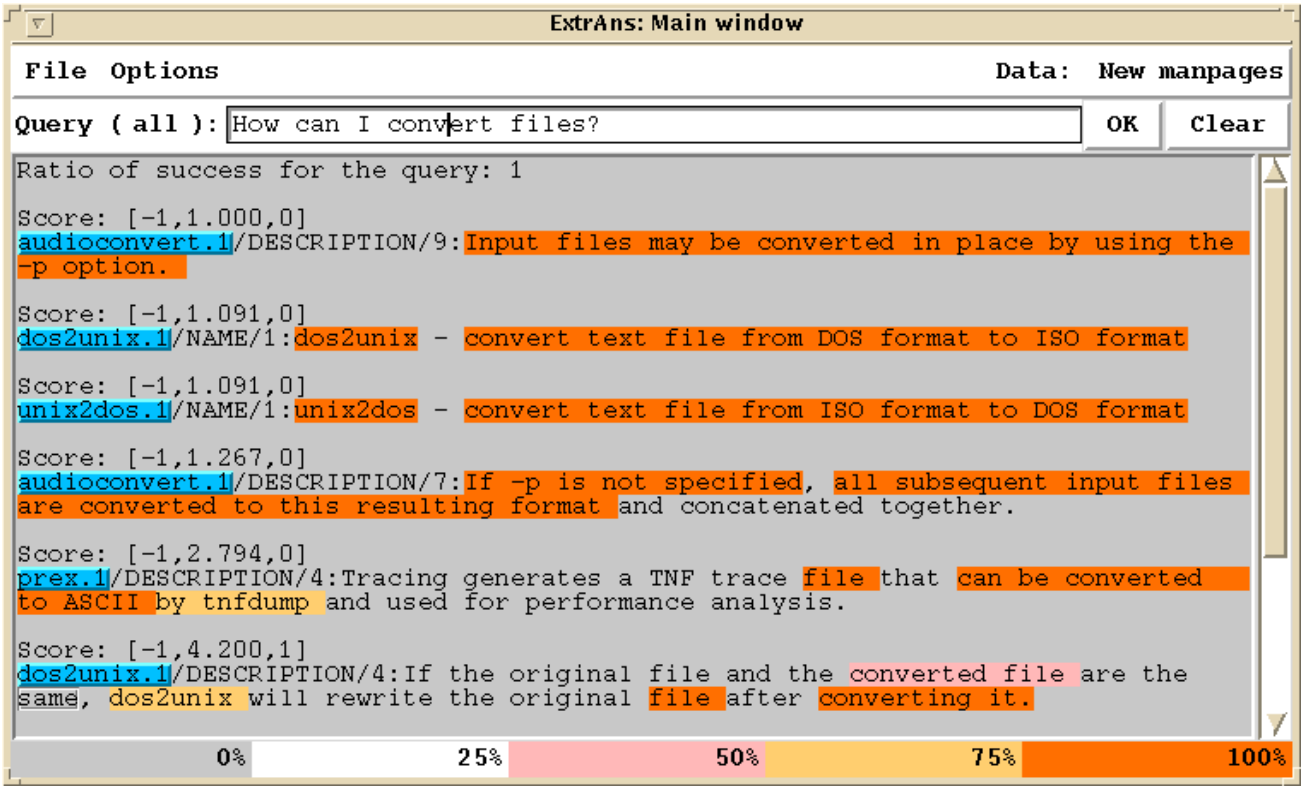

Figure 2: Identifying Relevant Parts of Sentences.

which are all correct to some degree but not entirely correct. We need some kind of weighting, exactly as in document retrieval, but again on the sentence level. The way this weighting should be performed is, however, less clear. One approach might be to find a representative set of correct answers by making a person write the ideal answers to a number of questions (labour-intensive but feasible), and then to find the sentences in the documents that are "semantically close" to these ideal answers automatically.

Semantic closeness between a sentence and the ideal answer, i.e. the weight of an answer sentence, could be computed by combining the two measures that one might call *"succinctness"* and *"correctness"*. Both measures compare a potential answer sentence with the ideal answer. Succinctness and correctness are the counterparts of precision and recall, respectively, but now on the sub-sentential level. These measures can be computed by checking the overlap of words between the sentence and the ideal answer (Hirschman et al., 1999), but we suggest a more content-based approach. Our proposal is to compare not words in a sentence, but their logical forms. Of course, this comparison can be done only if it is possible to agree on how logical forms should look like, to compute them, and to perform comparisons between them. The second and third conditions can be fulfilled if the logical forms are simple conjunctions of predicates that contain some minimal semantic information. In this paper we will use a simplification of the minimal logical forms used by ExtrAns (Schwitter et al., 1999). Below are two sentences with their logical forms:

(5) *rm removes one or more files.*
`remove(x,y), rm(x), file(y)`

(6) *csplit prints the character counts for each file created, and removes any files it creates if an error occurs.*
`print(x,y), csplit(x), character-count(y),` **`remove(x,z), file(z)`**`, create(x,z), occur(e), error(e)`

As an example of how to compute succinctness and correctness, take the following question:

Which command removes files?

The ideal answer is a full sentence that contains the information given by the question and the information requested. Since *rm* is the command used to remove files, the ideal answer is:

(7) *rm removes files.*
`remove(x,y), rm(x), file(y)`

Instead of computing the overlap of *words*, succinctness and correctness of a sentence could now be determined by computing the overlap of *unifying predicates*. The overlap of the unifying predicates ("overlap" henceforth) of two sentences is the maximum set of predicates that can be used as part of the logical form in both sentences. The predicates in boldface in the two examples above indicate the overlap with the ideal answer: 3 for (5), and 2 for (6).

Correctness of a sentence with respect to an ideal answer (recall on the predicate level) is the ratio between the

overlap and the number of predicates in the ideal answer. In the examples above, correctness is 3/3=1 for (5) and 2/3=0.66 for (6). This means that (5) is completely correct in that it returns all the relevant predicates while (6) is only partially correct in that it describes the removal of files by a command but that this command is not the "ideal command" (the removal is, in fact, merely a side-effect of a command whose primary purpose has nothing to do with file removal).

Succinctness of a sentence with respect to an ideal answer (precision on the predicate level) is the ratio between the overlap and the total number of predicates in the sentence. Succinctness is, therefore, 3/3=1 for (5), and 2/8=0.25 for (6). This means that (5) returns only relevant predicates while (6) contains some extraneous material.

Finally, a combined measure of succinctness and correctness could be used to determine the semantic closeness of the sentences to the ideal answer. By establishing a threshold to the semantic closeness, one can find the sentences in the documents that are listed as answers to the user's query.

The advantage of using overlap of unifying predicates against overlap of words is that the (semantically highly relevant) *relations between the words* also affect the measure for succinctness and correctness. We can see this in the following artificial example. Let us suppose that the ideal answer to a query is:

(8) *Madrid defeated Barcelona.*
`defeat(x,y), madrid(x), barcelona(y)`

The following candidate sentence produces the same predicates:

(9) *Barcelona defeated Madrid.*
`defeat(x,y),` **`madrid(y),`**
`barcelona(x)`

However, at most two predicates can be chosen at the same time (in boldface), because of the restrictions of the arguments. In the ideal answer, the first argument of "defeat" is Madrid and the second argument is Barcelona. In the candidate sentence, however, the arguments are reversed. The overlap is, therefore, 2. Succinctness and correctness are 2/3=0.66 and 2/3=0.66, respectively.

While these ideas have not been implemented yet they may be useful as a contribution to the question of how answers in AE systems should be weighted according to their quality. While the "gold standard" (the ideal answers) would have to be compiled by hand, comparisons against this standard could be done in a wholly automatic fashion.

6. Resources

Some of the resources that we used in our work are:

a The Aircraft Maintenance Manual (AMM) for the Airbus A320. The original SGML markup has been converted into XML for simpler processing (in English, 120 MB total, 45 MB excluding markup).

b The Aircraft Troubleshooting Manual (ATM) for the Airbus A320. Original SGML converted into XML (in English, 62 MB total).

c The on-line manual of Unix (Solaris) in English.

d A list of 524 real user questions about Unix.

e A terminology database (semi-automatically extracted) for the aircraft manuals (approx. 3000 terms).

f Terminology Visualization Tools.
Additional XML markup that denotes the extracted terms is automatically inserted into the manual. The new markup tags can be tied to presentational information (given e.g. by CSS stylesheets), so that when the manual is browsed the terms are highlighted and differentiated from the rest of the text. Most modern web browsers are capable of handling such specification of the information.

Of these resources all the manuals are copyrighted but the lists (questions, terms) are not.

Abstract

Much recent question answering research has focussed on supporting the textual retrieval needs of intelligence analysts. Question answering may also play a role in other less textual domains, such as sensor networks, or the Joint Battlespace Infosphere (JBI). We propose a connectivistic database to serve as the core of a lexicon which may be used to improve current methods of question answering, as well as other natural language and ontology processing application

1. Introduction

The question answering vision (Carbonell et al., 2000) and roadmap (Burger et al., 2000) documents describe a five year program for research and development for question answering systems with a focus on how such systems could support the needs of an intelligence analyst. DARPA's Office of Information Exploitation (IXO) program has the mission to ". . . develop sensor and information systems with application to battle space awareness, targeting, command and control, and the supporting infrastructure required to address land-based threats in a dynamic, closed-loop process." IXO is developing 1-, 5-, and 20-year vision statements to meet the challenges of these systems. These dynamic information environments require intelligent middleware to broker services to connect information users and sources. For example, users pose natural language questions, which must be translated into the query languages and ontologies of the heterogeneous systems making up the JBI (United States Air Force Scientific Advisory Board, 1999, 2000; Infospherics, 2001). While technologies in this area will build on current DARPA programs providing tools for efficient human creation of ontologies (DARPA Agent Markup Language, 2002; DARPA Rapid Knowledge Formation, 2002), because of the dynamic, rapidly changing environment represented by the JBI, it is necessary that more automated approaches to semantic interoperability be developed, as well.

We suggest the desirability of a connectivistic database to serve as the core of a lexicon which may be used to improve current methods of question answering, as well as other natural language and ontology processing applications. Specifically, we illustrate the use of such a lexicon in the Joint Battlespace Infosphere (JBI). Related work has been done on statistical tools that automate the process of mapping from one ontology or grammar to another (Thompson, 2001). We are interested in building on this work, as well as using mixed-initiative approaches (Haller et al., 1999) to provide human input, where needed.

2. Lexicon Development: Application of Linguistic Knowledge to Natural Language Processing

2.1. Properties of natural language which may be mimicked computationally

Three aspects of natural language are submitted for consideration:

- Grammars consist of categories which may be cognitively manipulated synchronically or altered diachronically (Heine, 1997), such as phones, morphs, words, and grammatical classes. The categories within grammars are defined with respect to each other, much as the words of a dictionary are defined with respect to other words in the dictionary, and do not therefore line up evenly across languages (Whaley, 1997). For instance, the study of languages as diverse as English, Tagalog, Manchu, and !Xhosa has resulted in the understanding that lexical classes in different languages do not all conform to the same mould. Some languages employ lexical classes which are not employed in English, and vice versa. Furthermore, the same class in different languages may not be easily reconciled with each other, and the distinctions between classes, even noun and verb, can sometimes become blurred. Morphologists and psycholinguists such as Joan Bybee (1988) and Ardi Roelofs (1992),

to name only two, have explored the idea of a connectivistic lexicon with some success, both conceptually and experimentally.

? Grammars do not consist only of minimal units and rules for combining them. It has been found that the human brain stores a far more redundant amount of linguistic information than had previously been thought. Work with aphasic patients shows that the use of rules in combining morphemes may be thought of as a back-up method for producing morphologically complex words when access to the lexicon fails (Badecker & Caramazza, 1998). Psycholinguistic experiments have shown that the timing of lexical access for morphologically simple words is not significantly different from the timing of lexical access for morphologically complex words, and phonetic and psycholinguistic studies indicate that some prosodic structures are stored as whole units alongside of the individual segments of which they are comprised (Levelt, 1999; Grzegorz Dogil, personal communication).

? Grammars are learned best by immature brains – brains with degraded short term memory – which may learn only general principles of grammar before narrowing down to specific principles (Deacon, 1997). Deacon outlines work done by others in cognitive and computer science which involved training of neural networks to learn a grammar to a relatively large degree of accuracy when the "short-term memory" of the network was disturbed. Studies by MacWhinney (1978) and Peters (1983) indicate that generalizations (rules) gradually emerge from stored rote forms, which are initially processed and stored as unanalyzed wholes, cf. (Bybee, 1988). These studies corroborate both the work done by Deacon, and the evidence that linguistic data stored in the lexicon is often redundant.

2.2. Proposal for the design of a lexicon which mimics these properties

A lexicon with five main components may serve to mimic these properties of natural language: a Pattern Finding Engine (PFE), Short Term Memory (STM), Long-Term Memory (LTM), Connectivistic Database (CD), and an Anchor Set (AS),

2.2.1. Pattern Finding Engine and Memory

The Pattern Finding Engine (PFE) searches a text for patterns, and, during the training phase of the lexicon, stores those patterns in the Short-Term Memory (STM), while the strings predictable from those patterns are stored in the Connectivistic Database. For instance, starting from scratch, the PFE recognizes a sentence such as "Johnny ate the apple" as a single unit. This imitates the theory derived from the work of Deacon, MacWhinney, and Peters above. This single unit is stored as a whole in the CD as an object of class "lexical unit." Exposure to more sentences, such as "Johnny ran away" and "The apple is red", enables the PFE to recognize "Johnny" and "the apple" as units, and to store them in the CD, along with "ran away" and "is red". Further exposure to sentences such as "Apples taste good" and "Jack and Jill ran up the hill" allows the PFE to recognize "ran" as separate from "away again", and "s" as a morpheme attached to "apple".

Initially, PFE is not better than chance at finding correct patterns. Therefore, potential patterns are stored in STM. As more and more occurrences of patterns in STM are found by PFE, the patterns in STM are stored in Long-Term Memory (LTM). Because some units larger than the segment or the word may occur with great frequency, the work of PFE together with STM and LTM allows an imitation of the theory that the lexicon is not redundancy free. This also allows us to capture idioms as whole chunks (Nunberg et al, 1994).

2.2.2. Connectivistic Database

An object of class "lexical unit" represents all of the information concerning a single unit. Within the object of class "lexical unit" is a set of objects of class "link". Each object of class "link" contains two variables: a pointer, pointing to one other object of class "lexical unit"; and a value corresponding to the strength of that connection. Each "lexical unit" also contains an activation value, which records and keeps track of the activation of that unit at all times. Activation is a measure of the probability that a certain unit will be the next one chosen out of the lexicon, and is determined by the amount of activation flowing to it through its connections with other activated units. Each "lexical unit" also has an abstract position variable, represented by an n-dimensional vector, which identifies a location for the "lexical unit" in an abstract n-dimensional Minkowsky space.

Throughout the training phase, with the help of PFE, STM, and LTM, the CD automatically organizes itself into an n-dimensional Minkowsky space. Categories are automatically approximated by defining opposing categories with respect to each other along a similar dimension. Sets of categories which are not defined with respect to each other are defined along different dimensions. Such definitions may be approximated without prior human or machine coding (Klein, 1998; Levine et al., 2001).

2.2.3. Anchor Set

Initial training of the lexicon is supervised by a human assigning certain "lexical units" to corresponding absolute concepts. Such "anchor points" provide the basis for translation from one grammar or ontology to another via the lexicon. English "chair" and German "Stuhl", for instance, refer to roughly the same concept. Therefore, the word "chair" in an English trained lexicon, and the word "Stuhl" in a German trained lexicon will both be anchored to the concept of "CHAIR". The Anchor Set (AS) can be used then to manipulate and align the abstract n-dimensional vector spaces of the two lexicons such that, by extrapolation, lexical units with nearly identical position vectors should theoretically be nearly identical in meaning or use, depending on the dimension. The more anchor points that are explicitly taught to the AS, the more accurate this alignment will be.

2.3. Discussion

To the best of our knowledge, though the ideas and evidence outlined in this paper in favor of a connectivistic view of the lexicon have been explored by linguists already, there has been no attempt to apply such a model to challenges in natural language processing. Certainly this may partially be attributed to the fact that the computing power necessary to undertake such a task has not long been available.

We believe that development of such a lexicon is relevant to Question Answering technology in several ways. First, the lexicon, whatever shape it may take, is an important and central part of any natural language processing application. Without it, language is simply noise. We believe therefore that the form of the lexicon has a direct effect on the overall performance of the application. Second, in answering a single question, it is often necessary to extract information from multiple sources of varying media and ontologies. The information coming from these disparate sources must somehow be fused together and outputted into yet another ontology or medium. Because this conception of a lexicon is easily trained, it is easily transportable across multiple domains and ontologies or grammars. As discussed in section 2.2.3, the Anchor Set allows translation from one ontology to another via the lexicon, thus enabling this kind of fusion of information. Finally, though certainly not exhaustively, the automatic categorization of words along different dimensions, and the connections between words may be helpful as a tool for word sense disambiguation.

3. Questions in the Infosphere

3.1. Background

Question answering in heterogeneous sensor networks involves some of the same issues as question answering in more textual domains, but also introduces other aspects. The answer to the question may not exist in the network at the time the question is asked. Sensors may need to be tasked to provide the answer. A mapping must be made between the language of the user and the descriptions of the functionalities of various sensors. There is high transaction volume in the Joint Battlespace Infosphere (JBI) and questions may overlap in various ways. Efficient question answering calls for query planning and optimization along the lines of work done in relational databases (Jarke & Koch, 1984) and knowledge bases, but with additional factors introduced by the distributed, mobile, highly dynamic nature of sensor networks. Also, because much of the data in these networks will be structured, question answering in this environment can also build on research on natural language interfaces to relational databases (Adroutsopoulos et al., 1995; Urro & Winiwarter, 2001).

The JBI consists of client users, databases, sensors, and filtering or fusion operations. These filtering or fusion operations are carried out by fuselets, lightweight data fusion elements. Fuselets use simple logical rules to take inputs from other elements of the JBI, such as sensors, or other fuselets, to derive fused information. The functionality of each fuselet is described using a Fuselet Markup Language (FML). The JBI is implemented as a publish and subscribe architecture, where each fuselet publishes its services and subscribes to the outputs of other elements of the JBI. Questions in the JBI are answered by breaking the question into components and efficiently routing the components through the JBI network of fuselets, databases, and sensors.

Although ontologies may be provided for various sub-domains, it may be necessary to rapidly create and map among ontologies on the fly. For example, a fuel truck may be represented in separate ontologies for target tracking and for logistics. It must be possible to: a) determine that the two representations are of the same type of entity, b) reason within the joint probability space represented by the two ontologies, and c) answer questions by fusing information from the two domains. We will investigate a variety of tools to achieve semantic interoperability. In addition to the linguistic approaches to lexicon development discussed in section 2, we plan to explore statistical, text-based mapping and subsumption tools (Woods, 1997; Buckland et al., 1999; Gey et al., 2001; Schatz, 2002).

3.2. A JBI Fuselet Example

As a simplified example of question answering in the Infosphere, consider the following. In a battlefield situation when an enemy target is to be fired upon, it is first necessary to ascertain that no friendly assets are in the vicinity that might be adversely affected. A subset of the JBI involving a network of sensors, radio transmitters operated by groups of soldiers, advanced Land Warrior personal GPS systems, current roster information, other sources of information, and fuselets would be needed to make this determination. The current location, velocity, and vector of all friendly assets would need to be determined. If processing this information takes too much time, the target opportunity might be missed. If the enemy target is fired upon without the information being processed accurately, friendly assets may become casualties. Personnel in the tactical operation center would submit a natural language query, "Are any friendly assets in danger of being hit, if the target at UTM grid coordinate XY123456 is fired upon?" This query would then be interpreted by the question answering system. Fuselet 1 would aggregate the outputs from the soldiers' radio transmitters. Fuselet 2 would aggregate the output of the GPS systems. Fuselet 3, with situational tracking software, would fuse the outputs of Fuselets 1 and 2. Fuselet 4 in the personnel services center would fuse outputs from databases with current roster information, as well as with outputs from other databases making adjustments to the current roster, e.g., lists of soldiers on medical leave. Fuselet 5 would fuse the outputs of Fuselets 3 and 4 and produce as output a report for the tactical operations center, answering the query.

4. Conclusions

We intend to address question answering issues in the JBI, in particular those concerning closed-loop sensor networks. Our domain has some overlap with that of the intelligence analyst described in the question answering vision and roadmap documents, but has significant differences, as well. We intend to build a sensor network integrated with textual messages. We will make use of

ontologies, such as a sensor markup language, but we will also explore connectivistic lexicon, corpora linguistic, and other techniques to learn about our domains in a more dynamic manner, as necessary.

1.0 Introduction

The question answering vision (Carbonell et al. 2000) and roadmap (Burger et al.,2002) articulate a research and development direction for the next five years. Although a range of question and answer types are described, the ability to interpret a question and provide an answer with respect to different perspectives and the ability to answer questions involving temporal dimensions are largely unaddressed. This position paper argues for the importance of multiple perspective and temporal question answering and attempts to outline some aspects of the problem that would be important to capture on the Q&A roadmap. We address these problems in the context of two ARDA Northeast Regional Research Center (NRRC) Workshops, held in the summer of 2002, focused on time and multiple perspectives (nrrc.mitre.org).

2.0 Multiple-Perspective Question Answering

2.1 Multiple-Perspective Questions

A question may explicitly request multiple perspectives, for example ``What are the positions of German political parties on UN resolution 53?" or "What opinions are being expressed in the world press about US plans to invade Afghanistan?" In addition, questions asking for speculations or opinions might most appropriately be interpreted as asking for answers from multiple perspectives. Examples are ``How should the US response be to the terrorist incident?'' and "Will the US economy improve in the next six months?" Even for other questions, a multiple-perspective treatment may be very useful to an analyst or consumer. The user could be given the option to ask for multiple perspectives, whatever the specific form of the question. Finally, questions themselves can signal the perspective of the source or speaker (who could hold distinct views) while at the same time eliciting a multiperspective response as in "What do the Europeans think about the short-sighted US policy in the Middle East?".

2.2 Multiple-Perspective Answers

Perhaps the most obvious situation in which a question may be answered differently from multiple perspectives is when people or groups hold different beliefs about what is factually true. However, answers from different perspectives also include ideological beliefs, religious beliefs, evaluations, judgments, and speculations. They might reflect personally held beliefs, or official positions in legal, political, religious, or ideological platforms. In addition, the source of the belief might be a specific person, a group, a political or economic sector, or even the general culture at large. Recognizing the type of perspective reflected in an answer is essential for knowing how to interpret the information and what we can learn about the source.

We can envision a system that does not provide a single answer but rather presents the various positions on a topic currently being expressed in the world press, to help the user answer the question for himself or herself.

For the results to be useful, they should be characterized and clustered for presentation to the user. Storing the results in a knowledge base would support reasoning about multiple

perspectives on a topic, and detecting changes in perspective and trends over time.

Thus, five main aspects of the problem are the following:

- ? Retrieval of text segments containing candidate answers from multiple perspectives (Wiebe 1994, Wiebe et al. 1999).

- ? Characterization of the type of perspective of each answer. The answer may be presented as factual in the original source, or as a belief or opinion. It might reflect personally held beliefs, or official positions in legal, political, religious, or ideological platforms. It might be positive or negative evaluative, or speculative.

- ? Characterization of the source of the perspective. The source of the perspective may be an individual, a group, a political or economic sector, etc. Because beliefs about beliefs about beliefs, etc., may be presented, a structured representation of sources is needed.

- ? Comparison and clustering of the answers into similar perspectives, for presentation to the user.

- ? Representation of the answers in a knowledge base. As questions are answered from multiple perspectives over time, storing the results in a knowledge base would support queries such as which sources have expressed negative evaluations toward various topics, or which perspectives have changed over time.

Following are examples of multiple perspectives expressed in text. First, here are different views expressed about the same topic in editorials.

"General Musharraf has wisely chosen to throw in his lot with the US." (from *The India Times*).

"Looking at the event from the beginning most people including myself were convinced that President Musharraf's decision to support the USA was ill-thought, ill advised and was only taken for financial reward in a hurry." (from *The Frontier Post, Pakistan*)

In the following passage, which describes a factual dispute, the sources of the perspectives are people mentioned in the text:

"Agha [Tayab Agha, spokesman for Taliban leader Mohammad Omar] claimed the Taliban continued to rule in Kandahar, Oruzgan, Zabol, Ghazni and Helmand provinces. Afghan and Western sources, along with travelers who arrived today in Spin Boldak, disputed his claim, saying the Taliban only control parts of most of these provinces and had no influence over Ghazni at all (from *The Washington Post Foreign Service*).

A rich representation is needed to capture the characteristics of perspectives, their sources, and their objects, which may themselves be perspectives.

In addition to involving answers from multiple perspectives, questions often refer explicitly to time sensitive information, the area of question answering which we consider next.

3.0 Temporal Question-Answering: When time makes a difference

Humans live in a dynamic world, where actions bring about consequences, and the facts and properties associated with entities change over time. For this reason, temporally grounded events are the very foundation from which we reason about how the world changes. To be sure, named entity recognition is crucial to analyst reporting, information extraction, and question-answering systems; but without a robust ability to identify and extract events and time-stamps from a text, the real "aboutness" of the article can be missed. Moreover, entities and their entities change over time as well; hence a database of assertions about entities will be incomplete or incorrect if it doesn't reflect such time-stamps (e.g., the status of the World Trade Center Buildings before and after Sept. 11, 2001). To this end, event recognition drives basic inferences from text.

The focus of the Time and Event Recognition for Question Answering (TERQAS) workshop (time2002.org) is to address the problem of how to answer temporally-based questions about the events and entities in news articles. Currently,

questions such as those shown below are not generally supported by Q&A systems:

1. Is Gates currently CEO of Microsoft? (*time-stamp* question)
2. When does the seminar take place? (*punctual event* question)
3. How long did the hostage situation in Berlin last? (*Duration of event* question)
4. On what days were there bombings in the Middle East? (*Quantified event* question)
5. What airplane crashes occurred shortly after assassinations? (*Quantified event* question with *relative event ordering*)
6. What terrorist actions occurred within a week of political speeches by extremist governments? (*Quantified event* question with *relative event ordering*)
7. What bombings have occurred during the occupation of the West Bank? (*Quantified event* question with *durative event overlapping*)

What characterizes these questions as beyond the scope of current systems is the following: they refer, respectively to the temporal properties of the entities being questioned, the relative ordering of events in the world, and events that are mentioned in news articles, but which have not occurred at all.

3.1 Temporal Question-Answering Challenges

There has recently been a renewed interest in temporal and event-based reasoning in language and text, particularly as applied to information extraction and reasoning tasks (cf. Pustejovsky and Busa 1995; Mani and Wilson 2000; 2001 ACL Workshop on Spatial and Temporal Reasoning). Several papers from the workshop point to promising directions for time representation and identification (cf. Setzer and Gaisauskas, 2001, Filatova and Hovy, 2001, Schilder and Habel, 2001). Many issues relating to temporal and event identification remain unresolved. In our efforts we aim to (a) to examine how to formally distinguish events and their temporal anchoring in text (news articles); and (b) to evaluate and develop algorithms for identifying and extracting events and temporal expressions from texts.

Relative to the first goal above, we are addressing four basic research problems:

1. Time stamping events (identifying an event and anchoring it in time)
2. Ordering events with respect to each other (relating more than one event in terms of precedence, overlap, and inclusion)
3. Reasoning about the ramifications of an event (what is changed by virtue of an event)
4. Reasoning about the persistence of an event (how long does an event or the outcome of an event persist)

3.2 TimeML and TIMEBANK

To answer these problems, we are presently working to define a specification language and an annotated Gold Standard corpus. A specification language, TimeML, will be defined and developed. This XML-compliant language should formally model most of the following properties of time and events:

1. How to represent the interval values of events (time-stamping);
2. How to represent aspectual properties of an event (what phase of an event is being time-stamped);
3. How to represent all possible temporal ordering relations between two events;
4. How to model shallow (entailed) ramifications of an event (what related events are triggered by an event's occurrence);
5. How to model when a state persists and when it does not (what states follow from an event)

Once the initial definition and specification of TimeML is complete, it will be necessary to begin annotation on a large number of news articles, in order to create a Temporal Gold Standard (TIMEBANK). This entails the annotation of at least 400 articles, taken from four separate sources: 100 DUC articles; 100 ACE articles; 100 AP News articles; and around 100 PropBank annotated articles. We are presently in the process of the construction of TIMEBANK, the annotated corpus that we will provide as a community resource when completed, subject to appropriate copyright restrictions.

The specification language TimeML will suggest but not determine the nature of how answers to temporal questions are best presented to the user. This remains largely an issue of habitability and

usability of the application. Nevertheless, answers to temporal questions may take one of several forms:

1. Selections from database entries, populated from the appropriate information extraction algorithms;
2. Textual fragments from news articles, indicating total or partial answers to the question;
3. Answers may be abstracted and represented visually in terms of a timeline or a hyperbolic visualization algorithm.

The second goal mentioned above involves the evaluation of existing, and development of new temporal extraction algorithms. The four research problems given above correspond roughly to extraction algorithms of increasing degrees of sophistication and complexity. Time stamping events is not too dissimilar from named entity recognition; event ordering identification is somewhat similar to relational parsing; and capturing persistence and ramification properties of events is similar to identifying dependencies in a dependency grammar.

The algorithms will be applied and tested against the development corpus of the gold standard, TIMEBANK. Evaluation against a blind test set will measure for accuracy of answers for a range of questions, as defined by the participants, paying particular attention to target the specific temporal properties of the text with different questions.

Significantly, the results of our workshop will enable the community to begin addressing an entirely new type of question-answering capability, and one that is necessary for answering questions pertaining to the deeper content of news articles.

4.0 Implications for Q&A Road Map

The above observations point to the importance of research into multi-perspective and temporal Q&A. Some of the key milestones on the roadmap include:

- Characterize the types and nature of multiple perspectives and temporal aspects
- Establish and iteratively refine an ontology of multiple perspectives both for question analysis and answer generation. Do the same for temporal questions.
- Create corpora that include both multiple perspective and temporal phenomena
- Create annotation standards for multiple perspective and temporal markup

The two NRRC workshops described in this article will contribute in the next three months to advancing the state of the art by creating:

- An ontology of perspective
- An annotated corpus of multiple perspective questions and answers
- A repository of linguistic clues indicative of perspective
- A baseline of experimental results (segmentation, property annotation, clustering)
- A standard markup language for temporal and event expressions, TimeML
- A gold standard corpus for temporal expressions, TIMEBANK

5.0 Conclusion

This paper describes two important aspects of question answering that have gone largely unaddressed: time and multiple perspectives. These are important elements that should be reflected in the Q&A roadmap.

Summarization-Based Japanese Question and Answering System from Newspaper Articles

Yohei Seki* and Ken'ichi Harada*

*Department of Computer Science, Keio University

yohei.seki@dream.com

Abstract

Recently, many researchers are focusing on the application of Natural Language Processing (NLP) techniques such as summarization, information extraction, and text mining. One of the challenges with these technologies is developing an accurate Question and Answering System (Burger et al., 2001). In this paper, we will discuss Japanese Q&A problematic issues that have appeared in our experimental system. Our system is implemented with multi-document summarization (MDS) techniques.

Keywords: Japanese Q&A System, multi-document summarization technique, information fusion from multiple newspaper articles, and QAC (Question and Answering Challenge)

1. Introduction

There is a year long workshop being held by the National Institute of Informatics in Japan called NTCIR-3. We participated in the 'Question and Answering Challenge' (QAC) dryrun (Fukumoto and Kato, 2001) in the winter of 2001: Japanese Q&A tasks. We created an experimental system for the Japanese Q&A to detect problems specific to the Japanese language. Our input data was Mainichi Newspaper articles from 1998 and 1999 Year. This included about 230,000 articles. In this paper, we propose a multi document summarization based approach for Q&A. We also discuss some Japanese related problematic issues.

This paper consists of seven sections. We explain the tasks of QAC in Section 2, and discuss details of our system design and approach in Section 3. Section 4 provides an overview of our system user interface. Section 5 contains a brief evaluation of our system with QAC problems. In Section 6, some problematic issues are discussed. Finally, we present our conclusions in Section 7.

2. Question and Answering Tasks in QAC

The Question and Answering Challenge workshop (QAC) (Fukumoto and Kato, 2001) consisted of three tasks. The first and second task contained the same 50 questions. A list of five accurate answers was the goal in the first task; The goal of the second task was to extract the correct answer set. The third task had 10 problems and each problem had one follow-up question. The dryrun with these three tasks was held on five consecutive days in December, 2001.

The Answers were to be noun phrases which indicated a person's name, organization names, money, size, date and so on. The source documents were a two-year-period of Japanese newspaper articles.

3. Our Multi-Document Summarization Based Approach for the Q&A System

Our approach for the Q&A System consisted of three procedures: question analysis, summarization of questions from various articles, and answer formation.

3.1. Question Analysis

The Question analysis process is basically divided in two parts. One is the detection of question type, and the other is the extraction of keywords with a numeric score that summarizes documents. We use the Japanese part-of-speech tagger, 'Chasen'[1] in order to break the question sentences into morphemes. Question types are categorized with keywords as follows:

- Interrogative pronoun
  - Nan(-i) (What)
    - modifying suffix
      - Nen (Year)
      - Gatsu (Month)
      - Nichi (Day)
      - Nin (How many people)
      - Kai (How much times)
      - Ken (How many units)
  - Dare (Who)
  - Doko (Where)
    - Kuni (Which country)
    - Kaisha (Which company)
  - Itsu (When)
  - Ikura (How much)
  - Dono, Dore (Which)
    - Kikan (How long)
    - Ryou (The amount)

Figure 1: Japanese Question Taxonomy

[1] http://chasen.aist-nara.ac.jp/

The question taxonomy above shows that Japanese question types are determined by a combination of an interrogative pronoun and a modifying suffix.

Another process is keyword detecting and scoring. We score keywords in each question as follows:

1. Each matching noun morpheme receives 1 point.
2. The proper noun or phrase containing the proper noun receives 3 points.
3. A time related adverb/noun receives 0.5 points.
4. Each verb or adjective morpheme (except some basic elements) receives 1 point.

3.2. Sentence Extraction with Multi-Document Summarization Technique

Next, we extracted sentences related to each question keywords from a two year supply of newspaper articles. The question keyword scores determine these individual sentence scores.

If a sentence contains a keyword, the keyword score is added to the sentence score, then the sentence score is divided by the sum of all the keyword scores in that question. Therefore, a maximum score of a sentence is 1. If a score of any sentence is more than 0.4, the sentence is extracted and stored into the answer file for that question. This is a kind of cut and paste summarization technique (Jing and McKeown, 2000) from a wide source of newspaper articles (McKeown and Radev, 1995). In order to accelerate our system's performance, some multi-document summarization techniques (Mani, 2001) with text segmenting and clustering (Stein et al., 1999) were also needed. When this MDS approach is adopted, the Q&A accuracy performance must be kept in mind. MDS has some information fusion or aggregation processes to avoid overlapping information. If this process was applied wrongly, the correct answer would be removed from summary. We did not implement this process at this stage but implemented a similar process at the answer formation stage.

3.3. Answer Formation from Summary Sentences

Answer Formation is the process of extracting answers from summary sentences using question types. We implemented this step as pattern matching according to question type information with Perl. We use question type information like Nan-Nen Nan-Gatsu (In what year and month did the event happen?), and encode that information in regular expressions like $/(0-9)\{1,2\}gatsu(0-9)\{1,2\}nichi/$ in order to detect answer candidates.

Some question types were needed to extract distance patterns or make answers with a parsing technique. We implemented noun formation functions according to question types with a recursive function about part-of-speech information (concerned with noun morpheme type). The noun phrase formation process was different according to question types and was localized with Perl functions. Some examples are as follows:

1. Who (Dare) Questions
   'Chasen' tagged personal names as 'noun-proper noun-personal name'. When 'Chasen' tagged a personal name correctly, the personal name is extracted based on the noun formation. In addition, an abbreviated name like 'J.F.K.' or some hard to place place noun needs to be extracted with an answer formation process. This type answer was not tagged correctly with the morpheme tagger. Therefore, we need some parsing technique to look before and after the part-of-speech information.
2. When (Itsu) Questions
   'When' questions' difficulties mainly stemmed from unknown details: What year, month, day, or time? We extracted answers from 'when' questions with time-related number extraction and formation. When some time-related suffixes were matched, this pattern was formed following Japanese conventional time-expressing order; year, month, and day. When time information was expressed with 'of' or other modifying terms, there might be gaps between some time expressions. For example, 'In Keicho 5 (1600), the war of Sekigahara started on the 15th September.' The year and the date are separated in the sentence but both are necessary in an answer. If that information together was expressed in one sentence, our system would have no problem extracting the correct answer to form one time expression.
3. Where (Doko) Questions
   'Where' questions also varied in their answers according to the details. To find a specific location of an event such as a war in East Timor in Indonesia, the initial input question might not be able to place 'Daerah Istimewa Aceh' province without wider geographic information. The morpheme tagger tagged a place noun as 'noun-...-place' and a country name noun as 'noun-...-place-country'. In our system, this distinction is judged mainly based on question keyword information. When the question was judged to be concerned with country name, the corresponding function was called.
4. Amount Questions
   In the Japanese language, amount information is characterized with a modifying suffix like 'liter' or 'cubic meter'. Therefore, this suffix information is key in extracting an answer. Number information was tagged correctly as 'noun-number' or 'prefix-auxiliary-number'. Our system formed these elements to make quantity noun phrases.

Extracted answers were scored with their source sentence score and their occurring frequencies. Some answer candidates with same meanings were merged to a single answer with information fusion or aggregation techniques to avoid overlapping answers.

3.4. Detecting Answers for Follow-up Questions

In Task 3, we employed a different approach because follow-up questions often contain pronouns instead of nouns and don't contain specific keywords. To extract an answer in a follow-up question, we use a summary from the first question and the question type pattern in the follow-up question. Some follow-up question examples are shown as follows:

1. (a) What are the titles of Mr. Natsume Soseki's most famous work?
   (b) What was his eldest son's occupation? (his = Mr. Natsume Soseki)
2. (a) When did the 'Aerosmith' make their debut?
   (b) What was their first hit at that time? (at that time = their debut time)
3. (a) What are the three biggest festivals in Japan?
   (b) Where are those festivals held? (those = the three biggest)

4. System User Interface

The Q&A system produced summaries including sentence weights and source article ID numbers. They were tagged in XML-style formats. When the answer formation process was executed, answers were provided with their occurring articles by using summary information. This system is shown in Figure 2.

5. Evaluation

QAC results were evaluated with MMR (Maximal Marginal Relevance) scoring (Mani, 2001) and F-score (or F-measure) (Stein et al., 2000) metrics. Some bugs in our system were removed after the dryrun was finished. The results of our present system are shown as follows.

1. Task 1 (Top five Q&A)
   Task 1 had 50 questions. We scored the top 5 answers as follows: if the best answer was in fact correct, 1 point was added to the score; if second best answer was correct, 0.5 points was added to the score; ...; if the fifth best answer was correct, 0.2 points was added to the score. The total score ranges are shown in Table 1.

Score	Rates
$1 \leq \quad - \quad$	$\frac{13}{50}$
$0.5 \leq \quad - \quad < 1$	$\frac{7}{50}$
$0 < \quad - \quad < 0.5$	$\frac{8}{50}$
0	$\frac{22}{50}$

Table 1: Scoring in Task 1

   Answer scores with over 1 point contained four time-related questions, two questions about organization and personal names, one question about great literary and artistic works, money, people, units, and countries.

2. Task 2 (Answer Set)
   Task 2 had the same questions as Task 1. The goal of Task 2 was to extract the correct answer set. Our system answered this task as the best 10 answers. F-score ($\frac{2 \times Precision \times Recall}{Precision + Recall}$) ranges are shown in Table 2.

F-score	Rates
$0.6 < \quad - \quad \leq 1$	$\frac{2}{50}$
$0.4 < \quad - \quad \leq 0.6$	$\frac{3}{50}$
$0.2 < \quad - \quad \leq 0.4$	$\frac{9}{50}$
$0 < \quad - \quad \leq 0.2$	$\frac{19}{50}$
$\quad - \quad$	$\frac{17}{50}$

Table 2: F-score in Task 2

   Questions with the best two scores were concerned with literary and artistic works and countries. Both questions contained multiple answers.

3. Task 3 (Follow-up Q&A)
   Task 3 had 10 follow-up questions to each of the original questions. Out of the 10 questions, two questions contained correct answers in the top rank: they were a time-related question and a question about debut work. Another three questions contained correct answers in the top five ranks. Another two questions contained correct answers. The remaining three questions did not come up with a correct answer: questions concerning occupations, ranks, and personal names.

6. Some Problematic Issues

In this research, we only used surface information and didn't use deeper semantic information like a thesaurus would provide. Our result set contained erroneous elements, but in Task 2, $\frac{2}{3}$ of the correct answers were found. There are two reasons why correct answers were not found: there was too much erroneous information extracted and the correct answers were not extracted and put in the initial summary.

The source input data of QAC contained a very large (about 230,000) amount of articles. Our system caused some time-consuming problems because our system extracted summaries with common weighing values for every question type. Some questions extracted too many summary and others didn't extract enough summaries. In fact, the assigned threshold 0.4 was very sensitive according to question types. When this threshold was set as '> 0.4' (not equal), some questions contained more accurate answers in the best 10 answer candidates, but other questions' answers were missed. Although our threshold , of course, can be changed easily according to question type, some explicit criteria between threshold values and question types were hard to establish. In addition, when commonly used and polysemous question keywords were detected, many sentences with erroneous elements were extracted.

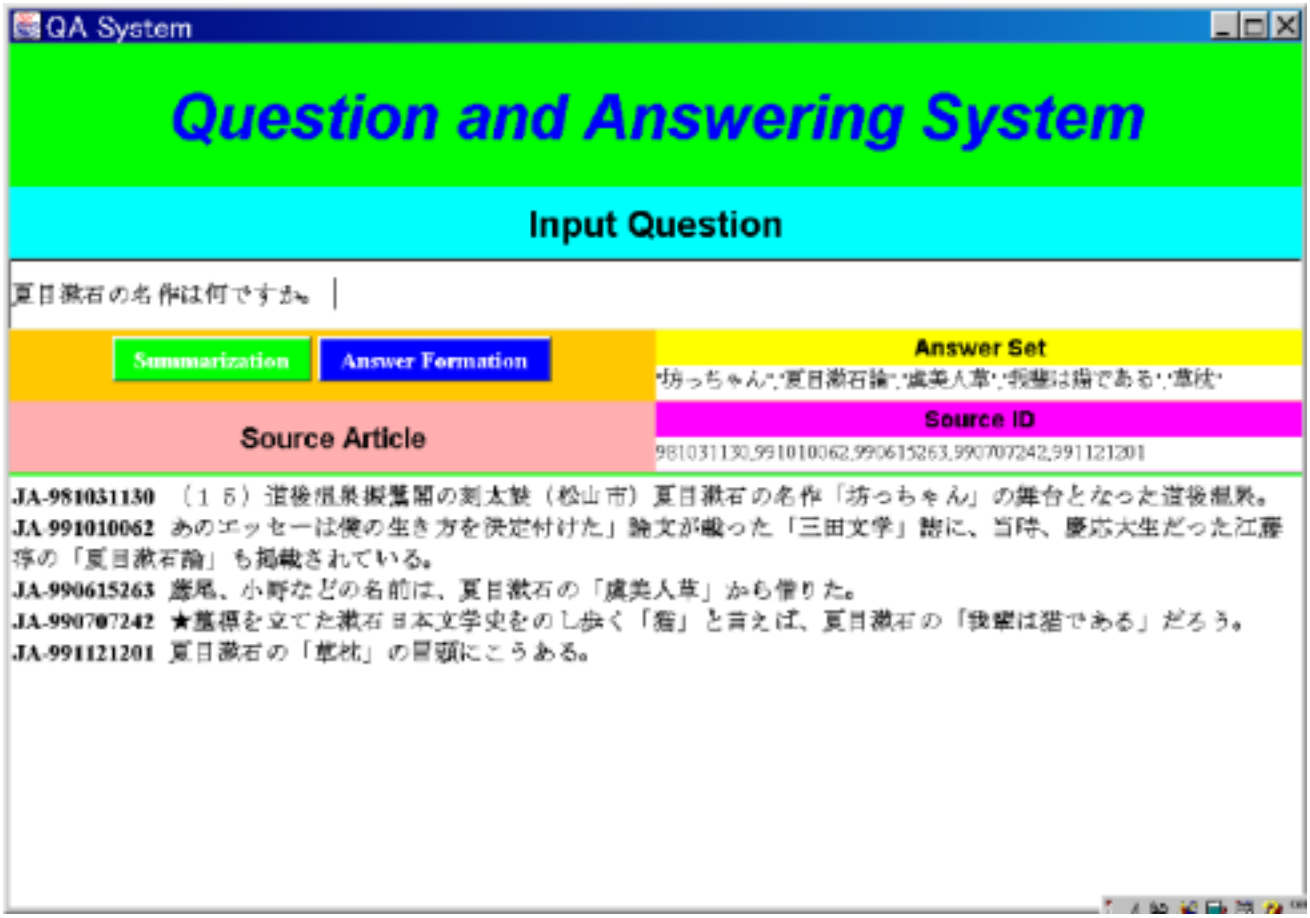

Figure 2: Q&A System

On the other hand, answer quality problems mainly stemmed from the question analysis quality. Questions which extracted too much erroneous information were mainly concerned with unique personal names or too specific place names. Other questions which did not contain correct answers were relatively unique-patterned questions. In order to increase the accuracy, we need to use a more semantic sensitive program.

We explained our improvement strategy for the Japanese Q&A problematic issues. In Japanese, there are two ways to say 'in the second place': "Dai-ni-i" and "ni-i". In the latter, the prefix "Dai" is omitted. We implemented a noun phrase formation to detect an answer with a parsing technique, but the two Japanese examples above came up with two different answers. A technique in detecting same meanings to make a single answer is also needed. This technique is a kind of multi-document summarization technique (Mani, 2001), especially for information fusion from multiple sources.

7. Conclusions and Future Direction

We tested our experimental Q&A System mainly using morpheme type information and the multi-document summarization based technique. Our results contained $\frac{2}{3}$ of the correct answers and each answer was provided with its occurring article ID number. Therefore, our system is useful for checking results with people.

In Japanese, question analysis process is a little more complex than English because question type is determined with the combination of interrogative pronoun and modifying suffix. A parsing and information fusion techniques regarding Japanese morphemes are needed in implementing the answer formation process.

In order to improve our results, some semantic information for the question category or taxonomy of inquiries (Burger et al., 2001) may be needed to reduce the amount of incorrect answers from a large summary source. In addition, if the assigned threshold for summarization is changed according to question type information, better results will follow. In order to determine precise thresholds according to question types, we will try more Q& A tasks and adjust our system.

Abstract

In this paper we would like to present several issues related to our long-term research on question answering in Polish. Experiment-generated corpus of question-answer pairs, as well grammatical resources for developing Q&A systems for Polish language are presented.

1. Introduction

The research reported in this paper is a part of a long-term project aiming at the software platform with emulated linguistic competence to study man-machine interaction (Vetulani, 2000b; Vetulani & Marciniak, 2000). A question answering system constitutes an essential part of this project. The name POLINT stands for successive versions of systems derived from the Polish module to the ORBIS system (Colmerauer, Kittredge). What makes an essential difference with respect to its predecessors is that POLINT may be used as an interface in real-time systems because of substantial efficiency improvement. The recent version[1] of the system enables the user to ask questions concerning an episode of a football match (cf. Appendix 1). Two further systems are now being developed: the ACALA virtual robot controlled by the natural language interface (Vetulani & Marciniak, 2000) and a virtual "interactive glass case" for Archeological Muzeum in Poznan (MUZARP, by Vetulani and Gribko).

Our research, the substantial part of which is presented in this paper, focussed first of all on the following issues among those mentioned in the Q&A Roadmap Paper (Burger et al., 2002):

1) question taxonomies (and formal models),
2) question processing (syntax, semantics, parsing, understanding),
3) real time question answering (efficient processing),
4) interactive Q&A (dialogue structure),
5) user profiling for Q&A.

2. Empirical background: reference corpus for system design and evaluation

The development of POLINT was preceded by empirical studies on question answering in Polish. This preparatory work consisted in collection of a small but highly annotated corpus of information-acquisition-oriented question-answering dialogues. This corpus contains of 582 question-answer pairs collected during 30 sessions with human subjects. The questions were collected at sessions involving two participants: the information seeker and the information provider. The information seeker was supposed to formulate written questions to the information provider about the content of a picture (with regard to an intentionally banal subject: a scene with St. Claus, children, gifts, etc.). The information seekers were given a partial knowledge of the scene: the same picture with several blank areas. This very special setting and a particular mode of communication amounted with a number of observations, which, despite obvious limitations, are of interest especially at the early stage of QA system design. Examples of the observed syntactic phenomena of general interest are:

- short questions (average between 6 and 7 words in a question and between 2 and 3 words in a nominal group),
- rare ellipsis of whole constituents,
- low complexity of questions (small number of polypredicative questions: 35/582),
- rare use of relative clauses in questions,
- practical absence of questions with negated predicate,
- ...

Besides these purely syntactic observations, the corpus permitted preliminary studies on various discourse related phenomena such as: anaphorical links between answers and questions, long distance anaphora in dialogues, focus structure, dialogue structure and internal linking devices (anaphora, ellipsis, common-pattern-links, linking words).

Another practically useful result (used when designing POLINT) was the typology of observed syntactic structures (of course very much biased by the experiment setting, domain, mode etc.). The corpus attests mainly questions which require relatively little inferences. Most of them belong to the following categories (according to Arthur Graesser's taxonomy, cf. Burger et. al., 2002):

- verification,
- disjunctive,
- concept completion,
- feature specification,

[1] An early version of the system was tested as a front-end to the EXPÆRT system to store information retrieved from text documents about arts (Martinek&Vetulani, 1991).

- quantification,
- request/directive.

Within the typology of questions proposed in (Vetulani, 1989) these are mostly *basic questions*, in opposition to *non-basic questions* (cf. *compound questions* discussed in Belnap & Steel (1976)) rare in the kind of question-answering discourse oriented to the acquisition of factual, fine granulated information.

The St. Claus Corpus is supplied with rich annotations (only for questions). What follows is an annotated question-answer pair from this corpus.

Question: Co trzyma Mikolaj w prawej rece? /What is St. Claus holding in his right hand?
(1) $X_{subst,a}$;$V_{f,p(3)}$;N_n; $_{<w>}N_l$
(2) (?)[Arg_1: Mikolaj; Predicate: trzyma; Arg_2: ?; Arg_3: w prawej rece]
(3) [Arg_1: $_3$(N_n); Predicate: $_2$($V_{f,p(3)}$); Arg_2: $_1$($X_{subst,a}$);Arg_3: $_4$($_{<w>}N_1$)]
(4) Predicate=TRZYMAC-CZYMS(Arg_1,Arg_2,Arg_3)
Answer: Nic/Nothing

The structure (1) shows the surface linear ordering of different parameterised categories (X - interrogative phrase, N_g - noun phrase in genitive etc.); it is *called formal linear model* of the sentence. The lines (2) and (4) form the so called *predicate-argument structure* of the sentence (the line (4) describes the type of semantic requirements of the predicate). Somehow more abstract representation of the sentence is formed by (3) together with (4) (abstraction is made of surface forms, but relative position of the surface string (beginning of) is noted using the left-low numerical index, cf. for example the value 3 in $_3(N_n)$). Theoretical models for corpus annotation were introduced as an application of the unification-oriented concept of question-answer relationship (Vetulani, 1989) being inferred from the classical works by Ajdukiewicz (1965), Belnap and Steel (1976) and others.
What has appeared to be particularly useful are formal models (1) because they may be used as a skeleton of a formal grammar. Although the initial corpus is relatively small (due to time consuming and complex hand annotation procedure) it may be extended in a coherent way at any moment because the documentation of corpus generating experiment is very detailed and the collection procedure is simple (cf. Appendix 2). The corpus (now called St. Claus Corpus) and its methodology has been thoroughly described in paper publications (Vetulani,1989, 1990) and has been recently included as a basic resource in the data part of the Polish national project aiming to create NL evaluation tools for Polish (as announced at LREC1998 by Bien (1998)). Now, the St. Claus Corpus[2] is being prepared for free distribution for non-commercial purposes and will soon be available through the Internet. (This is a good reason for its presentation at the present QA Workshop.)

[2] Its substantial enlargement is being planned for the nearest future.

An important part of the above mentioned MUZARP project is based on empirical studies as well. In this project (now under development) the human user will be allowed to ask questions to virtual individuals represented in the "virtual interactive showcase". Questions will be about the "virtual showcase" world. In order to define the profile of a hypothetical user we have begun corpus collection where the (potential) human users were asked to imagine questions they *would like* to ask to the virtual scene participants *if* they were apt to do so. (The scene represents ancient country people at work.). The corpus collection is in progress and no systematic processing has started yet. It is already clear, however, that the MUZARP corpus will be substantially different from the StClaus Corpus (which is not surprising at all).

3. Generic grammatical resources of POLINT

The strength of any NL parsing (understanding, processing, etc.) system is measured by the power of its grammar and dictionary. These two modules contain the essential part of linguistic information about the language being processed but the respective role of each of them varies from case to case. In the POLINT system grammatical information is spread between rules and dictionary items, forming a lexicon-grammar. This solution will enable application of linguistically motivated heuristics to limit (at linear cost) the search during the rules-driven parsing.

3.1. Grammar rules

The POLINT grammar is composed of DCG-like rules. (It is implemented in PROLOG, but the parsing technique is much more sophisticated then the standard parsing algorithm inherent to PROLOG). That means that they have context free shape and allow arbitrary terms, including variables, as parameters. As POLINT was conceived as NL understanding system, the main goal of syntactic rules is to result in sentence segmentation useful for further (or parallel) semantic evaluation. The chosen theoretical model is the predicate-argument model, as described in (Vetulani, 1989). As a linguistic grammatical background we use the traditional phrasal approach, with some simplifications when compared to the traditional syntactic categorisations. For example we have removed some classical, very common but for us superfluous categories, as e.g. *subject phrase* or *direct/ indirect complement.* Instead, in both cases, we are using the category *noun phrase* to denote the sentence phrase which function will be specified by values of morpho-syntactic parameters (as, e.g., case: genitive). In principle, we have assumed that a sentence is composed of one or more noun phrases (arguments) and just one verbal phrase (predicate) in an order which is highly free in Polish. In practice, because of over-generation of rules, the initial (generic DCG-like) grammar has been transformed into more effective one, based on a "new" category of *sentence_segment* (*sentence_segment* is composed *of noun_phrase/verbal_phrase + sentence_segment*). This solution involving recursion will permit to control

effectively parsing by involving special control parameters (cf. Vetulani 1997) which function as heuristics calculated at the pre-analysis stage. (A "normal" grammar, i.e. grammar not involving rules engaging the category *sentence_segment* may easily be obtained from the POLINT grammar.)

At present, the POLINT system is based on ca 150 grammar rules encoded in PROLOG (ca. 60KB of the source ASCII code). These rules may be grouped as follows:

? sentence level rules: ca 35
? argument level rules: ca 45
? predicate level rules: ca 20
? other and auxiliary rules: rest

What follows is an example of a relatively simple rule encoded in PROLOG. These rules recognise the kernel of the verb group, based on a non-transitive finite verb, possibly reflexive or/and negated and optionally complemented by an adverb.

```
gv0(A,gv0_1(M),[[Ro,Li,Os,Cz],[R,L,mian,T],Rel],
[czas_0,0],[Tz,Neg,[Wcz,[Ro,Li,Os,Cz]]],
[[W,N]|X0],X4) :-
 neg_pred(A,Neg,[[W,N]|X0],X1),
 slo9(0,czas_0,[[Ro,Li,Os,Cz],Rel0,[R,L,mian,T]],
 X1,X2),
 eqw(X1,[[Wcz,_]|_]),eqw(Ro,R),eqw(Li,L),
 pron_refl_1(A,Rel0,X2,X3),
 eqw(X3,[[_,K]|_]),
 case([adv_poss(1,K) ->
gr_adv(A,1,M,S,X3,X4),
adv_poss(2,K) ->
gr_adv(A,2,M,S,X3,X4)|
gr_adv(A,3,M,S,X3,X4)]),
 sem(A,[gv_0(Neg),Tz,Rel0,S,Rel]).
```

3.2. Dictionary

The POLINT grammar requires a dictionary of the kind of lexicon-grammar, i.e. a lexicon where predicative words are supplied with syntactic information. At the pre-analysis stage the sentence is being scanned word by word for all predicative words, the syntactic requirements are read out from the dictionary and compared to properties of surrounding words. This observation usually permits formulation of a plausible hypothesis about syntax of the considered sentence in form of an expected configuration of sentence arguments. Such configurations are used as input parameter to the parsing module in order to make parsing more deterministic. This method proved particularly efficient while analysing sentences of medium size and medium complexity. The POLINT grammar has been tested with a dictionary containing ca 3000 dictionary entries (one word form per entry). Now, work is in progress to generate automatically (or semi-automatically) the system's dictionaries. The following resources are being tested as possible support of automatic dictionary generation: the morphological analyser LEM by Vetulani and Obrebski, cf. (Hajnicz, Kupsc, 2001), the resources of POLEX, GRAMLEX and CEGLEX projects (reported at LREC 2000 (Vetulani, 2000a)).

At present, the grammar is being translated into our new formalism FROG based on DCG-like rules well suited for free order languages with frequent discontinuity phenomena (Vetulani, 2002). This is a preparative step for further enhancement of the system's grammatical coverage to fully include discontinuous constructions. In this form, free distribution for non-commercial purposes is planned.

4. Coverage

In order to characterise the grammatical (and functional) coverage of the system we have listed a number of problems covered by POLINT:

- confirmation questions ("Czy" + affirmative sentence?)
- questions about arguments ("Kto/Who...?", "Co/What...?", "Z kim/With whom...?", etc.)
- questions concerning place ("Gdzie znajduje sie...?" / "Where is...?")
- questions concerning time ("Kiedy...?" / "When...?")
- questions concerning existence (Kogo nie ma...?/Who is absent...?)
- questions concerning name ("Jak nazywa sie...?" / "What is the name of...?")
- concerning type, position in a hierarchy ("Kim jest...?" / "Who is...?")
- about complement ("Czyim bratem jest...?" / "Whose brother is ....?")

At the predicate-argument level the word order is arbitrary (the system ignores differences in the degree of pragmatic markedness depending on the order of arguments).

The system recognises correctly a large class of nominal constructions. The following are the main types of noun phrases the system understands: proper names, complex proper names, complex noun group, common names, pronouns, genitive (possessive-like) constructions, complement nominal constructions. The nominal groups may be also completed with relative clauses (with possible iteration or embedding), adjectives etc. The predicates may take one, two or tree referential or locative arguments (Vetulani 1989). The predicate group may be, e.g.: personal forms of verbs, constructions with the auxiliary "byc" ("to be"), construction with noun in the instrumental case or with an adjectival group, constructions based on a supporting verb, construction with negation. The POLINT grammar was tested against the StClaus Corpus with satisfactory result (80% syntactic coverage for non-polypredicative, non-elliptical questions).

5. Efficiency

Contrarily to the most of NL systems written in PROLOG, the parser of POLINT is a real time system. This effect is difficult to reach for languages with flexible word order, like Polish, because of intensive and costly backtracking if grammar rules observe traditional grammar encoding procedures (various rules for various surface orderings, each rule reflecting the surface ordering of words). The main idea applied in the POLINT system to improve efficiency was to precede application of the grammar rules by a pre-analysis module. The pre-analysis was based on the concept of "lexical witness" for syntactic phenomena and on systematic usage made of lexicon

grammar dictionary. A lexical witness (as, e.g., relative pronoun for relative clause) may help to select appropriate grammar rule in a deterministic way. Exploration of syntactic or/and semantic requirements may help to limit the grammatical search space up to making the search deterministic in many cases. This additional information may be obtained from the dictionary when reading-in the sentence (in linear time).

6. Acknowledgements

The Author wishes to thank Alain Colmerauer for having hosted him as a young research fellow at GIA in Marseille, many years ago. This exercise permitted him to discover the charm of the Computer Question Answering Challenge.

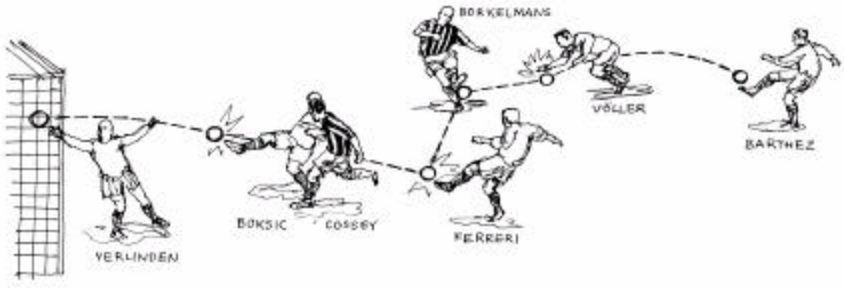
Appendices

Appendix 1. Example of soccer game scene askable in POLINT

Information represented picturally in Figure 1 is encoded in the form of PROLOG predicates and accessible through POLINT.



User: - Jak nazywa sie pilkarz, który strzelil bramke? /What is the name of the player who scored?/
System: - Boksic.

Figure 1. Episode represented in the data-base[3] and a question-answer exchange.

Appendix 2. Experiment design

We are presenting here a detailed description of the St. Claus experiment setting.

1. Participants: A and B.

2. The scene (S) is represented by a complete picture (P) and an incomplete picture (P') (see below).

3. The participant A has the picture P'.

4. The participant B has the picture P.

5. Goal for A: to complete his knowledge about S.

6. Scenario for A: to ask questions to B (in writing).

7. Scenario for B: to answer the question (in writing).

8. Both A and B control (see) all previous questions and answers.

9. Restrictions:

- a single answer follows a single question (but no restrictions on the form of questions and answers),
- A and B are not permitted any form of communication (oral, gesture),
- dialogues are limited to 20 question-answer cycles (which corresponds to 30 min.-1h. sessions),
- a human supervisor is present during the session.

10. It is implicitly suggested to the participants that the experiment is a part of psychological research.

11. Instructions are read by the supervisor at the beginning of the dialogue session and no other explanations are allowed; the instructions are, however, available to participants (in writing) during the session.

Abstract

While in many branches of linguistics monolingual reference corpora are widely used, in translation research as well as translation practice the concept of a translation reference corpus has not yet assumed a similarly important role. In this paper, we present the design of a German-English and French-English translation corpus and explore its use as a reference corpus for translatologists as well as translators. First, we introduce the basic computational techniques needed to build such a translation reference corpus, covering the preparation of the corpus as well as its linguistic annotation. Second, discussing some typical translation problems that occur in English-German and English-French translations, we show how the corpus can be queried making use of the linguistic annotation.

1. Introduction

In the last decade or so natural language corpora have assumed an increasingly important role in descriptive linguistics. Not only are they employed to inform lexicologists, lexicographers and grammarians in the construction of dictionaries and grammars, but also they gain importance as works of reference for linguists more generally. There are many corpora—especially for English (e.g., BNC[1], ICE[2], Bank of English[3])—that have been made accessible via the Internet with special user interfaces which allow one to query a corpus by means of KWIC concordances.

Also in translation research, corpora have started to become acknowledged as an important source of information in the investigation of theoretical issues in translatology, such as the question about the status of translations as a special kind of text with specific, possibly universal, properties. Here, the typical corpus is a parallel corpus consisting of two subcorpora, one containing source language (SL) original texts and the other containing translations of those texts into a target language (TL), where SL and TL texts are aligned (e.g., the Chemnitz corpora[4]). Some researchers advocate a three-way corpus design, where original texts in the TL are included as well (e.g., the Oslo corpora[5] as well as the work carried out at Saarbrücken (Teich & Hansen, 2001; Teich, 2001)), the latter being called a comparable corpus (cf. Baker, 1995; 1996). Also in translation practice, parallel corpora are increasingly being used in the form of translation memories. The compilation of such translation memories is supported by translation corpus workbenches. Thus, parallel corpora assume an increasingly important role both in theory and practice.

In this paper we explore the role of translation corpora as works of reference for translatologists as well as translators. It seems to us that there is a lacking interaction between the developers of corpus tools and researchers and practitioners in the field of translation. The goal of the present paper is to initiate such an exchange. We proceed in the following way. First, we discuss the basic computational techniques needed to make a corpus usable as a translation reference corpus (Section 2). We show how a corpus needs to be prepared (alignment, encoding) and how it should be enriched with linguistic information, so that it becomes possible to pose queries to it that are interesting and relevant from a translation point of view. Second, we show how a translation corpus can be queried with a parallel concordancing tool. We illustrate the use of an English-German-French translation reference corpus for solving some typical translation problems that occur in translating from English into German and from English into French (Section 3). Section 4 concludes the paper with a summary and some issues for future work.

2. Computational techniques

Corpus preparation. For the creation of a translation reference corpus, a parallel corpus needs to be aligned. For this purpose, an alignment program must be applied. One such program is Déjà Vu (Atril, 2000). Figure 1 shows a German SL and an English TL text aligned with this tool.

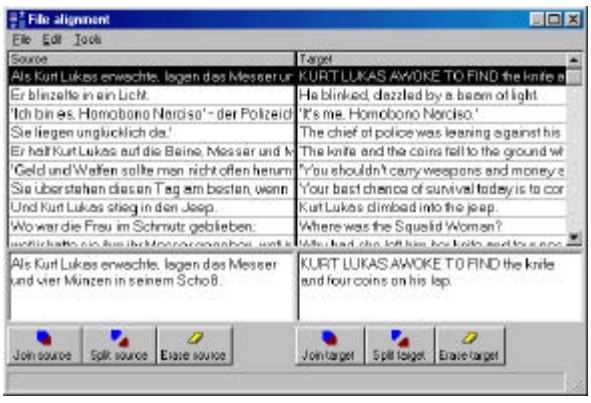

Figure 1: Multilingual corpus alignment

Déjà Vu aligns a text and its translation on sentence basis, storing the aligned texts in one file or in two separate files depending on the requirements of the query tool used in later stages of analysis. Files can be exported to translation workbenches and to Microsoft Excel and Access. Figure 2 shows a Déjà Vu output in a TSV (tab separated vector) format.

"Als Kurt Lukas erwachte, lagen das Messer und vier Münzen in seinem Schoß." "Kurt Lukas awoke to find the knife and four coins on his lap."
"Er blinzelte in ein Licht." "He blinked, dazzled by a beam of light."
"'Ich bin es, Homobono Narciso' - der Polizeichef stand an seinen Jeep gelehnt -, 'fast hätte ich Sie überfahren. Sie liegen unglücklich da.'" "'It's me, Homobono Narciso.' The chief of police was leaning against his jeep."
"Er half Kurt Lukas auf die Beine, Messer und Münzen fielen herunter, Narciso hob sie auf." "The knife and the coins fell to the ground when he helped Kurt Lukas up."

Figure 2: Déjà Vu alignment format

Also, we encode each text of the corpus in terms of a header that provides meta-information such as title, author, publication, translator, etc as well as text type/register information (domain, tenor and mode of discourse). This is important to enable corpus queries according to register or other independent variables.

Text files are encoded in XML using a modified version of the Text Encoding Initiative (TEI) standard[6] (a short header including meta-information is illustrated in Figure 3) and employing a standard XML editor (here: XML Spy[7]). The text body is annotated for headings, sentences, paragraphs, etc.

Figure 3: XML corpus encoding

Corpus annotation. A translation reference corpus should at least be annotated with part-of-speech and syntactic information. Part-of-speech tagging is carried out fully automatically, either using a rule-based or a statistical approach, where recently, statistical approaches prevail. For multilingual applications, it is important that the tagger can be used for more than one language. Analyzing a corpus in terms of syntactic structure is still a challenging task and cannot be carried out automatically with satisfactory accuracy yet. Recently researchers in computational linguistics who are interested in the accurate parsing of large amounts of text promote what has been called interactive parsing, where a parser carries out a shallow parse and a human may correct or add information to the proposed parse. For example, the parser assigns syntactic labels to the elements of a clause, but does not resolve syntactic ambiguities of particular kinds, such as PP-attachment, leaving this to the human to deal with.

One system which combines part-of-speech tagging and shallow parsing is the ANNOTATE system (Plaehn & Brants, 2000) under development in the TIGER[8] and NEGRA[9] projects. ANNOTATE uses the TnT tagger (Brants, 2000) that can be applied multilingually and has been trained on a number of languages, including English and German. The tag set used for English is the Susanne tag set (Sampson, 1995); the one for German is based on the Stuttgart-Tübingen tag set (Hinrichs et al., 1995). ANNOTATE carries out an analysis of phrase categories as well as grammatical functions using a program based on Cascaded Markov Models (CMM (Brants 1999a, 1999b)). During the interactive annotation with ANNOTATE (see Figure 4), terminal nodes are labeled for parts-of-speech and morphology, non-terminal nodes are labeled for phrase categories and edges are labeled for grammatical functions.

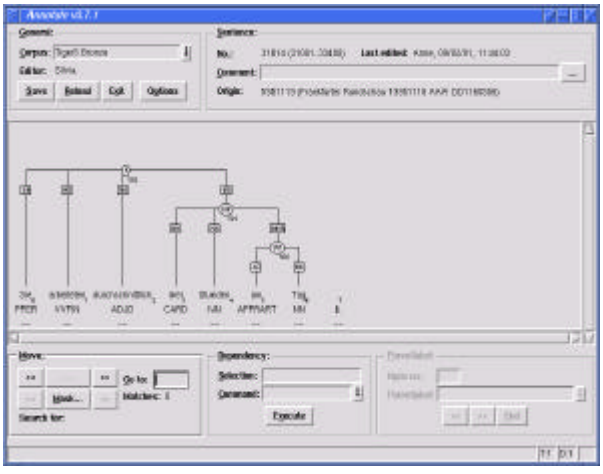

Figure 4: Interactive annotation with ANNOTATE

The tagged and parsed corpus data are stored in the form of a relational database, but can be exported to text format.

Corpus querying. For parallel concordancing, query tools such as the IMS Corpus Workbench (Christ, 1994)

[6] http://www.tei-c.org/index.html
[7] http://www.xml-spy.com
[8] http://www.ims.uni-stuttgart.de/projekte/TIGER/
[9] http://www.coli.uni-sb.de/sfb378/projects/NEGRA-en.html

can be employed. Its query processor (CQP) allows queries for words and/or annotation tags on the basis of regular expressions. For an example of a query executed on a parallel English-German corpus see Figure 5.

```
# Query: DE_EN; passives-de = [pos="VB.*"] [] {0,1} [pos="VVN.*"];
#------------------------------------------------------------------------------
   729: newspaper . A ferry had <been sunk> just off the island . ' I
  -->de_de: In den Gewässern vor der Insel war eine Fähre gesunken .
   850: country ' s future will <be decided> today . Yours too , perha
  -->de_de: Zukunft des Landes entscheidet sich heute .
   927: nced , because shots had <been fired> at a remote polling stati
  -->de_de: Der Schriftsteller und er müßten aufbrechen , in einem
```

Figure 5: Sample query with CQP

3. Solving translation problems with a translation reference corpus

With a corpus annotated in the way described in the preceding section, we now have available a translation resource that is searchable in a meaningful way. While with a raw text corpus we can only formulate string searches, we can now make use of the annotations in querying the corpus. In the following, we discuss some examples of translation problems between English, German and French. The examples are taken from two genres, narrative and factual writing. For querying the corpora selected, we use CQP (cf. Section 2).

English present and past perfect. While both English and German have present and past perfect tenses, their usage conditions differ cross-linguistically and it is sometimes hard to tell whether a one-to-one translation is the appropriate choice. The French tense system also has present and past perfect, but there are other options as well. Figure 6 shows two parallel concordances for English present and past perfect in narrative texts.

```
# Query: DE_EN; [pos="VH.*"] [pos="RR.*"] {0,1} [pos="VVN"];
#------------------------------------------------------------------------------
 509: night , he said . Adaza <had run> them off and was selling
-->de_de: Der Fotograf Adaza habe sie angefertigt und verkaufe sie für
 1120: igure and the blood that <had discoloured> a whole patch of grass
-->de_de: Die Fahrt endete vor einer Zwergschule , in der das Wahllokal
war , vor einer Blutlache , die ein ganzes Rasenstück färbte , vor einer
 2779: footsteps . Their guest <had appeared> on the terrace . Kurt Luk
-->de_de: Der Gast hatte auf die Terrasse gefunden .
 2953: ' Very few of our guests <have ever found> their way to this
-->de_de: ' Nur wenige unserer Gäste haben bisher auf diese Terrasse
gefunden

# Query: FR_EN; [pos="VH.*"] [pos="RR.*"] {0,1} [pos="VVN"];
#------------------------------------------------------------------------------
 1239: ver ventured there ; she <had even built> a low wall with her own
-->fr_fr: l ' épouse du pasteur avait même construit de ses mains un
 1395: sk , until the last rose <had dropped> into his open handkerchie
-->fr_fr: Il continua sa besogne , jusqu ' à ce que la dernière tête de rose
fût tombée dans son mouchoir ouvert .
 1478: , ' Do you realize what <has happened> to you ? When you
-->fr_fr: - Te rends-tu compte de ce qui vient de se produire en toi ?
 1499: ted Sheikh , and now you <have turned> into a thief ! I have
-->fr_fr: En arrivant ici ce matin , tu étais un cheikh respecté , et
maintenant tu es devenu un voleur !
```

Figure 6: Parallel concordances for English perfect

What can be seen here is that in translations into German, the translational choice is in fact often one-to-one, but also, past tense or present subjunctive is used. In the French parallel texts, we find direct translations, but also *passé anterieur* and "venir de".

English reduced relative clauses. Reduced relative clauses are a typical feature of English and French, but not so much of German. We can thus expect translational problems from English into German. A concordance query to a parallel corpus shows the translational options available (cf. Figure 7).

```
# Query: DE_EN; [pos="N.*"] [pos="VVN"];
#------------------------------------------------------------------------------
 197: g away under tin roofs . <Carcasses suspended> from chains
-->de_de: An Ketten hängend , bluteten zuckende Rinder aus . Schweine
 2180: ed behind on his own . A <crucifix reposed> on his lap in place of
-->de_de: An Stelle des Buchs lag ein Kreuz in seinem Schoß .
 2833: And the mountains wore <cloud-caps frayed> at the edges by
-->de_de: Und die Berge trugen Wolkenhüte , die zur Sonne hin
ausfransten .

# Query: FR_EN; [pos="N.*"] [pos="VVN"];
#------------------------------------------------------------------------------
1864: of him . This time , the <instrument provided> by Providence was
-->fr_fr: L ' instrument de la Providence fut cette fois un passe-temps
 2812: the presence of all the <people gathered> on the Blata , and in his
-->fr_fr: ' Le cheikh Francis et le patriarche se donnèrent l ' accolade
devant le peuple réuni sur la Blata , et dans son sermon , sayyedna parla
```

Figure 7: Parallel concordances for English reduced relative clauses

We see that English reduced relative clauses are indeed translated into French one-to-one (or zero-equivalent), whereas in German translations we find the present participle or full relative clauses (or zero-equivalent).

English cleft sentences. Cleft (and pseudo-cleft) constructions are a typical feature of the English grammatical system (cf. Erdmann, 1990). While they do exist in German as well, German has other options of realizing information distribution patterns, e.g., by word order variation. Because here, the search space for a translational choice is rather wide, finding a translational equivalent for an English cleft construction is therefore a notorious problem in translating from English into German. Again, a parallel concordance can provide help (cf. Figure 8).

```
# Query: DE_EN; [word="it|It"] [pos="VB.*"] [pos!="JJ.*"] {1,2}
[pos="DDQ.*|PNQ.*|CST"];
#------------------------------------------------------------------------------
 8620: simply as N , because <it is N that> makes this one-way function
-->de_de: Es ist dieses N, das die Einwegfunktion umkehrbar macht,
 8967: cells growing . <It is these properties that> make them attractive
-->de_de: Gerade diese Eigenschaften lassen sie als Wirkstoffe gegen
Krebs vielversprechend erscheinen.
 9112: is in control . <It is they alone that> persist from one generation to
-->de_de: Nur die Gene bleiben in der Generationenabfolge erhalten.
 9523: History records that <it was Galileo who> was foremost in
-->de_de: Die Geschichte belegt, daß vor allem Galilei die Zeit als eine
fundamentale Größe im gesetzesgleichen Wirken des Kosmos etablierte.
```

Figure 8: Parallel concordance for English clefts

The concordance shows that for compensation a focus particle or adverb (e.g., `gerade´) can be used to signal the syntactic focus.

4. Summary and conclusions

In this paper, we have suggested that translation corpora can assume the role of works of reference for translators and translatologists. In order for translation corpora to serve this purpose, they need to be enriched with linguistic information (Section 2). We have shown that some minimal linguistic annotation (part-of-speech, shallow phrase structure) can already make a translation corpus a valuable resource for dealing with some typical translation problems (Section 3).

While parallel concordancing tools operating on the basis of syntactic annotations already offer useful information, there are a number of further developments that can increase the value of a translation corpus. First, in corpus searches, it may be useful to be able to express constraints on the target language expression as well. Only few parallel concordance programs allow for this. Second, it could be very useful to be able to refer to a comparable TL corpus as well for a comparison of the translations with original TL texts. Third, for dealing with more complex kinds of translation problems, a translation corpus should be annotated with more abstract kinds of linguistic information, e.g., semantic and discourse information. This requires more comprehensive annotation methods and more sophisticated query facilities – both of which are current research issues in computational linguistics (cf. Teich et al., 2001).

Finally, from the perspective of the developers of corpus tools, translation corpora are an invaluable source for testing the applicability of such tools in multilingual contexts.

Comparable Corpora in Translation Research: Overview of Recent Analyses Using the Translational English Corpus

Maeve Olohan

Centre for Translation and Intercultural Studies
UMIST
PO Box 88
Manchester
M60 1QD
maeve.olohan@umist.ac.uk

Abstract

This paper discusses the use of a comparable corpus in translation research, where a comparable corpus comprises, on the one hand, a corpus of translations and on the other hand a corpus of non-translated texts, both corpora being similar in composition, size and other attributes. The Translational English Corpus, housed at the Centre for Translation and Intercultural Studies in Manchester, is presented as an example of a comparable corpus used in researching translation. The rationale for using a corpus of this kind to research translation is addressed. Results of a number of empirical analyses are then summarised, and the potential development and future exploitation of this corpus resource are outlined.

1. Corpora and Translation Studies

According to Michael Stubbs (2001: 151), corpus linguistics is concerned with "what frequently and typically occurs", as opposed to isolated, unique instances of language: "Corpus linguistics […] investigates relations between frequency and typicality, and instance and norm. It aims at a theory of the typical, on the grounds that this has to be the basis of interpreting what is attested but unusual". The corpus-based approach to studying translation has rapidly gained in popularity over the past eight to ten years, with a wealth of data now emerging from studies using parallel corpora, multilingual corpora and comparable corpora. In addition, corpora, whether of the ad-hoc or the reference kind, are proving a useful tool in the translator training classroom. Furthermore, most specialised translators would now be lost without their translation memory system, i.e. essentially an aligned parallel corpus of source texts and their translations.

This paper focuses on the first of these applications of corpora, namely corpora in translation research. The special issue of *Meta* on this topic published in 1998 is useful for an overview of work in this area, as is Chapter 3 of Kenny, 2001). Olohan (forthcoming b) highlights some of the strengths and limitations of corpus-based translation studies, based primarily on views put forward by Maria Tymoczko (1998) and Ian Mason (2001). This paper therefore does not present an overview of the literature nor does it address the criticisms levelled at corpus-based translation studies. Instead it assumes an understanding of corpus-based translation studies as the application of corpus analysis techniques, both quantitative and qualitative, to the study of aspects of the product and process of translation. Built into this is the recognition that there are differing opinions as to what aspects of translation we can apply these techniques to, and that the methodology requires refinement through application, discussion of findings and critical assessment. This process is now being undertaken by an ever-growing number of scholars in translation studies and it will ultimately lead to a better understanding of the scope, significance, usefulness and appropriateness (or not) of corpora to study translation processes and products.

2. Translation as Process and Product

The empirical study of the translation process emerged almost twenty years ago in translation studies, following on the heels of developments in second language research. It has since involved the identification, description and analysis of what happens during translation, i.e. of the mental steps taken by translators between, and including, reception of the source text and production of the target text. Introspection (in particular the think-aloud method) has been the principal methodological tool used in investigations of the translation process, and the introspective studies carried out to date have been largely data-based and descriptive, often focusing on specific aspects of the translation process (e.g. use of reference material, decision-making criteria). While a number of researchers have carried out descriptive empirical research in this area using the think-aloud method, there are methodological difficulties with research of this nature and, as a result, these attempts to investigate the cognitive processes at work during translation have met with scepticism from some quarters. Criticism has focused in particular on the methodology for data elicitation and collection, including its inability to provide access to thought processes which are subconscious or automated, but also on issues of scale and object of investigation.

While translation process researchers have readily acknowledged the potential shortcomings of this data elicitation method, it has been welcomed as a means of gaining some insight into something which is otherwise not accessible to the researcher. However, an alternative approach to translation process research is suggested by Bell (1991), who proposes that a model can and should be developed through a combination of induction (i.e. inferring processes from the product) and deduction (i.e. using introspective data such as diaries) (ibid.: 29). He suggests describing "translation competence in terms of generalizations based on inferences drawn from the

observation of translator performance" (ibid.: 39). He proposes to observe translator performance by analysing the translation product: "by finding features in the data of the product which suggest the existence of particular elements and systematic relations in the process" (ibid.). This approach lends support for the suggestion that the compilation and use of corpora of translations would allow us to analyse features of translation products which can provide evidence of translation processes, both conscious and subconscious, particularly if we can investigate "relations between frequency and typicality, and instance and norm", as advocated by Stubbs (2001: 151).

3. TEC – Translational English Corpus

TEC (Translational English Corpus) is a corpus of translated English held at the Centre for Translation Studies in Manchester. It consists of contemporary written translations into English of texts from a range of source languages and it was designed specifically for the purpose of studying translated texts. There are currently just under 7 million words in the corpus, made up of full running texts falling into four text types – fiction, biography, newspaper articles and in-flight magazines – with fiction representing more than 80% of the total. The translations are by native speakers of English, both male and female, and mostly date from 1983 onwards. In addition to the texts themselves, information is held on the translator and translation process, compiled via questionnaires to translators and publishers, and stored in header files.

One of the fundamental concepts in corpus-based translation studies has been the notion of comparable corpus, defined by Mona Baker (1995: 234) as "two separate collections of texts in the same language: one corpus consists of original texts in the language in question and the other consists of translations in that language from a given source language or languages…both corpora should cover a similar domain, variety of language and time span, and be of comparable length". Baker's initial groundbreaking work posited a number of features of translation which could be investigated using comparable corpora (Baker, 1996), for example, that translations tend to be more explicit on a number of levels than original texts, and that they simplify and normalise or standardise in a number of ways.

Much of the empirical analyses carried out thus far have focused on the literary component of TEC, namely fiction only, or fiction and biography. Thus, the corpus of original English put together for use as a comparable corpus is a set of texts selected from the imaginative writing section of the British National Corpus (BNC). It has been constructed specifically to match TEC in terms of both composition and date of publication (from 1981 onwards). As in the case of TEC, the BNC texts are produced by both male and female authors, all native speakers of English. Unlike TEC, however, some of the texts in the BNC subcorpus are extracts – albeit as long as 40,000 words. This was not deemed a significant difference in the current studies as they investigate intrasentential patterns. The Translational English Corpus is being added to all the time, which means that successive studies present data from TEC at different stages in its growth and the composition of the BNC subcorpus is modified accordingly.

Given that TEC and the BNC subcorpus are comparable in terms of parameters such as size and composition, features of the language of translation identified in the corpus of translation may thus be compared with features of non-translated language as found in the BNC subcorpus. Much of the work with TEC carried out to date has focused on syntactic or lexical features of translated and original texts which may provide evidence of the processes of explicitation, simplification or normalisation mentioned previously. It is possible to catch glimpses of these processes in think-aloud protocols where the translators are conscious of them and are employing them as part of controlled cognitive processes. However, corpus data may provide evidence which may constitute the result of such processes operating on a more subconscious level too.

4. Examples of Comparable Corpus Analyses

It is beyond the scope of this paper to present in detail the studies which has been carried out thus far using TEC and a BNC subcorpus. However, the results of some recent studies are summarised here, followed by an outline of some future directions for translation research using comparable corpora.

4.1. Optional Reporting *that*

The first large-scale empirical study using TEC and the BNC subcorpus indicated a substantially heavier use of the reporting *that* with verbs SAY and TELL in constructions such as examples [1] to [4] in TEC than in the BNC subcorpus, and it was suggested that this may be evidence for a tendency towards explicitation in translated English (Olohan and Baker, 2000).

[1] *He **says that** the ship is now forty-eight hours overdue and he wants explanations* (BNC)

[2] *He **says** the whole army is unsettled because it's known that Famagusta will never give up while it expects a relieving ship to arrive* (BNC)

[3] *I **told** him **that** I didn't know who it was he wanted to speak to, but he was quite insistent that he had seen you come in* (TEC)

[4] *I **told** him I thought it was a stupid thing for him to do* (BNC)

Explicitation has long been considered a feature of translation and has been investigated by a number of scholars (e.g. Vanderauwera, 1985, Blum-Kulka, 1986) who have identified different means or techniques by which translators make information explicit, e.g. using supplementary explanatory phrases, resolving source text ambiguities, making greater use of repetitions and other cohesive devices. In general, explicitation has referred to the spelling out in the target text of information which is only implicit in a source text. In these corpus-based studies, however, we are interested in the making explicit in a translation of information which is less likely to be made explicit in a non-translated text of the same language.

Scott Burnett (1999) examined the behaviour of some forms of other verbs of this type, and Olohan (2001) looked

at PROMISE, which can also take an optional *that*. The same pattern of heavier use of *that* in TEC compared with BNC was also found in these smaller-scale studies.

4.2. Other Optional Syntactic Features

Olohan (2001 and forthcoming a) presents a broad overview of some other optional syntactic features in English and their occurrence in TEC and the BNC. Since the focus of the research was subconscious processes of explicitation and their realisation in linguistic forms in translated texts, optional syntactic features were pinpointed, based on the hypothesis that, if explicitation is genuinely an inherent feature of translation, translated text might manifest a higher frequency of the use of optional syntactic elements than written works in the same language, i.e. translations may render grammatical relations more explicit more often – and perhaps in linguistic environments where there is no obvious justification for doing so – than authors in English.

Working with untagged corpora only, the analysis focused predominantly on frequency of occurrence of optional features and less so on the relationship between occurrence and omission. It can thus be regarded as a first step only. However, initial findings certainly encourage more detailed examination, suggesting for example that the use of the relative pronoun *which* is twice as frequent in TEC than in the BNC subcorpus. Similarly, a study of *who* (in the following constructions: *who is, who's, who've, who have, who'd, who did, who had* and *who would*) found that TEC has a significantly higher overall occurrence of the *who* form. Closer investigation of the co-text, which would be required to differentiate interrogative from relative usage, and to determine the optional vs. non-optional nature of the relative pronoun in each case, has not yet been carried out for all of these forms. However, in the case of *who is* and *who's*, a separation into interrogative and non-interrogative use showed that 44% of BNC occurrences were interrogative, as opposed to only 15% of TEC occurrences.

The occurrence of the complementiser *to*, which is optional following HELP, was analysed (see examples 5 and 6).

[5] *You have special skills and experience which will* ***help*** *us* ***to*** *achieve our objective.* (BNC)

[6] *She only wished Antonia were there with her to* ***help*** *her think over all the things Thomas said.* (BNC)

The data showed that although the word form *help* is more frequent in TEC, its verbal use in both corpora is quite similar. Of these verbal uses, the complementiser *to* is used in 37.5% of TEC instances, compared with only 26% of the BNC occurrences.

The use of *while* preceding a gerundial, i.e. *while *ing*,* and *after* preceding *having + participle* was measured in both corpora. *While *ing* was seen to occur more than twice as often in TEC than in BNC. A count of *after *ing *ed* (which obviously does not take irregularly formed past participles into account) also shows a tendency for TEC to use this construction more frequently than BNC, although the construction was relatively rare in both corpora.

Finally, *in order* may be omitted before *to* and may occasionally be omitted before *for* or *that*. While the investigation of every instance of the items *to, that* and *for* to see whether an *in order* has been omitted is not practical, it is possible to measure usage of *in order to, in order for* and *in order that* and compare results from the two corpora. This investigation showed a marked difference in usage of *in order to*, with 250 instances in BNC compared with 1,225 in TEC. The other forms, *in order for* and *in order that*, were infrequent in the two corpora but both occurred more often in TEC than in the BNC subcorpus.

4.3. Personal Pronouns

A small-scale study of the use of personal pronouns in both corpora is also presented in Olohan (forthcoming a). Frequencies of personal pronouns occurring with verb forms *will, have, am, is, has* and *are*, both within verb contractions and within non-contracted forms, were recorded. The data show that, when used in conjunction with these particular verb forms, personal pronouns *I, you, he, she, we* and *they* are more common in the BNC subcorpus than in TEC. The differences are extremely striking in the case of *I* (23,409 in BNC; 16,178 in TEC), and also quite marked in the case of *you, she* and *we*. The pronouns *he* and *they* occur with these verbs with almost the same frequency in the two corpora.

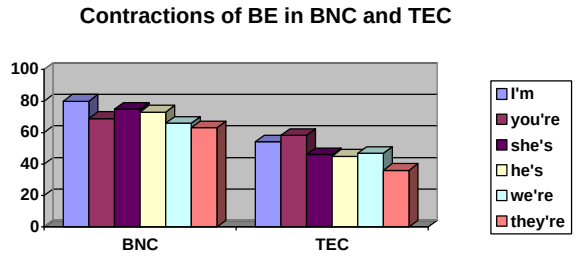
4.4. Contractions

As reported in Olohan and Baker (2000), the linguistics literature on use and omission of *that* with a range of verbs indicated that omission was more likely in informal contexts. Preliminary analysis of co-occurrence of *that* omission and contracted forms (as a crude measure of informality) revealed a definite correlation in both corpora between use of contracted forms and omission of *that.* Thus, despite lower incidence of contractions in TEC and higher incidence of that omission in BNC, the likelihood of co-occurrence of a contracted form and omission of *that* (in the same concordance line) was very similar in both corpora. In other words, the BNC texts were more likely to omit *that* and use contractions; the TEC texts were more likely to include *that* and not use contractions. This correlation suggested that contractions merited further investigation.

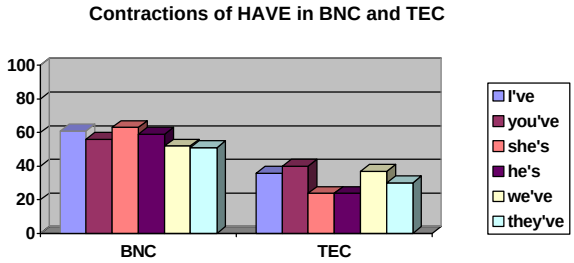
Further detailed analysis of all contracted forms in the corpora revealed that there are higher occurrences and a greater variety of contracted forms in BNC than in TEC. In many cases, the number of occurrences of a form in BNC is double that seen in TEC. (It is worth noting again at this point that the corpora under investigation are extremely similar in terms of size and composition.) In addition, there was a general preference for contracted forms over the corresponding long forms in BNC, while the TEC data showed a general tendency to use the long form in preference to the contracted one. For example, for all *'s* contractions (not including the possessive*'s*, thus for the following forms: *it's, that's, he's, there's, she's, what's, let's, who's, where's, here's, how's*), the contracted form is significantly more common than the long form in BNC. This is not true for TEC, where the long form is the more frequent in 8 out of the 11 forms. In TEC, the contracted form is more frequent only for *that's, what's,* and *let's*, but in these cases represents a smaller proportion of the

combined total occurrences of long and contracted forms than does the long form in BNC.

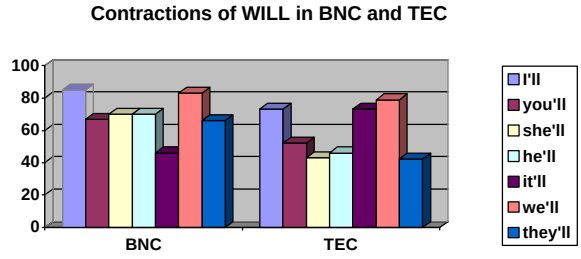
Splitting the analysis into verbs, we can see from Graphs 1, 2 and 3 that there is a greater incidence of contracted forms with personal pronouns in BNC than in TEC for present-tense forms of BE, HAVE and WILL.



Graph 1 Contractions of BE in BNC and TEC, represented as percentage of combined total for contracted and long forms



Graph 2 Contractions of HAVE in BNC and TEC, represented as percentage of combined total for contracted and long forms



Graph 3 Contractions of WILL in BNC and TEC, represented as percentage of combined total for contracted and long forms

As far as common *not*-contractions are concerned, the overall tendency in both corpora is to contract. However, the proportion of contracted forms is smaller in TEC than in BNC in all cases, and for 2 forms examined, *couldn't* and *wouldn't*, TEC is, in fact, more likely to use the long form. Biber et al. (1999: 1131) show that DO + *not* is contracted almost 100% of the time in conversation, around 75% in fiction, 60% in news text and 5% in academic text. From the data used in this study, on average across forms *don't, doesn't* and *didn't*, the rate of contraction of *not* with DO in BNC is 74%, thus very close to Biber et al.'s finding of 75% for fiction. In TEC, on the other hand it is 58%, thus considerably lower.

4.5. Dialectal features

Most of the contractions which featured in the analysis above were of verbs BE, HAVE and WILL or of the negation *not.* However, the BNC subcorpus had a selection of other types of contractions. Many are typical of spoken English, such as the contraction of multisyllabic modifiers e.g. *actu'lly, accident'lly, contradict'ry, prob'ly, fav'rite, gen'rous*. Some interjections also had contracted forms, e.g. *ah'm* and *fuck'em*, again characteristic of the spoken language, as were contractions of *ing* (e.g. *bleed'n*), *and* (e.g. *this'n*) and *than* (*better'n*). Some contractions were also clearly dialectal or sociolectal, with indicators of regional variations such as the dropped *h* in *be'aviour, be'ind, ware'ouse*, or the Scottish *does'na* and *hav'na* (where there is, in fact, no elision between the two words). There were 102 occurrences of *e's* in BNC (dialectal version of *he's*) and none at all in TEC. Finally, other forms found were *d'* (= *do*), *y'* (= *you*), *th'* (=*thou* or *thy*) and *t'* (= *to* or *to the*). All occur considerably more frequently in BNC than in TEC, e.g. *y'know* occurs 22 times in BNC and only once in TEC; *d'you* occurs 362 times in BNC, compared with 72 occurrences in TEC. The last two in particular indicate regional variation and do not occur at all in TEC; by contrast, *t'*, representing *to, to the* or *the* occurs in front of 99 different nouns or modifiers in BNC (see examples 7 and 8), and *th'* occurs 137 times (see example 9).

[7] *"It's a blessing it's a mild winter up ti now," he commented. "It would've been a bad time for* ***t'road*** *between* ***t'two*** *farms ti be blocked wi' snow."* (BNC)

[8] *"We're to go down* ***t'village****, to* ***t'stables****," George told his father, as he retrieved the reins.*(BNC)

[9] *"****Th'mind*** *what I say and* ***th'll*** *doubtless find there's no better place than Jarman House."* (BNC)

5. Directions of Future Research

The picture which emerges from these sets of data and the more detailed quantitative and qualitative analyses which have been done is one of a general preference for longer surface forms in TEC where there is an option between longer and shorter forms. This appears to apply as much to potential contractions of word forms as to syntactic explicitation of relations between clauses, for example in the use of the optional *that* with certain verbs or in the inclusion of relative pronouns where they are optional, i.e. in relative clauses where the co-referential NP is not the subject of the relative clause.

Furthermore, the tendency towards explicitation may extend to lexical choices, where some kind of repetition of nouns in translation may be preferred over use of pro-forms. In addition, TEC appears to contain a more standard variant of the English language, with fewer dialectal or sociolectal markers.

A tentative attempt has been made to link these findings with Biber's dimensions of English (1988 and 1995), with a view to determining to what extent TEC fiction is similar or different to the features of English fiction as analysed by

Biber. These preliminary findings seem to indicate that TEC fiction is not as typical of fiction in English as the works of fiction in the BNC subcorpus. Furthermore, some of the results suggest that TEC fiction may exhibit features more typical of academic prose in English. If this is borne out by future investigations it may contribute to an understanding of the nature of literary translation and its reception in the British literary system. However, there are many features to be investigated in the future to shed further light on this issue.

A criticism sometimes levelled at translation scholars is that we focus too much on literary text and literary translation. One area in which this research can be broadened is to add other genres to TEC. A subcorpus of non-fictional translated works of social science, politics, history etc. would provide an interesting contrast to the fiction subcorpus. Similarly, a bigger biography component would enable useful analyses of that genre to be carried out, taking into account in particular its position somewhere on the continuum between fictional and factual writing.

One aspect of research of this kind which has not been discussed in this paper is the investigation of individual translators. Due to the design of TEC and the incorporation of more than one translation by several translators, it is possible to compare translators and their practices; for example, Baker (2000) discusses the development of a methodology for investigating the style of a literary translator and Olohan (forthcoming b) examines the contraction patterns of two well-known translators across a number of translated works. There is much scope for further research of this kind.

At a conference workshop such as LREC where the emphasis is on practical application of technology in the translation process, one might question the relevance of this kind of detailed analyses of lexical or syntactic patterns in translated language. However, if studies of this nature ultimately give us a better understanding of how translators use language, i.e. how translators translate and what (cognitive) processes are involved, it will be of relevance, not just in the teaching of translation but also in the development of effective technological resources for translators in the future.

Corpora in Translation Practice

Federico Zanettin

Università per Stranieri di Perugia

zanettin@unistrapg.it

Abstract

The aim of this paper is to trace links between work in the corpus linguistics community and the world of practicing translators. The relevance to translation work of corpora in general, and bilingual and parallel corpora in particular, is evaluated by comparing corpora and translation memories and by drawing an analogy between different types of corpora and more traditional reference tools, i.e. dictionaries. Corpus resources available to translators are placed along a cline going from "robust", stable corpora (e.g. large reference corpora such as the BNC) to "virtual", ephemeral corpora (e.g. DIY web corpora). Finally, a few suggestions are put forward in order to encourage a wider diffusion of corpora and concordancing software among professional translators.

1. Introduction

The translator's workplace has changed dramatically over the last ten years or so, and today the computer is undoubtedly the single most important tool of the trade for a translator regardless of whether he or she is a literary translator working for a small publisher, a technical translator working for a translation agency or a legal translator. Today, translators compose their texts on the computer screen, often receive their source texts in electronic format and sometimes their translations will only live as digital information as in the case of web site localization.

The specific hardware and software resources individual translators will resort to will vary depending on the task to be done. While in the case of most literary translators the translated text will probably take shape by means of a general purpose word processor, in the case of technical translators the target text will be produced with the help of the most sophisticated "translator workbench", equipped with all sorts of CAT tools, translation memory and terminology systems, and localization software.

The computer has also flanked, if not substituted, other technological supports in providing access to traditional tools and resources. Translation aids such as monolingual and bilingual dictionaries, terminologies and encyclopedias are now available not only on paper but also in electronic format. Colleagues and expert informants can now be consulted via e-mail and newsgroups besides via telephone, fax and face-to-face encounters. The storage capacity and processing power of personal computers have made access to linguistic and content information easier and quicker than ever before, and the Internet has opened up highways of communication and information retrieval. The problem is now not finding a piece of information, but finding the right and reliable piece of information without wasting too much time.

Corpora and concordancing software can be a way of gaining access to information about language, content, and translation practices which was hardly available to translators before the present stage of ICT development. Corpora and corpus analysis software have been around for quite a long time, but their use is only now beginning to extend beyond a restricted segment of language professionals, such as lexicographers, language engineers, as well as linguists in educational and training institutions.

I would like to suggest that corpora and concordancing software could find a larger place in the translator computerised workstation, and that more corpus resources could and should be made more accessible to professional translators. In order to do so, however, corpus builders and software producers should take into account the specific needs of this group of users. Learning to use corpora as translation resources should also be part of the curriculum of future translators and become part of their professional competence.

2. Corpora and translation

According to the EAGLES text typology elaborated by John Sinclair (1996) we can make a general distinction between Monolingual and Multilingual (including Bilingual) corpora. As regards bilingual (and multilingual) corpora a further distinction can be made between Comparable corpora (corpora compiled using similar design criteria but which are not translations) and Parallel, or Translation Corpora, which are texts in one language aligned with their translation in another. This picture can be further complicated by involving variables such as direction and directness[1] of translation, number of languages, number of translations per text, etc., producing bi-directional, reciprocal, control, star and diamond corpus models (cf. Johansson, forthcoming; Teubert, 1996; Zanettin, 2000; Malmkiaer, forthcoming). Still another type of translation related corpus is the Monolingual Comparable Corpus (Baker, 1993), or a corpus composed of two sub-sections, one of texts originally composed in one language and the other of texts translated into that same language (from a number of other languages). This type of corpus, however, while undoubtedly an extremely useful tool for translation theorists, researchers and students, is arguably of less immediate relevance for professional translators dealing with actual translation jobs.

Professional translators working in the technical sector are perhaps more familiar with the parallel concordancing feature of translator memory systems. A translation memory is data bank from which translators automatically retrieve fragments of past translations that match, totally or to a degree, a current segment to be translated, which must match, totally or to a degree - an already translated

[1] (i.e. whether a translation is produced directly from the original text or via an intermediate translation in another language).

segment. But it can also be seen as a parallel corpus which translators manually query for parallel concordances of (already translated) specific terms or patterns. Aligned translation units are conveniently displayed on the screen, offering the translator a range of similar contexts from a corpus of past translations. A translation memory is, however, a very specific type of parallel corpus in that:

a) it is "proprietory": TMs are created individually or collectively around specific translation projects. They are highly specialized and very useful when used for the translation or localization of program updates – indeed that is their origin – but are not much help when starting a new translation project on a different topic or text type.
b) TMs tend to closure, to progressively standardize and restrict the range of linguistic options. This may be an advantage from the point of view of terminological consistency and of processing costs for clients or translation agency managers, but is often detrimental for readability (texts translated using a "Workbench" can become very repetitive) and the translators eyesight (translators using a well-known Workbench often testify to a "yellow-and-blue-eye-syndrome).

Translation workbenches and translation memories have indeed become the most successful technological product to be created for professional translators, but – as it often happens with MT products – their use is best limited to specific text types, such as online help files, manuals and all types of reference work which do not require sequential reading and for which the scope of translation can be limited to the sentence of phrase level (and thus left to a machine). When dealing with other types of texts translators are perhaps better off with a different kind of language resource, i.e. the type of corpora which are more familiar to lexicographers and linguists and which are only now beginning to enter the selection of tools available to professional and trainee translators.

3. Corpora as translation aids

The respective potential uses on the part of professional translators of monolingual target corpora, bilingual comparable corpora, and of parallel corpora can be illustrated drawing an analogy with other respected tools of the trade, i.e. dictionaries: Monolingual target corpora can be compared to monolingual target language dictionaries, and comparable source corpora to monolingual source language dictionaries. While dictionaries favor a synthetic approach to lexical meaning (via a definition), corpora offer an analytic approach (via multiple contexts).[2] Translators can use target monolingual corpora alongside target monolingual dictionaries to check the meaning and usage of translation candidates in the target contexts. Like source language dictionaries, source language corpora can be consulted for source text analysis and understanding. Large reference corpora (BNC, CORIS/CODIS, etc.) can function as general dictionaries, while smaller, specialized and bilingual comparable corpora can be seen as analogous to specialized monolingual dictionaries (either or both in the source and in the target language).

Parallel corpora can instead be compared to bilingual dictionaries, with a few important differences: bilingual dictionaries are repertories of lexical equivalents (general dictionaries) or terms (specialized dictionaries and terminologies) established by dictionaries makers which are offered as translation candidates. Parallel corpora are repertoires of strategies deployed by past translators, as well as repertoires of translation equivalents. In selecting a translation equivalent from a general bilingual dictionary a translator has to assess the appropriateness of the candidate to the new context by starting from a definition and a few usage examples. A parallel corpus will offer a repertoire of translation strategies past translators have resorted to when confronted with similar problems to the ones that have prompted a search in a parallel corpus.

Parallel corpora can provide information that bilingual dictionaries do not usually contain. They can not only offer equivalence at the word level, but also non-equivalence, i.e. cases where there is no easy equivalent for words, terms or phrases across languages. A parallel corpus can provide evidence of how actual translators have dealt with this lack of direct equivalence at word level. For example, in the translations by two different Italian translators of a number of novels by Salman Rushdie (Zanettin, 2001b), the word "edges", which usually collocates with a preposition, as in the phrases "around the edges," or "at the edges," was never translated literally, but rather omitted:

1. …biting the skin around the edges of a nail…
   …*mordicchiandosi la pelle attorno all'unghia…*
2. …around the edges of Gibreel Farishta's head…
   …*intorno alla testa di Gibreel Farishta…*
3. …around the edges of the circus-ring…
   …*intorno alla pista da circo…*
4. …and there was a fluidity, an indistinctiness, at the edges of them…
   …*vicinissime a loro c'erano una fluidità e un'indeterminatezza…*
5. …the horses grew fuzzy at the edges…
   …*i cavalli diventavano sempre più sfocati…*
6. …blurred at the edges, my father…
   …*con la mente annebbiata, mio padre…*
7. …looking somewhat ragged at the edges…
   …*con l'aria di un uomo distrutto…*
8. …Mrs Qureishi, too, was beginning to fray at the edges…
   …*anche Mrs Qureishi si stava consumando…*

In all these cases, the two professional translators have consistently chosen to resort to "zero-equivalence", which being a translation strategy rather than a case of comparative linguistic knowledge would be hardly reported in any bilingual dictionary.

4. Corpus resources for translators

Not all dictionaries are the same, nor are all corpora. Apart from translation memories, corpus resources which are of potential use for professional translators could be classified along a scale which goes from "robust" to "virtual." A "corpus" is a collection of electronic texts assembled according to explicit design criteria which usually aim at representing a larger textual population. "Robust" corpora are ready-made corpora created and

[2] So-called "production dictionaries", which focus on usage information, can be thought of as standing somehow in between the two.

distributed by the research community and the language industry on CD-ROM or accessible through the Internet. Prototypical examples are large reference national corpora, such as the *British National Corpus* (BNC) for British English, and the *Dynamic Corpus or Written Italian* (CORIS/CODIS) for Italian. This type of resource, which requires a large building effort, is only now becoming available to the wider public outside the (corpus) linguistics community, and will probably require some "customisation" effort in order to become more widespread among language services providers.

Parallel corpora are usually smaller and even less available to the general public than monolingual corpora. Their construction requires more work than that of monolingual corpora. Among other factors, text pairs (rather than single texts) have to be located and before they can be used they need to be aligned, at least at the sentence level (cf. Véronis, 2000).

There are of course varying degrees of robustness, according to the effort and care which has been put in achieving a balanced and representative selection of texts, in providing explicit linguistic and extralinguistic information (corpus annotation) and the means (the software) to query the corpus for that information (McEnery & Wilson, 1996). Corpus design criteria also vary according to the purpose for which a corpus is built, e.g. a comparable monolingual corpus for descriptive translation research. In this sense, the less "robust" (i.e. the more "virtual") corpora are the most truly professional type, with reference to translators, since they are "rough-and-ready" products created for a specific translation project. A distinction is usually made by corpus linguists between "corpora" and "archives" of electronic texts. An "archive" is simply a repository of electronic texts: In this sense the WWW is an immense (multimedia) text archive. Virtual or "disposable" corpora are created by a translator using the WWW as a source "archive". The WWW and HTML documents need not to be the only source for small, specialized DIY corpora, and textual archives of various types and targeted to various users (newspapers, collections of laws, encyclopedias, etc.) are available on cd-rom. The WWW is however certainly the most familiar and user friendly environment for translators: it is always available; it is the most comprehensive source of electronic texts, and corpus creation, management and analysis can be a relatively straightforward operation (Austermühl, 2001; Zanettin, forthcoming). Building a corpus of web pages basically involves an information retrieval operation, conducted by browsing the Internet to locate relevant and reliable documents which can then be saved locally and made into a corpus to then be analysed with the help of concordancing software. The additional time required by creating and consulting a corpus is compensated for by saving in other translation-related tasks, such as dictionary consultation (both on paper and electronic), paper documentation (often in the form of "parallel texts", e.g. Williams, 1996), help from experts, and by the fact that the corpus contains information not available elsewhere. Moreover, the effort is rewarded by improving quality in terms of terminological and phraseological accuracy (Friedbichler & Friedbichler, 2000).

A number of studies have reported on experiments in translation and language teaching classes with DIY corpora, either made of "disposable" web pages (e.g. Varantola, 2000, forthcoming; Maia, 1997, 2000, forthcoming; Zanettin, forthcoming; Pearson, 2000) or of texts taken from other electronic sources such as newspapers (Zanettin, 2001a) or magazines (Bowker, 1998) on CD-ROM. Corpora created from sources other than web pages can require more time and effort to be built, and can be more or less "disposable" depending on the size of the translation project and on the resources available to create and manage them.

Reports on the use of corpora by professional translators are fewer: Friedichler & Friedbichler, drawing on their experience as translators of medical texts and trainers of technical translators, suggest that domain-specific target language corpora may usefully complement dictionaries and the Web as resources in the translation process, filling the gap between the two. Jääskläinen and Mauranen (2000) report on an experimental study involving a team of researchers from the University of Savonlinna and a team of professional translators translating for the timberwood industry. The researchers created a corpus from a variety of sources (web sites, PDF documents, etc.) following suggestions from the translators, and then trained them in using concordancing software (*WS Tools*, Scott, 1996) to analyse the corpus. In exchange, the translation team agreed to answer a questionnaire. One of the results of the study was learning that translators often complained that the user-friendliness of the concordancing software was very low. This complaint was seconded by translator trainees in other studies with "disposable" corpora where students, usually working in groups, collected a corpus of HTML documents and used them to help them translate a specific text.

These studies have underlined, nonetheless, the value of corpus building as a way of getting acquainted with the content and terminology of the translation. They have stressed the importance of type and topic of the text to be translated as well as of the target language (some text types, topics, and target languages are better helped with corpora than others) and also of adopting sound criteria in choosing suitable texts for inclusion in the corpus. Most of the corpora in these experiments were target monolingual corpora, though some use of bilingual comparable and even parallel corpora was reported.

The main benefits and shortcoming of DIY corpora may be summed up as follows:

Benefits:

- They are easy to make.
- They are a great resource for content information.
- They are a great resource for terminology and phraseology in restricted domains and topics.

Shortcomings:

- Not all topics, not all text types, not all languages are equally suitable or available.
- The relevance and reliability of documents to be included in the corpus needs to be carefully assessed.
- Existing concordancing software is not well equipped to handle HTML or XML files, i.e. web pages. There are no or few parallel corpora, since while some parallel texts (i.e. source texts + translations) can be found on the Internet, hardly all of them could be included in a parallel corpus designed to provide instances of professional standards (Maia, forthcoming).

DIY web corpora stand midway the WWW itself, which can be used as if it were a corpus and robust, "proper"

corpora. As for the Web, a "quasi-concordance" view of documents indexed and retrieved is provided by such as search engines Google (http://www.google.com) or Copernic (http://www.copernic.com). Corpus linguistics-oriented software currently being constructed for browsing the WWW as a corpus, such as *KwicFinder* (Fletcher, 2001) and *WebConc* (Kilgarriff, 2001), will certainly prove a useful tool for translators among other language professionals. However, while this "web as corpus" approach has certainly advantages in terms of time over DIY web corpora (the "corpus" is always already there), it necessarily looses in precision and reliability.

The advantages of "robust" corpora over "virtual" corpora can instead be summed up as follows:

- They are usually more reliable.
- They are usually larger.
- They may be enriched with linguistic and contextual information.
- If parallel, they are already aligned.
- They come with user-friendly, customised software (though, again, not necessarily targeted to the needs of professional translators).

5. Conclusions

Translators can tolerate the learning curve necessary to adopt corpora and concordancing software among their everyday working tools only if they derive benefits. These benefits are the fact that corpora provide information not available elsewhere at an affordable cost.

As a way of concluding, I would like to point out possible improvements for existing corpora and concordancing software:

a) "Robust " reference corpora need to become more accessible: for instance, a BNC license is still relatively expensive and the interrogation software might do with some customization; the CORIS/CODIS corpora and others have limited access.

b) In order for "virtual" corpora to become more widespread among translators, concordancing software for work with small monolingual corpora has to become capable of dealing with HTML and, increasingly, XML texts. For example, it may be useful to interface the concordancing software with the Internet browser to provide facilities for file downloading and management, and for allowing the user to switch between concordance lines and full text view, in order to take advantage of multimedia features of electronic texts.

c) Bilingual and parallel corpora are scarcely available and usually of limited size. Bilingual concordancers require bilingual corpora, and given what it takes to locate and align text pairs, it is not very likely that individual translators will resort to consulting parallel concordances unless parallel (aligned) corpora are already available. The creation of more corpora of this kind is a matter of computational resources (especially parallel concordancers and efficient aligning utilities) as well as of more awareness of the usefulness of this resource among translators and language resources providers.

BancTrad: a web interface for integrated access to parallel annotated corpora

Toni Badia, Gemma Boleda, Carme Colominas, Agnès González, Mireia Garmendia, Martí Quixal

Universitat Pompeu Fabra
Rambla 30-32 ,

{toni.badia,carme.colominas,marti.quixal}@trad.upf.es, gemma.boleda@iula.upf.es

Abstract

The goal of BancTrad is to offer the possibility to access and search through (parallel) annotated corpora via the Internet. This paper presents the design of the whole process: from text compilation and processing to actually performing queries via the web, while it describes as well its technical architecture.

The languages we work with are Catalan, Spanish, English, German and French. Queries are possible from any of these languages to Spanish and Catalan and vice versa (but not between the language pairs formed by French, German and English). The texts go first through a pre-processing and mark-up stage, then through linguistic analysis and are finally formatted, indexed and made ready to be consulted. The web interface has been created through the integration some *ad hoc* applications and some ready-to-use ones. It provides three different levels of query expertise: basic, intermediate and expert.

The paper is structured as follows: section 1 gives an overview of the project; section 2 describes the text compilation process; section 3 explains the corpora building and parsing stages; section 4 details the search machine architecture; finally, section 5 describes foreseen applications of BancTrad.

1. Overview

The original idea of BancTrad[1] was to obtain a tool with pedagogic applications (see work done e.g. by Gaspari, Hansen, S.) especially thinking of translation and interpreting courses held at the Translation and Interpretation Faculty (FTI) of the University Pompeu Fabra (UPF). It was meant to be a translation databank that could serve both teachers and students to search for prototypical translations or texts containing special features that would make them interesting from the translator's point of view. Afterwards, the target user of BancTrad was broadened to e.g. professional translators and linguists (see section 5), through the creation of different search modes and the expansion of the expressiveness of the queries, in order to adapt to the user needs or knowledge.

As an annotated translation databank, BancTrad offers the possibility to work with Catalan, Spanish, English, German and French. Queries are possible from any of these languages to Spanish and Catalan and vice versa (but no queries are possible between the language pairs formed by French, German and English), as well as between Catalan and Spanish in both directions. The web page of the project can be accessed from http://glotis.upf.es/bt/index.html

2. Text collecting, extra-linguistic tagging and alignment

The corpora in BancTrad aim at being representative for translated texts. In other words, they don't have a normative character but a descriptive one. Therefore we have chosen to collect documents from very different sources, representing a variety of text types, subjects and registers.

The main sources we have focussed on are faculty professors, work done in translation courses, publishing houses and the Internet. Many faculty professors work also as freelance translators, which constitutes a good source of high quality translations. Besides, the fact that we include (supervised) work done in translation courses can have many advantages regarding academic self-evaluation. Specially, because they give evidence of the text types, subjects, etc., which have been worked on with pedagogical purposes. As for translations from the Internet, some supervision is done on them before they are selected to be introduced in BancTrad (for the sake of quality).

Selected texts are semi-automatically processed to be marked up with SGML tags and aligned with their respective original texts. Both the originals and the translations are marked up with some extra-linguistic information by means of a special MS Word form coded in Visual Basic (see Fig. 1).

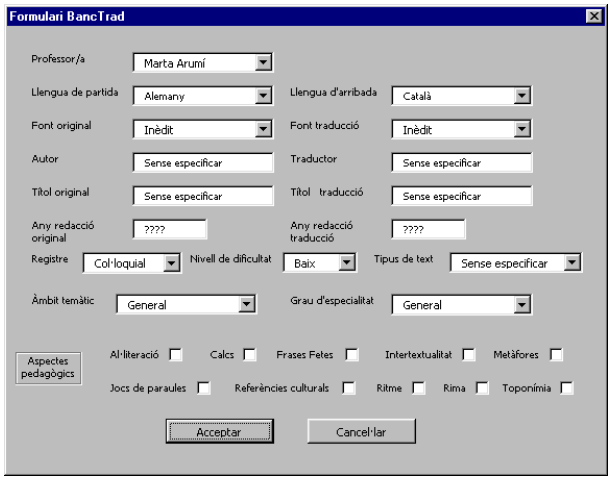

Figure 1: MS Word form used for the mark-up of extralinguistic features of the texts

[1] This project is running under the auspices of the "Programa d'Innovació Docent" (Educational Innovation Program) sponsored by our university (Universitat Pompeu Fabra) and has also been partially financed by the Spanish Government and by the 2001FI 00582 grant from the autonomous Government of Catalonia.

This mark-up takes the following parameters into account:

- name of the person who introduced the aligned texts (i. a., in order to track translation quality)
- source and target languages
- original and translation references
- publication date (for both the original and the translation)
- register (colloquial, standard, learned, etc.)
- type of text (normative, descriptive, literary, etc.)
- subject matter (economy, science, politics, etc.)
- degree of specialisation (low, middle, high).

Besides these parameters, and bearing in mind that BancTrad was originally conceived as a tool with pedagogic applications, we include information on certain aspects such as idioms, metaphors, puns, degree of difficulty, etc. All of these parameters, as well as the information coded within them, were consensuated with the teachers and researchers of the FTI. It is relevant to note that this mark-up allows us not to make a rigid classification of the texts in the corpus (see section 3).

By clicking on the *Acceptar* ("Accept") button, the options selected in the form are marked in the text in SGML format and a script tags the paragraph structure of the document. Otherwise, this very valuable piece of information on the text structure would be lost in the alignment step.

Texts are aligned at a sentence level with the align tool of the DéjàVu Database Maintenance, software by Atril (http://www.atril.com). DéjàVu aligns texts and allows editing in quite a user-friendly way.

The tasks described so far, although only semi-automatic, require neither special skills in computing nor much time (the time to go through them for a 400 word-long text -both source and target texts- is 5 to 10 minutes). We could have chosen to tackle the alignment task fully automatically instead, but the error rate of automatic aligners (notably errors in sentence identification) would have increased too much the error rate in the subsequent linguistic analysis. However, it should be kept in mind that, according to our architecture, the use of a particular tool for the mark-up and alignment independent of the rest of the process, so that other tools could be used in the future.

Finally, the texts are transferred to our Linux server to proceed with the text processing, which from this moment on will be completely automatic.

3. Linguistic Processing and Corpus Building

Once the texts are in the server, they undergo two further steps: linguistic tagging and corpus formatting. Both steps are completely automatic.

3.1. Linguistic Processing

Each language follows a different tagging process. On the one hand, Catalan texts are parsed with CATCG (Badia *et al.* 2000), a Catalan shallow morphosyntactic parser based on a constraint grammar developed by the Computational Linguistics group at UPF. Spanish texts will be handled with a Spanish version of it in a year's time. On the other hand, the linguistic analysis for English, German and French texts is made with TreeTager, a part-of-speech tagger developed at the IMS (see Schmid 1995, 1997). Both CATCG and TreeTager are shallow parsers.

La	**noia**	**de**	**el**	**port**	**de**	**Barcelona**	**dorm**
the	***girl***	***of***	***the***	***harbour***	***of***	***Barcelona***	***sleeps***

</s>
```

Figure 2: Input and output of CATCG

It is important to note that, despite the use of different tagging tools for exploiting the linguistic information of our texts, all languages receive a minimum of uniform kind of information: lemma and POS tag (syntactic function is only there for Catalan). Thus, all the languages can be processed and made queries upon in the same fashion, independently of the tagging tool used. This favours modularity, for the linguistic processing of a certain language can be modified without changing any of neither the other linguistic processes nor the interface. We now proceed to roughly characterize CATCG and TreeTagger.

3.1.1. CATCG

CATCG is a linguistic-based parser that assigns each word a lemma, a POS tag and a syntactic function. It uses three major devices:

a) a Perl module for the preprocessing
b) a morphological tag mapping tool that uses a word-form dictionary created with a morphological generator developed at UPF (Badia *et al.* 1997)
c) three grammars using the Constraint Grammar formalism developed at the University of Helsinki (Karlsson et al. 1995, Tapanainen 1996), which perform the morphosyntactic disambiguation task and the partial syntactic analysis.

Fig. 2 gives an example of the input and output of our system. The SGML tags are the result of the preprocessing, and in the example they mark a contracted form, an entity and the sentence boundaries. The columns list the linguistic information: word form, lemma, part of speech tag, complete morphological information in an compressed tag and syntactic function (in order of appearance). The last piece of information is shallow and partial in the sense that it doesn't fully indicate dependency: note that the

preposition *de* (“from”) in the PP *de Barcelona* gets a tag indicating that it modifies a noun to its left (<*NA*, left adjoining Nominal Adjunct); however, no clue is given about whether it modifies *Barcelona* or *port*.

3.1.2. TreeTager

TreeTager is a probabilistic tagger that uses decision trees. It provides each word with a lemma and a POS tag (at the moment, no syntactic information is given).

3.2. Corpus formatting

After being annotated, the text files are eventually formatted and processed with the Corpus WorkBench (CWB) tools, a set of linguistic information exploitation tools developed at the IMS in Stuttgart (Christ 1994; Christ *et al*. 1999[2]). Thus we build the actual corpora making them ready to be consulted with CQP, the Corpus Query Processor, a tool from the CWB. This tool allows very flexible and expressive queries for any of the pieces of information encoded (be it the word form, lemma, POS tag or syntactic function). In fact, as a far as one gives corpora the adequate structure, one can have as a many attributes as one pleases.

One of the most significant (to us) features of the CWB is the fact that it can process aligned corpora. Not only is it possible to view the aligned sentences, but it is also possible to place restrictions both on the source and on the target language in a query (see section 5). It has also been crucial to us the special module that lets CQP interacting with the web (see next section).

4. The search machine and the web Interface

Technically speaking, the novelty of BancTrad is the integration of several tools that make available parallel annotated corpora via the Internet. This entails that the system has to be able to (1) interpret the query made by the user, (2) search for the query, (3) present the results. For this purpose, two devices were needed: a graphical user interface (GUI) with a fill-in form and an external program interface (to allow browser/server communication)

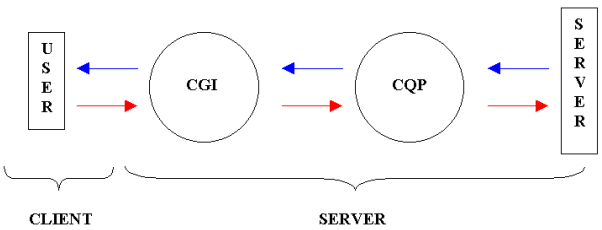

Figure 3: Query routing through the client/server architecture (query from left to right, results the other way round)

a) The GUI for query input

The GUI is intended to be adaptable to the user expertise, to have open access and to be platform independent. For our GUI to accomplish the two last features, an HTML-based interface seemed to be the best option. To qualify for the first one, the interface had to offer at least three search possibilities: common, intermediate and expert mode (see next section for details).

b) The external program interface

This is the module of the architecture that actually makes the query processing. It interprets the user's query, it searches for it in the corpora and gives the result back. The program that does the work is commonly called a cgi (Common Gateway Interface, term whose original sense has been extended to mean “external program interface”). Our cgi is composed of the following packages:

i) Common Gateway Interface (CGI)

The CGI (properly so named) is a standard device to interface with information servers (such as HTTP servers). It passes a web user's request on to an application program and gives the resulting data back to the user. Herewith the server interprets the user’s query.

ii) HTML::Entities

This formatting package ensures that special characters (tildes, cedillas, etc.) are properly transferred during the client/server session.

iii) WebCqp::Query, a web adapted version of the CQP

This package was designed by the creators of the CWB (see above) to let it interact with the web. It can perform the same kind of queries that CQP performs in its PC-Linux version. It thus allows a powerful query setting through regular expressions, access to linguistic tags (through the defined number of features in the corpora) and aligned corpus querying.

5. Exploiting BancTrad

This section outlines different ways in which to exploit BancTrad, from two different but related perspectives regarding its potential users. It describes the search possibilities that BancTrad offers (section 5.1), which relates to the user's level of expertise. Besides, it sketches some possible applications for which BancTrad is indicated (section 5.2), which relates to the user's professional or academic profile.

5.1. Search possibilities

5.1.1. Three levels of expertise

The web interface of BancTrad had to enable the users to access the corpora without having to be experts neither on linguistics nor on regular expressions. Moreover it had to offer the possibility of exploiting the full-fledged regular expressions that CQP allows, as well as the chance of profiting from the quite detailed linguistic annotation of the corpora. Therefore, BancTrad offers three different search modes (corresponding to levels of query expertise):

a) **basic mode:** allows searching for sequences of specific word forms (with possibly their equivalence in a target language).

b) **intermediate mode:** allows searching for sequences of five

[2] See also the web page of the CWB: http://www.ims.uni-stuttgart.de/projekte/CorpusWorkbench/

quadruples (form, lemma, morphosyntactic tag, and syntactic function), including the iteration of identical elements

Fig. 4 is a screenshot of a search in this mode: it searches for causative constructions from Catalan into English, that is, for the causative verb *fer* followed by any verb (see next section for the results).

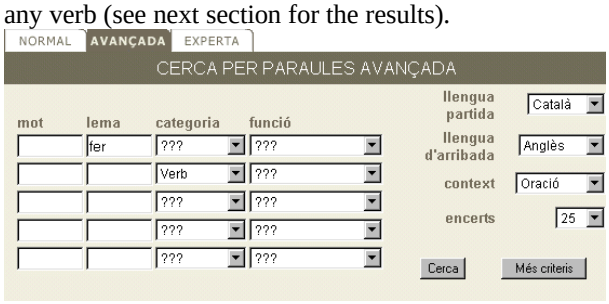

Figure 4: Screen shot of the intermediate query mode of BancTrad

expert mode: to set queries expressed in the full regular language provided by CQP.

5.1.2. Restrictions on extralinguistic features

Additionally to the word units searched for, the user can place restrictions on extra-linguistic features of the texts containing them. This is possible through the initial mark-up stage (see section 2) while formatting the corpora. Thus, through an extended web-form, the user can restrict the occurrences of e.g. the word "bank" to appear in economic texts.

This kind of mark-up gives rise to a different search possibility, planned for the original purpose of BancTrad (which was being useful for teaching purposes at the FTI): the full text query, which allows the user to search for complete texts and their translation, restricting them by the extra-linguistic features mentioned above. Fig. 5 shows a text query in which the user wants to retrieve essays (*Assaig*) on Arts originally written in German (*Alemany*) and translated into Spanish (*Castellà*).

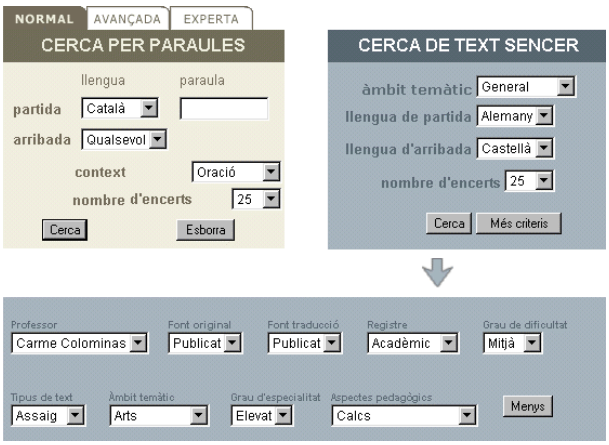

Figure 5: Screenshot of the text query mode of BancTrad

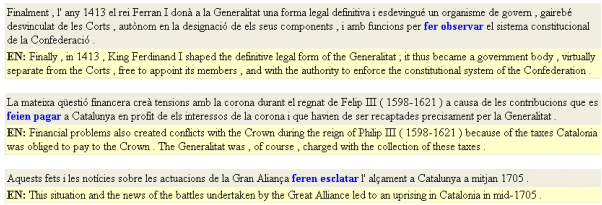
5.1.3. Showing the results

As for the presentation of the results, they are shown by default as aligned full sentences, although it is foreseen that the user can switch to other presentation forms: a full paragraph or just some words to the left and/or right sides of the query target. Of course all the capabilities listed so far are indebted to the Corpus Query Processor that we use as a searching engine.

Fig. 6 shows some of the results for the query on causative constructions made on section 5.1.1:



Finalment , l' any 1413 el rei Ferran I donà a la Generalitat una forma legal definitiva i esdevingué un organisme de govern , gairebé desvinculat de les Corts , autònom en la designació de els seus components , i amb funcions per **fer observar** el sistema constitucional de la Confederació .
EN: Finally , in 1413 , King Ferdinand I shaped the definitive legal form of the Generalitat ; it thus became a government body , virtually separate from the Corts , free to appoint its members , and with the authority to enforce the constitutional system of the Confederation .

La mateixa qüestió financera creà tensions amb la corona durant el regnat de Felip III (1598-1621) a causa de les contribucions que es **feien pagar** a Catalunya en profit de els interessos de la corona i que havien de ser recaptades precisament per la Generalitat .
EN: Financial problems also created conflicts with the Crown during the reign of Philip III (1598-1621) because of the taxes Catalonia was obliged to pay to the Crown . The Generalitat was , of course , charged with the collection of these taxes .

Aquests fets i les notícies sobre les actuacions de la Gran Aliança **feren esclatar** l' alçament a Catalunya a mitjan 1705 .
EN: This situation and the news of the battles undertaken by the Great Alliance led to an uprising in Catalonia in mid-1705 .

Figure 4: Screen shot of the intermediate query mode of BancTrad

5.2. Applications of BancTrad

There are several uses one can think of for BancTrad. Of course, the most direct and obvious one is the one for which the parallel databank was thought: educational use. But there are at least two other kinds of applications that were held in mind while developing the project: research and professional applications. The three of them are outlined, with some examples, in this section.

5.2.1. Teaching

For educational purposes, all of the search modes (be it string or text queries) outlined in the previous subsection are relevant. However, as the full text query has already been exemplified, we will concentrate on the first one. The string equivalence query, which we foresee to be the most significant application for the corpora included in BancTrad, is the search of bilingual equivalences among language pairs. This includes the search of word equivalence, restricted by its form in one of the languages, by its lemma, or by its form or lemma and its morphosyntactic tag. Thus typical searches (which demand different levels of expertise in the search mode) could be:

a) translation of the English form 'stores' into Catalan. Result: *botigues* (noun), *guarda* (verb).
b) translation of the English lemma 'store' into Catalan. Result: *botiga*, *botigues* (noun), and the whole paradigm of the verb *guardar*.
c) translation of the lemma 'store' with part-of-speech 'verb' into Catalan. Result: the whole paradigm of the verb *guardar*.

Note that as in standard corpus search engines, word forms and lemmata can be searched for in specific contexts, as well as particular combinations of forms, lemmata or part-of-speech tags. For example:

d) translation of the gerundive form of the verb 'indicate' right after a colon.

In addition, a specific search condition on the aligned text can be set. For example:

e) translation of the gerundive form of the verb 'indicate' just after a colon provided that in the translated sentence into Catalan no gerundive is present; alternatively, provided that the verb 'indicar' is used.

5.2.2. Professional and research applications

In fact, these kind of applications just follow from the examples described above and the characteristics of the corpora in BancTrad. On the one hand, as far as the corpora are real translated texts (see section 2), and provided the search possibilities sketched above, BancTrad appears to be a useful tool for professional translators. They could look for evidence of previous translation decisions and even have the information of the person in charge for that translation.

On the other hand, linguists and translation theorists (see work done by Baker, M. and Teubert, W.) could also take advantage of this search engine. In fact, this is something we have already been doing with the grammar-developing task we have been carrying on for the last three years. We can retrieve data such as most frequent readings, syntactic structures, etc. This helps us concentrate on problems arising when dealing with written text and develop more data-driven linguistic-based grammars. It is also interesting to note that searches can be made on a sole language, that is, they must not be bilingual.

Other possible applications for BancTrad include creating further Language Resources, such as multilingual dictionaries, chunkers, stochastic-based machine translation systems, etc.

5.2.3. An added value

Finally, it is important to note that an added value to BancTrad's web interface is the fact that it can incorporate other corpora (also monolingual ones) with little amount of work. This would enable our users to query on several corpora, not only the ones prepared at the FTI, in a user-friendly and familiar web interface. For instance, we already have the British National Corpus as part of our searchable corpora and we are planning to integrate the Frankfurter Rundschau corpus soon as well.

6. Conclusions and future work

We have presented a parallel-annotated corpora web interface that integrates several linguistic tools, both for exploiting linguistic information and for exploiting the linguistically enriched texts. It was originally thought to be a translation teaching help tool, but its possibilities have been so extended that it can be of use to both common public and professional users.

Technically speaking, BancTrad integrates tools from different techniques and fields. On the one hand, we use parsing tools developed at our centre, which have been developed with linguistic techniques. Moreover, we are planning to use parsers developed with stochastic techniques (TreeTagger, see above). On the other hand, we have been taking advantage of several ready-to-use packages for client/server interaction. Thus, we feel our project provides evidence of the necessity of academic co-operation to produce tools for the exploitation of linguistic information.

7. Acknowledgments

Thanks all teachers of the FTI for their collaboration. Feedback from the anonymous reviewers was also very useful.

ParaConc: Concordance Software for Multilingual Parallel Corpora

Michael Barlow

Rice University
Dept. of Linguistics
Houston, TX 77005
barlow@rice.edu

Abstract

Parallel concordance software provides a general purpose tool that permits a wide range of investigations of translated texts, from the analysis of bilingual terminology and phraseology to the study of alternative translations of a single text. This paper outlines the main features of a Windows concordancer, ParaConc, focussing on alignment of parallel (translated) texts, general search procedures, identification of translation equivalents, and the furnishing of basic frequency information. ParaConc accepts up to four parallel texts, which might be four different languages or an original text plus three different translations. A semi-automatic alignment utility is included in the program to prepare texts that are not already pre-aligned. Simple text searches for words or phrases can be performed and the resulting concordance lines can be sorted according to the alphabetical order of the words surrounding the searchword. More complex searches are also possible, including context searches, searches based on regular expressions, and word/part-of-speech searches (assuming that the corpus is tagged for POS). Corpus frequency and collocate frequency information can be obtained. The program includes features for highlighting potential translations, including an automatic component "Hot words," which uses frequency information to provide information about possible translations of the searchword.

Keywords: alignment, parallel texts, concordance software

ParaConc is a tool designed for linguists and other researchers who wish to work with translated texts in order to carry out contrastive language studies or to investigate the translation process itself.

1. Alignment

The successful searching and analysis of parallel texts depends on the presence of aligned text segments in each language corpus (and, of course, on the availability of parallel corpora). The alignment, an indication of equivalent text segments in the two languages, typically uses the sentence unit as the basic alignment segment, although naturally such an alignment is not one in which each sentence of Language A is always aligned with a sentence of Language B throughout the texts, since occasionally a sentence in Language A may, for example, be equivalent to two sentences in Language B, or perhaps absent from Language B altogether. (More difficult problems arise in cases where the translation of one sentence in Language A is distributed over several sentences in Language B.) The size of the aligned segments is not set by the software, however. It would be possible to work with paragraphs as the basic alignment unit, but then the results of a search will be more cumbersome because the translation of a word or phrase will be embedded within a large amount of text, which is especially difficult in cases in which the language is not well-known.

The alignment utility in *ParaConc* is semi-automatic. When files are loaded, the user enters information about the format of the files either through reference to SGML tags or via specifications of patterns. The user specifies the form of headings and the form of paragraphs. *ParaConc* uses the information to align the documents at this level and the user can make adjustments by merging/splitting units, as appropriate. Sentence level alignment, if it is not indicated by SGML tags, is performed using the Gale-Church algorithm (Gale and Church, 1993). The alignment information is saved to a file as part of the workspace, as described in Section 6.

No use is made of bilingual dictionaries or of any kind of language-particular information, but the user can enter pairs of anchors, such as cognates, numerals and dates, which the program will track. These anchors are not used in the alignment process itself, but aligned units which do not contain the appropriate corresponding anchors are highlighted for manual checking by the user.

If the parallel texts are pre-aligned, then it is simply necessary to indicate the manner in which the alignment is marked.

2. Loading the Parallel Corpus

When the LOAD CORPUS FILE(S) command is given, a dialogue box appears, enabling particular parallel files to be loaded, as shown in Figure 1.

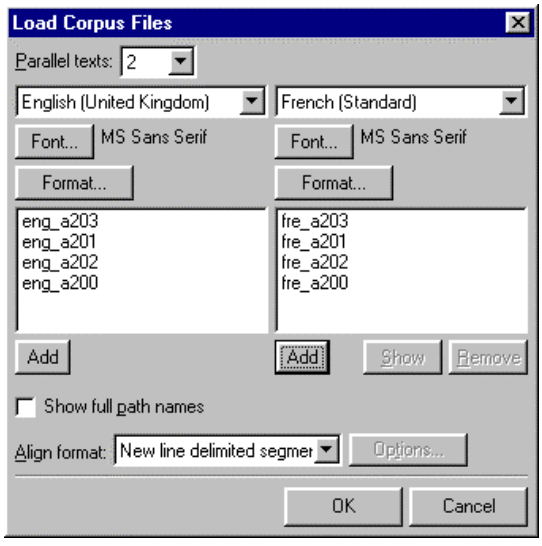

Figure 1. Loading Corpus Files

The heading PARALLEL TEXTS at the top of the dialogue box is followed by a number in the range 2-4 (i.e, two to four different languages). The FORMAT buttons allow the user to describe the form of headings, paragraphs, and sentences, as discussed above. Filenames can be reordered by dragging them to the appropriate position.

3. Searching and Analysing Parallel Texts

The program processes the files as they are loaded, counting words, recording the position of alignment indicators, and processing other format information.

Once a corpus is loaded, some new menu items related to the analysis and display of the text appear on the menu bar. These are FILE, SEARCH, FREQUENCY, and INFO. In addition we can obtain information in the lower left corner of the window relating to the number of the files loaded and in the lower right corner a word count for the two corpora is provided.

Selecting SEARCH from the SEARCH menu initiates the search process and the program starts to work though the loaded files looking for the search string. The search can be based on any of the languages represented: either English or French in this example. (The basic search is fairly simple: a word or a phrase can be entered, including simple wildcard characters if necessary. The symbols acting as wildcards are user-defined, but the default symbols are ? for one character; % for zero or one characters; and * for zero or more characters. The symbol @ covers a specified range of words. Information on the span covered by @ and other information such as a list of characters that act as word delimiters is available in SEARCH OPTIONS.)

Below the results of a search for *head* are illustrated. The instances of *head* are displayed in a KWIC format in the upper window. Clicking on one particular example of *head* in English highlights both the English and French lines. (Double-clicking on a particular line evokes a context window, which provides an enlarged context for the particular instance of the searchword.)

The lower part of the window contains the French sentences (or text segments) that are aligned with the hits displayed in the top window. This display of equivalent units in the two languages is, of course, a consequence of the alignment process. Thus if the first instance of *head* occurred in segment 342 of the English text, then the program simply throws segment 342 of the French text into the lower window, and this process is repeated for all instances of *head*.

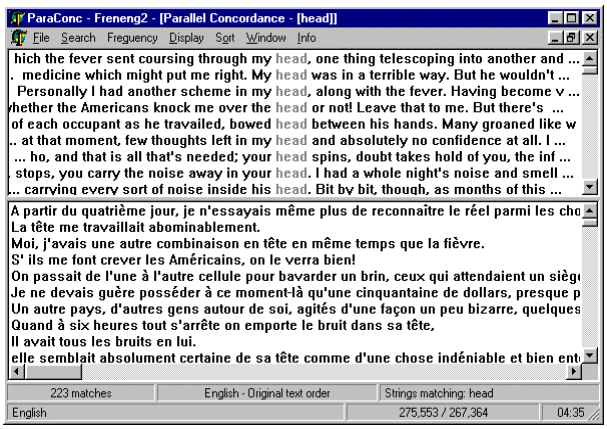

Figure 2: The Results of a Simple Search

Let's follow this example further. Once the search is ended, we can bring to bear the usual advantages of concordance software to reveal patterns in the results data. One may be interested, for example, in different uses (and translations) involving *head: big head, company head, shower head*, etc. One way to find out which English words are associated with *head* is to sort the concordance lines so that they are in alphabetical order of the word preceding the search term. The advantage of performing this 'left sort' is that the modifiers (adjectives) of *head* that are the same will occur together. One easy way to achieve this ordering is to select 1ST LEFT, 1ST RIGHT, from the SORT menu.

It can perhaps be seen from Figure 2. that while all the instances of *head* are clearly displayed, it is difficult to look through the equivalent French segments in order to locate possible French translations of *head* within each segment. To alleviate this, we can highlight suggested translations for English *head* by positioning the cursor in the lower French results window and clicking on the right mouse button. A menu pops up and we can select SEARCH QUERY which gives access to the usual search commands and hence allows us to enter a possible translation of *head* such as *tête*. The program then simply highlights all instances of *tête* in the French results window.

We can now change the context for the French results so that the results in the lower window are transformed into a KWIC layout (at least for those segments containing *tête.)* First, we make sure that the lower window is active. Next we choose CONTEXT TYPE from the DISPLAY menu and select WORDS. Finally, we rearrange the lines to bring those segments containing *tête* together at the top of the French results window. To achieve this, we choose SORT and sort the lines by searchword, and 1st left. The sorting procedure will then rearrange the results in lower window. (The SORT and DISPLAY commands are applied to whichever window is active.) The two text windows then appear as shown in Figure 3. Naturally, only those words in the French text that have been selected and highlighted can be displayed in this way. By sorting on the searchword, all the KWIC lines are grouped together at the top of the text window; the residue can be found by scrolling through towards the bottom of the window. This is a revealing display, but we have to be careful and not be misled by this dual KWIC display. There is no guarantee that for any particular line, the instance of *tête* is in fact

the translation of *head*. It could simply be accidental that *tête* is found in the French sentence corresponding to the English sentence containing *head.*

The idea behind dual KWIC display is to let the user move from English to French and back again, sorting and resorting the concordance lines, and inspecting the results to get a sense of the connections between the two languages at whatever level of granularity is relevant for a particular analysis.

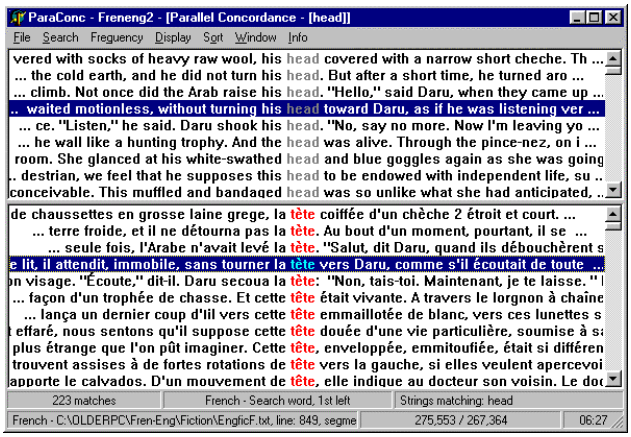

Figure 3: Parallel KWIC displays

4. Hot Words

In the previous section, we described the use of SEARCH QUERY to locate possible translations in the second window. In this section we will look at a utility in which possible translations and other associated words (collocates) are suggested by the program itself. We will refer to these words as *hot words*. First we position the cursor in the lower (French) half of the results window and click using the right mouse button. If we used SEARCH QUERY earlier, we need to select CLEAR SEARCH QUERY and then choose HOT WORDS, which invokes a procedure which calculates the frequency of all the words in the French results window and then brings up a dialogue box containing the ranked list of hot words. The ranked list of candidates for hot words based on *head* are displayed as shown in Figure 4.

To select words as hot words, the program looks at the frequency of each word in the results window and ranks the words according to the extent to which the observed frequency deviates from the expected frequency, based on the original corpus. The words at the top of the list might include translations of the searchword, translations of the collocates of the searchword, and collocations of translation of the searchword.

In addition to the basic display of hotwords, a paradigm option (if selected) promotes to a higher ranking those words whose form resembles other words in the ranked list. This is a simple attempt to deal with morphological variation without resorting to language-particular resources.

Some or all the hot words can be selected. Clicking on OK will highlight the selected words in the results window, and again the words can be sorted in various ways.

Figure 4: Hot Word List

5. Frequency information

ParaConc furnishes a variety of frequency statistics, but the two main kinds are corpus frequency and collocate frequency. The command CORPUS FREQUENCY DATA in the FREQUENCY menu creates a word list for the whole corpus (or parallel corpora), according to the settings in FREQUENCY OPTIONS. The results can be displayed in alphabetical or frequency order and the usual options (such as stop lists) are available.

Choosing COLLOCATE FREQUENCY DATA from the FREQUENCY menu displays the collocates of the search term ranked in terms of frequency. In *ParaConc,* the collocate frequency calculations are tied to a particular search word and so the frequency menu only appears once a search has been performed. The collocation data produced by the COLLOCATE FREQUENCY DATA command is organised in four columns, spanning the word positions 2nd left to 2nd right. The columns show the collocates in descending order of raw frequency.

One disadvantage of the simple collocate frequency table is that it is not possible to gauge the frequency of collocations consisting of three or more words. To calculate the frequency of three word collocations, it is necessary to choose ADVANCED COLLOCATION from the FREQUENCY menu and select one or more languages. The top part of the dialogue box associated with ADVANCED COLLOCATION allows the user to choose from up to three word positions, for example, SEARCHWORD 1ST RIGHT, 2ND RIGHT. The program counts and displays the three-word collocations based on the selected pattern.

6. Workspace

The loading and processing of a parallel corpus in particular can take some time since the program has to process alignment and annotation data before searching and analysis can begin. Since the same sets of corpus files are often loaded each time *ParaConc* is started, it makes sense to freeze the current state of the program, at will, and return to that state at any time, rather than starting *ParaConc* and reloading the parallel corpora afresh. This is the idea behind a workspace. A workspace is saved as a special (potentially large) ParaConc Workspace file (.pws), which can then be opened at any time to restore

ParaConc to its previous state, with the corpus loaded ready for searching. Searches and frequency data are, however, not included in the saved workspace. (Only the search histories are saved.)

A workspace can be saved at any time by selecting the command SAVE WORKSPACE or SAVE WORKSPACE AS from the FILE menu. The usual dialogue box appears and the name and location of the workspace file can be specified in the normal way. Once a filename for the saved workspace has been entered, the user is asked to choose some different workspace options. The line/page and the tracked tag info can be saved as part of the workspace. (The saved workspace consists of a saved file and an associated folder of the same name.)

7. Advanced Search

The simple searches described in Section 3 will suffice for many purposes and are especially useful for exploratory searches. The basic TEXT SEARCH is also very useful when used in conjunction with a sort-and-delete strategy. Particular sort configurations can be chosen to cluster unwanted examples (words preceded by *a* and *the* perhaps), which can then be selected and deleted. For more complex searches, however, we need to use the ADVANCED SEARCH command. This command brings up a more intricate dialogue box (displayed in Figure 5), which at the top contains the text box in which the search query is entered.

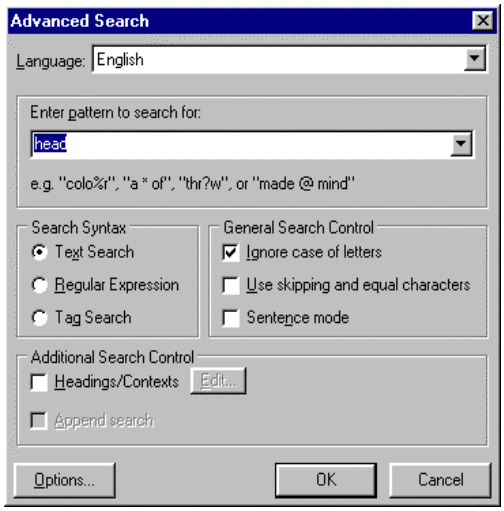

Figure 5: Advanced Search

The most important part of the ADVANCED SEARCH dialogue box is labelled SEARCH SYNTAX. The three radio buttons allow users to specify the kind of search they wish to perform. The first, TEXT SEARCH refers to the basic searches described in the section above.

The REGULAR EXPRESSION search allows for search queries containing boolean operators (AND, OR and NOT). For example, a regular expression to capture the *speak* lemma might be given as **sp[eo]a?k[se]?n?**. This expression will match the string *sp* followed by *e* or *o*, an optional *a*, a *k*., an optional *s* or *e*, followed by an optional *n*. (Word boundaries or spaces would also have to be specified in order to eliminate words such as *bespoke*.) The software also supports the expanded set of regex metacharacters: \d, \w, \s, \S, etc.

The third option in the advanced search dialogue box is TAG SEARCH, which allows the user to specify a search query consisting of a combination of words and part-of-speech tags, with the special symbol **&** being used to separate words from tags in the search query. This search syntax is used whatever particular tag symbols are used in the corpus. (Thus it is necessary to enter the form of the tags in TAG SETTINGS before a tag search can be performed.) To give an example: the search string **that&DD** finds instances of *that* tagged as a demonstrative pronoun, which may appear in the corpus as *that<w DD>*. Similarly, a tag search for **&JJ of&** will find all instances of adjectives followed by the word *off*. (The dialogue box in Figure 5 contains a variety of other options controlling the search function, which will not be discussed in this paper.)

Finally, one kind of search tailored for use with parallel texts is a parallel search, which is one of the options within the SEARCH menu. This type of search, shown in Figure 6, allows a search to be constrained based on the occurrence of particular strings in the different parallel texts.

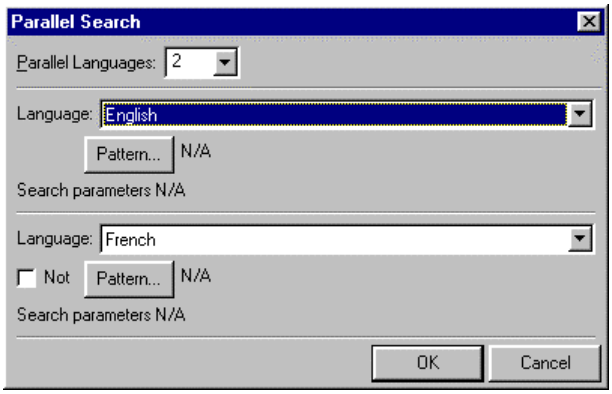

Figure 6: Parallel Search

Clicking on the Pattern box under Language: English brings up the normal advanced search dialogue box and a search query can be entered. In this case, the search term **head** has been entered. Moving to Language: French and again clicking on Pattern, it is possible to enter another search string such as **tête**. Clicking OK initiates the search routine and the software locates examples in which head occurs in the English text segment and tête is also found in the corresponding French segment. If the NOT box (under Language: French) is selected, then the search routine will display head only if tête does not occur in the equivalent French segment.

8. Summary

This paper has provided a brief overview of a Windows parallel concordance program which can be used by a variety of researchers working on the analysis of multilingual texts for translation or linguistic purposes. This article has focussed on the overall design and operation of the software and no linguistic analyses have been presented here, but the potential for cross-linguistic analyses and for the investigation of the translation process is, we hope, reasonably clear.

The main factor impinging on the usefulness of the software is probably the availability of aligned parallel corpora and of parallel corpora in general.

Corpora for Terminology Extraction – the Differing Perspectives and Objectives of Researchers, Teachers and Language Services Providers

Belinda Maia

bmaia@mail.telepac.pt

Abstract

Using corpora to find correct terminology is an activity that is interpreted rather differently according to the final objectives of those involved. This paper will try to show how the perspectives and objectives of researchers, teachers and language services providers do not always coincide, and how this lack of mutual appreciation and understanding can sometimes cause confusion. We shall first look at the more speculative aspects of current terminology research for the possibilities they offer in the future, even though some of this work is not directly related to translation, and consider the reasons why correct terminology is growing in importance in the lives of both domain specialists and language services providers. We shall then briefly consider both the older prescriptive notions of standardisation and the descriptive approach made feasible by technology and corpora today. Corpora in the broadest sense – from formally constructed and officially approved collections of texts to the disposable, do-it-yourself corpora anyone can now collect off the Internet for information on a specific subject – come as part of the information revolution provided by technology. They provide possibilities for any user of language and knowledge that were unthinkable a few years ago, but there are also problems and drawbacks.

1. Introduction

The compilation of terminology used to consist largely of collecting the words and phrases considered to be specific to a certain domain and bringing them together to form glossaries, with or without definitions or information on how or where the information was gathered. Since translators often had a vested interest in finding, or providing recognised equivalents in several languages, these glossaries would often become bi- or multilingual at a later stage. With the increase in availability of electronic text, the advantages of using corpora for term extraction are now generally recognised, particularly since the prescriptive view of terminology work has given way to a more descriptive approach, and the storage of definitions and other information on the terms has been made possible by relational databases.

This paper assumes that there are three classes of people with a particular interest in this terminology work. First there are the researchers in various areas of linguistics in general, as well as more specific terminology research. Many, but not all of these people, are also the teachers who try to train the professional language services providers needed today. The word 'linguist' as someone proficient in two or more languages has become ambiguous since the advent of 'linguistics' as an academic discipline, and the tasks required of someone with a good knowledge of languages are increasingly varied. I have therefore chosen the term 'language services provider' to refer to those who not only provide traditional translation and interpreting services, but also those who write and revise texts professionally, specialise in localisation, sub-titling, dubbing and making web pages, create terminological databases and translation memories, work with machine translation, and both use and take advantage of the information technology now available for a wide variety of projects and customers.

2. Terminology research

Those involved in this workshop on translation work and research will tend to see terminology research as primarily interested in supplying the needs of the translator for specialised terminology, but this is only one aspect of the overall picture. A good deal of terminology research is monolingual in nature and directed at the standardisation and categorisation of the relationship between concepts belonging to certain domains of knowledge and the terms used to describe them. This type of work is typically carried out by the domain experts, with or without the assistance of linguists, and, more often than not, in major languages like English, French and German. The subsequent translation of these standardised terms into other languages is by no means as simple or as well organised as it might be, despite official efforts to the contrary.

Standardisation of terminology has a long history, and its objectives have typically been to prevent confusion in the transmission of knowledge, with all the economic, social, legal and political consequences involved. Some areas of knowledge, like engineering, have a long-standing tradition in producing standardised terminology, but even they find it difficult to keep up with technical and scientific developments. Many other domains have little or no organised terminology resources and what exists is often 'local' in nature, in the sense that it is the property of certain organisations, companies and other entities, of varying size and importance.

The information revolution caused by the Internet, however, has led to demands for better systematisation of knowledge and improved accessibility. For this reason, the computational side of terminology research today is increasingly orientated towards facilitating information retrieval and knowledge engineering (see Budin, 1996, and Charlet et al, 2001). Traditional terminology work tends to be painstaking and slow, and is not adapted to coping with the exploding need for retrieving knowledge. For this reason, efforts are being made by computational linguists and computer scientists to speed up the process of identifying, extracting and processing terminology (see Bourigault et al (Eds.) 2001, and Veronis (Ed). 2000).

3. Computational terminology

So much information is now processed in computer-readable form that there are obvious advantages to be drawn from this for machine (assisted) translation, translation memories and their related terminology databases. The corpora required for this type of research need to consist of texts that are not just well written, in the sense that they represent texts normally produced in a particular domain of knowledge: they need to use terms that are generally accepted in the community that works in that domain. When translations exist of these texts, they, too, need to conform to the same standards of text and terminology in the target language if one is to produce good aligned parallel corpora.

The experimental work done in computational terminology usually involves standardised texts in which both originals and translations are considered to be of high quality. Some of these texts have been provided by organisations like XEROX (see Bourigault 1994). The texts are often chosen for their linear compatibility (See Blank, 2001), which allows for easy alignment at, at least, sentence level, and the standardisation of their technical terminology. This is understandable, since it will only be possible to proceed with the analysis of a wider variety of texts when some sort of procedure has been worked out on the basis of these controlled corpora – rather as machine translation is better at translating controlled language than Shakespeare.

There is, of course, a lot of textual material that apparently conforms to the needs of this type of research. The European Commission has worked hard at making as many of its multilingual texts available as possible. In order to do this, the translation services have effectively created enormous translation memories full of texts translated by themselves, and one can presume that the terminology used is usually supported by the EURODICAUTOM database, which is itself the result of many years of effort by a large number of people. The large multinational companies that have invested heavily in translation memory software and terminology databases could also provide a vast amount of material. Organisations like the International Standards Organisation could provide invaluable material once its standards are efficiently translated in other languages. After all, not only do these standards and their translations represent ideal parallel corpora, but the very purpose of the texts themselves is to standardise the terminology used.

4. 'Real-life' terminology

There can be no doubt that a lot of the work to which we have just referred is impressive and of high quality and, therefore, a reliable source of information for the most necessary function of all these texts – the communication of knowledge. However, anyone who has worked seriously on producing terminology with the collaboration of experts will realise that the notion of 'one concept = one term' is an ideal, not a reality. International classifications that do exist have sometimes tried to escape the problems of normal language in different ways, as when natural species are classified in Latin, or chemical and mathematical concepts use formulas and symbols.

There are various reasons why the 'one concept = one term' notion is an ideal. It is easy enough for the linguist to understand the fluidity of the lexicon. After all, one of the perennial problems of general linguistics is how to deal with it in an easily classifiable way, hence all the work with projects like Wordnet (at: http://www.cogsci.princeton.edu/~wn/). On the other hand, experts in any particular domain are also aware of the fluidity of concepts and probably spend a good deal of time arguing about how to stabilise them for practical purposes - and stable terminology is only one aspect of this problem. In practice, they often resort to diagrams, images and other pictorial representations in order to circumvent or supplement the limitations of language. The general public, however, likes to believe in the stability of both language and concepts, and, for the practical purposes of communication, we all accept that there has to be some sort of 'social contract' whereby we agree to this stability in order to understand each other.

Prescriptive terminology has usually aimed at providing this stability in an organised fashion and most specialised dictionaries and glossaries are the result. The technology of databases, however, allows for a more descriptive approach, with all the implications this has for including all the information terminologists collect in the course of their work. When one is no longer limited by space on paper – a major factor in previous lexicographical work – the prospects of including all the information available and/or prescribed by international standards for terminological databases are, to say the least, tempting. These prospects may seem unnecessary to the more immediate problems of communication, but they contribute in no small way to various visions of the systematisation and documentation of knowledge.

Terminology is not the simple accumulation of words, their equivalents in other languages, definitions and a certain amount of grammatical information. Nor is it the simple matching of term to concept. One has to deal with all the usual problems of language - social, geographical, historical, political, and other aspects of style and register. At the level of standardisation, one can even become involved in authentic battles between academics or commercial companies who want to see the words they use to describe their particular theories or products prevail.

5. 'Real-life' corpora

When one is not working for the interests of computational terminology, one will probably not have access to the type of standardised corpora already described, except for the online documentation of the European Commission. Besides this, these standardised texts, no matter how well written or translated, tend to reflect a degree of deliberate homogenisation of style and register across languages. In the more routine terminology work carried out in universities and other institutions, every terminology project will come up against a different situation, and circumstances will play an important role.

First of all, one has to find what texts are available in the domain one is studying and it is more than likely that the most important ones will not be in digital form. We have found that this is often the case when one wants to use first-class academic texts published by well-known publishers. Working with industrial or commercial institutions or companies is one way of obtaining texts, but we have not yet tried this, partly because it will

require careful negotiation, and partly because we have found several academic partners interested in cooperating on a serious and more unbiased basis.

One can always scan texts, and there are, of course, plenty of texts already in digital form. It is often easy enough to obtain permission to use these texts if one explains why one needs them and what one intends to do with them, as there is plenty of interest among domain experts to see their terminology systematized. The Internet, as we all know, can provide an enormous amount of material in certain areas, but is less useful in others. For example, we have found it of limited interest for certain engineering terminology projects because both the high level expert-to-expert type of academic article and the more didactically orientated teaching text are not freely available to the general public. Too often one ends up with commercial sites trying to sell certain types of engineering equipment, and the information thus obtained is not necessarily very reliable. In the area of population geography, however, where one is dealing with a subject that cuts across the disciplines of geography, sociology and demography, one project group was able to find a sizeable amount of material in several languages, of both a parallel and comparable nature, precisely because there are plenty of official or governmental institutions who want to publish such material on-line. The other interesting aspect of this area is that the subject is relatively new and the relative instability of the terminology was observable in the texts found.

As our projects must have a Portuguese component, one of the problems we have found is that some languages are more equal than others. If the languages involved are English, French or German, there is a chance that one will be able to find reliable texts of a parallel or comparable nature, but the same will not be true of less used languages. We have found this to be true at all levels of text we look for. We have also found that the translations of websites - whatever the original language - are often of poor quality and cannot be used as parallel corpora.

6. Teaching and Project work

The type of project work we have done over the years started as a typical translation exercise in vocabulary research that owed much of its dynamics to the fact that the translation classroom contained PCs connected to the Internet. Our curriculum had been formulated by believers in the notion that 'general translation', together with six months placement at the end of the course, was sufficient for training Modern Languages students to become translators. Our experience, and that of our graduates, soon told us that this was far from enough and we developed specialised subject project work as a way of training students in LSP (see Maia, 1997 and Maia, 2000) within the limitations of the curriculum. We have now moved on to interdisciplinary postgraduate training in terminology and translation work, working with professors from the Engineering Faculty and History and Geography departments. Our early wordlists processed in Word have now developed into more sophisticated terminology work in Excel and Multiterm, and include definitions, sources, images and other data fields. We soon hope to have our own database system and make it available online.

Corpora have always been obligatory elements of our project work but, although we have collected quite a lot of specialised mini-corpora over the years, we admit that they have not always been the most successful part of the projects. There are various reasons for this. On the one hand, perhaps the biggest enemy of terminology related corpora work is the large number of existing on-line glossaries on everything under the sun that our students soon discover from each other. One can, of course, argue that these glossaries, which are often easy to copy or download, are in themselves language resources of the type we are discussing here. However, they are usually monolingual, largely in English, often rather general in scope, and infrequently backed up by any form of official recognition. When the glossaries are good, complete, and officially recognised, adding Portuguese terminology to them is usually beyond the scope of an undergraduate project. Of course, one might argue that beginners could do worse than discover how to convert them into their own languages.

The big problem here is that such work merely encourages the idea that finding the 'right word' is enough. This means they miss out on the didactic strengths of making mini corpora - the understanding of the subject itself, brought about by having to find and read texts, the appreciation of different types and styles of text gained while doing this, and the extraction of terms in context. Although students are encouraged to use software like Wordsmith to look for keywords and to study concordances of both general language words and specialised terminology, there is always a preliminary stage when the actual reading of the texts is necessary – at least from a pedagogical point of view. If they are lucky, they will also find definitions in the texts, although these are not as frequent, or as reliable, as the literature on the subject would have us believe.

There are successful types of glossary work that do not require corpora, such as some excellent ones our students have done on tools of various types – e.g. carpentry and gardening tools - in which the 'corpora' were largely catalogues with images, and students had to work hard to make the words in both languages match the pictures provided, a process that involved plenty of questioning of individuals, but little text work.

7. Conclusions

Corpora and terminology research can work well together, but they are not always equal partners. Ideally, students should be able to find good texts and extract terms, definitions and other information from them. When mini-corpora form the basis for terminology work, the process of producing the terminology project is didactically more valuable, and it is an easy step from collecting and aligning texts, and then using concordancing, to understanding the theory behind translation memories and other software and making them work in practice. As we have said, however, valuable terminology work can be done without resort to corpora. Perhaps the most important attitude to adopt towards project work is flexibility, since each domain brings its own circumstances and problems. If at the end of the experience our undergraduate students have learned how to take special languages seriously, the main objective has been achieved. Our postgraduate students already know

how important they are and need to learn how to progress further, and perhaps even join the process of research into computational processes that will speed up the accumulation of valuable resources for all of us who do not want to see the world speaking only one language.

Working Together: A Collaborative Approach to DIY Corpora

Lynne Bowker

School of Translation and Interpretation, University of Ottawa,
70 Laurier Avenue East, Room 401, Ottawa, Ontario, K1N 6N5, Canada
lbowker@uottawa.ca

Abstract

Corpora can be invaluable resources for translation students, but creating DIY corpora on a frequent basis can be a time-consuming exercise. This paper describes an experiment whereby the students in a translation class worked in collaboration to build corpora for use in their technical translation course. The guidelines used for this collaborative approach are outlined, and the results of the experiment are discussed. A general discussion on the value of the World Wide Web as a resource for building DIY corpora is also include.

1. Introduction

Researchers such as Zanettin (1998), Yuste (2000), and Bowker and Pearson (2002) have amply demonstrated the value of using corpora as translation resources in the context of translator training. However, there are relatively few "ready-made" or "off-the-shelf" corpora available for use in specialized domains, so translator trainers and/or students typically need to construct their own. This paper outlines an experiment that was conducted with 4th-year undergraduate students in a French-to-English technical translation course. The purpose of this experiment was to see if it was possible for the class to collectively build "DIY" or "disposable corpora" (Varantola, forthcoming) that could be used as resources for their translation course work.

My previous experiments with corpus building had proceeding following either a teacher-centred approach or a learner-centred approach. Both of these approaches had a number of drawbacks. In the case of the teacher-centred approach, the translator trainer was responsible for constructing all the corpora – a job which proved to be very time consuming (resulting in relatively small corpora) and which excluded the students from the design phase of the corpus building process. In the case of the learner-centred approach, each student was individually responsible for building his or her own corpora. This approach also proved to be inefficient, with students building corpora that were often small and generally poorly designed.

It was hoped that by adopting what Kiraly (1999 and 2000) and Yuste (2001) refer to as a learning-centred and collaborative approach, the resulting corpora would be larger and more useful, and the students would engage in active discussions with the trainer and with each other and would move towards becoming empowered critical thinkers and more independent learners.

2. Setting the parameters

In order to ensure that things ran smoothly during the collaborative exercise, it was necessary to first establish a number of guidelines or ground rules. The following strategy was developed and refined based on our experience over the academic year. It addresses the following issues: a) coordinators, b) number of texts contributed by each student per corpus, c) quality of texts, d) time frame, and e) file format.

2.1. Coordinators

For each corpus, two students would act as coordinators. When students were acting as coordinators, they did not have to contribute texts to the corpus (but they still had to do the actual translation homework). Essentially, the coordinators were to act as a sort of clearing house. Students in the class would e-mail their texts to a special account set up for the coordinators, who would 1) evaluate these texts for relevance, and 2) eliminate duplications (i.e., cases where the same text had been submitted by multiple students). The remaining texts would then be collated into a single corpus that would be posted on the class Web site.

2.2. Number of texts contributed by each student per corpus

Each student (with the exception of the coordinators) would try to identify three relevant texts that would make a good addition to the corpus. Given a class of between 20 and 30 students (this class had 22 students), this number was considered to be a reasonable goal; however, it was not an absolute. If a student could only identify two suitable texts, these would still be welcome; likewise, if a student located four or five relevant texts, they could all be submitted.

2.3. Quality of texts

The students agreed to put some time and care into selecting their three texts. It was noted that if everyone were to simply submit the texts corresponding to the first three hits that came up using a Web search engine, then there would be a lot of duplication and the texts may not be pertinent, which would limit the value of the corpus.

2.4. Time frame

In order for the process to run smoothly, a reasonable amount of time had to be given for both the contributions and the coordination. It was agreed that each target text would be distributed three weeks in advance. Students would have one week to identify suitable texts and e-mail them to the coordinators. The coordinators would have one week to check the texts for relevance and for

duplication, to amalgamate the texts into a corpus, and to post this corpus on the class Web site. All the students would then have one week to consult the corpus.

2.5. File format

Students e-mailed their contributions to the coordinators as attachments in plain text (ASCII) format. This simplified the job of the coordinators as it meant that they did not have to worry about having access to different types of computers or software packages and they did not have to manipulate different file formats. It also ensured that the corpus would be in a format that could be manipulated by the corpus analysis software to which the students had access (i.e., WordSmith Tools). In addition, it reduced the chances of spreading viruses.

3. Results of the Collaborative Corpus Building Exercise

In order to give some coherence to the course, the theme of "computer security" was selected and seven different source texts – each of a different text type and each focusing on a different subject relating to computer security – were chosen. Table 1 summarizes the corresponding comparable corpora that were compiled as part of the exercise.

4. Discussion

This section will outline strategies used by the students in selecting the texts and compiling the corpora; difficulties that were encountered and solutions used to overcome them will also be discussed. In addition, some general comments will be made on the suitability of the World Wide Web as a resource for building comparable corpora. Specific details about techniques used to extract translation-related information from the corpora have been detailed elsewhere in the literature (e.g., Bowker, 2000; Bowker and Pearson, 2002) and so will not be repeated here.

The first corpus to be constructed was on the subject "passwords", and the text type was a FAQ, which is a list of *Frequently Asked Questions* (and answers) about a given subject. In total, the students submitted 58 texts for possible inclusion in the corpus; however, there was a high degree of duplication and the final corpus ended up containing only 23 texts.

A class discussion following the creation of this first corpus revealed that most students preferred to use the Web to identify comparable texts. Other resources, such as CD-ROMs and online databases, were available in the university library; however, many students had Internet access from home and found it more convenient to work from there. Their preferred method of identifying texts for inclusion in the corpus was to read the source text and then select potential subject key words to enter into a search engine. In the course of the discussion, it was revealed that most students used the Alta Vista search engine, and many of them had not been very discerning when it came to selecting the three texts that they contributed – they often simply took the first three hits that came up. In order to identify a wider selection of texts for future corpora, students agreed to make an effort to look beyond the first three hits. Moreover, we discussed the fact that different search engines index different Web sites, which means that the hits returned by one search engine may be different than those returned by another. Students agreed to use a wider range of search engines (and meta search engines) when looking for comparable texts, and it was hoped that by doing this, there would be less duplication in future corpora.

The next three corpora were intended to help translate an instructional text on "antivirus programs", a popularized informative text about "encryption", and a buyer's guide for "firewalls". In the world of computer security, these are all popular subjects and common text types, so there was a lot of information available. In particular, popularized informative texts are among the most common type of text on the Web, and many of the texts identified by the students were quite long, which elevated the word count of the encryption corpus considerably. Given that there were many texts to choose from, a number of students submitted more than three texts each. Moreover, the degree of duplication for these three corpora was reduced as a result of the students' efforts to use different search engines and to look beyond the first three hits.

The corpus on "steganography" was supposed to be used to help students translate a product description. Steganography is much less common than other security measures and there are a limited number of products on the market. Consequently, the students found that there were fewer texts to choose from with the result that only 35 texts were submitted, and of these, only 14 were retained. Of the texts that were rejected, many were duplicates; however, the coordinators also rejected a number of texts that were not of an appropriate text type. Given the relative scarcity of comparable texts, some of the students had submitted texts that were about steganography, but which were not product descriptions. Similar behaviour has been observed by Pearson (2000), who notes that translation students sometimes show poor judgment when sourcing terminology and phraseology from comparable texts. For example, they are often primarily concerned with identifying texts that deal with the subject matter in question, but they do not ensure that the texts they choose are comparable to the source text with respect to its other features, such as register, technicality and text type. In a class discussion, the matter was raised and it was emphasized that in order for a text to be "comparable", it had to take into account text type as well as subject matter.

The source text on biometrics was an extract from a research article. There were 29 comparable texts submitted, but only 12 of these were retained. However, since research articles tend to be long, the word count was still reasonably high. The main problem that the students had was in finding the relevant text type on the Web. Although there were a number of hits that looked promising, many of these links led to Web sites that required a paid subscription in order to gain full access to the contents of the site (e.g., online journals). This led to a discussion about other non-Web resources that may be useful for building corpora, including the *Computer Select* CD-ROM, INSPEC abstracts and a variety of online

journals that were part of the university's library collection. It was noted that although students would rather work from home (hence their preference for consulting the Web rather than the library databases), it was not unreasonable to expect them to make a trip to the library in order to consult more appropriate resources.

Subject	Text type	Texts submitted	Texts rejected	Number of texts / words in corpus
Passwords	FAQ Web page	58	35	23 texts / 40,600 words
Antivirus programs	Instructional	78	22	56 texts / 170,919 words
Encryption	Informative/popularized	74	19	55 texts / 216,522 words
Firewalls	Buyer's guide	63	18	45 texts / 136,017 words
Steganography	Product description	35	21	14 texts / 7,401 words
Biometrics	Research article	29	17	12 texts / 69,651 words
Cookies	Technical encyclopedia entry	41	19	22 texts / 11,754 words

Table 1: A brief description of the corpora produced as part of the collaborative corpus building exercise.

Finally, the source text on "cookies" consisted of an entry taken from a technical encyclopedia. Once again, there were relatively few submissions (41 texts), coupled with a high degree of duplication (only 22 texts were retained). This was because there are a limited number of electronic technical encyclopedias that could serve as comparable texts. Furthermore, it was observed that the entries in such encyclopedias tend to consist of short texts, which resulted in a relatively low word count for the corpus as a whole.

5. General observations about using the Web as a resource for building DIY corpora

In addition to discussing particular problems that came up when creating specific corpora, the class also discussed a number of more general points, many of which concerned the nature of the Web and its suitability as a resource for building DIY translation corpora. For example, it was noted that there are many texts on the Web that are of poor quality and which therefore do not make good translation resources. When asked to reflect on potential reasons for this poor quality, students came up with the following possibilities. Firstly, they noted that anyone can post information on the Web, including non-subject field experts and non-native speakers, and that Web documents are not always subject to an editing process in the same way that printed documents usually are. Furthermore, the Web is seen by many as an ephemeral resource; people are interested in communicating information, but unlike the case with printed documents, this information may not be preserved for long (i.e., a Web page can be revised, updated or removed very easily) and so people are less willing to invest much time or effort in formulating that information. In other words, many people feel that a Web page does not need to be elegant (or even grammatically correct!) as long as it adequately conveys the essential information.

Another comment focused on the types of texts that are commonly found on the Web. Given that the Web is most often used as a means of disseminating information to a non-expert audience, it contains primarily informative or instructional texts that are popularized. More specialized material and different text types can be accessed via the Web, but such information is often available only by paid subscription. This means that while the Web can a valuable resource for constructing corpora that deal with popularized informative texts, it may prove less helpful for constructing corpora that must comprise other types of texts.

A similar observation was made about the languages of texts available on the Web. The students in this class were attempting to compile comparable corpora containing English-language texts, of which there are many on the Web; however, they noted that for translators working in less widely-used languages, there may be fewer texts available (at least for the present, though hopefully this will change over time).

The very nature of the Web gave rise to two other observations. Firstly, the idea behind hypertext is that people can jump from page to page to view associated information. Good Web design dictates that there should be a limited amount of information on each page so that people are not required to scroll unnecessarily; related pieces of information should be provided on separate pages with relevant links between them. When compiling a corpus from the Web, each page must be copied/saved separately and then later amalgamated into a corpus. Therefore, from a corpus builder's point of view, it would be preferable to have a single page containing a lot of information, as this page could be copied/saved in one operation, rather than having that same information spread over several pages, which would then need to be copied/saved separately. This basically means that good Web design is not conducive to easy corpus building! Secondly, the multimedia nature of the Web is another characteristic that is not always conducive to building text-based corpora. On a number of occasions, students rejected Web pages that would have been extremely useful sources of information but which could not easily be incorporated into a text-based corpus because their primary value resided in their graphical or audio content. This raises an important point: a corpus can be an invaluable resource, but it is not a panacea. There are many other complementary types of resources that can

also provide helpful information, and these should not be ignored.

Finally, the sheer volume of information that is available on the Web made students aware of the importance of formulating search queries carefully in order to be able to focus in on relevant material. As previously mentioned, students tended to read the source text first in order to get ideas for potential key words. These words were then entered into a search engine, and the resulting hits were examined for relevancy as well as for ideas for other key words that could be used for further searches. In addition to key words that dealt with the subject matter, students also found that it could be useful to enter key words relating to the text type. For instance, a search using only the subject key word "cookie" returned many irrelevant texts such as recipes; however, a more carefully formulated search that combined subject and text type key words, such as *+cookie +computer +encyclopedia*, returned hits for entries for "cookie" in resources such as *The Grand Encyclopedia of Computer Terminology*, *TechEncyclopedia* and *PC Webopedia*. Other tricks, such as remembering to search for alternate spellings (e.g., encyclopedia/encyclopaedia) also helped to increase the number of relevant hits. In addition, as mentioned previously, the students also found it useful to conduct a search using a variety of different search engines or a meta-search engine. Bergeron and Larsson (1999) provide additional tips for effective Internet search strategies for translators.

6. Concluding Remarks

Overall, the collaborative corpus building exercise proved to be a worthwhile experience. The students demonstrated that they were eminently capable of working together to construct valuable translation resources, which they could then consult to identify relevant lexical, phraseological and stylistic information. Not surprisingly, of the seven collective corpora that were built, the larger ones, such as those on antivirus programs and encryption, tended to contain a greater number of examples. Of more interest, however, is the fact that even the small corpora, such as those on steganography and cookies, contained useful information. This supports the point made by researchers such as Rogers and Ahmad (1994), who note that when working in specialized fields, it is not necessary to have the sort of multimillion word corpora that are typically required for general language work.

In addition to furnishing students with an opportunity to explore the merit of corpora as translation resources, this exercise also provided a valuable opportunity for a shift in pedagogical strategy. The collaborative corpus building exercise made it relatively easy for the trainer to take on the role of facilitator (rather than information provider), which in turn allowed the students to become independent learners and critical thinkers, who were encouraged to reflect on the characteristics of different text types and on the suitability of the World Wide Web as a translation resource. Acting as both contributors and coordinators, students learned to identify relevant features of texts and to be more discerning with regard to the appropriateness of a text (e.g., in terms of quality, text type, nature) for use as a resource for the translation at hand.

Abstract

This paper aims at raising awareness about electronic language resources (henceforth LR) in the translation community at large. Examining how technological advances in the profession have transformed the notion of translating itself and what is expected from a qualified translator today, the paper goes on to focus on resources, rather than tools. It then discusses what type of LR should feature in the training of professional translators, and how these should be tackled in various translation-training settings. It contains several useful pointers throughout the article and an extensive bibliography covering the various issues addressed herewith.

Keywords: translation profession, language professional, qualified translator, translation training, tools, resourceful, resources, language resources (LR), corpora, translation technology and HLT, academic training, vocational training, collaborative approach, real-life scenarios, translation workflow, multi-user access, corporate language, content management, resource creation / maintenance / evaluation / validation / exchange, exchange standards

1. Introduction

Traditionally speaking, translation has been regarded as a craft, a fairly unusual gift that, for some, did not even require formal academic training, let alone continuous education on (technological) advancements in the profession. From that standpoint, the translator's major asset, and only utensil, is his or her own competence for translating, that is, some special ability to transpose meaning from one language to another. But even if natural linguistic talent is always desirable, translators cannot solely rely on it to succeed as language professionals today. Translating has become a complex and permeable professional activity, which among other things requires plenty of intercultural sensitivity and disposition to adapt to new work patterns.

In fact, professional and qualified translators (against the unqualified intruders that slip in the translation profession) do usually gain respect and recognition (and in practical terms, are more employable) for being *resourceful* and acquainted with the *tools of the trade*. But what do we mean by 'resourceful' here? 'Resourceful' in that they are expected to be capable of resolving linguistic problems (and/or cultural misinterpretations) efficiently and at once? Or perhaps, 'resourceful' in that they ought to be familiar with resources that allow them to find the right information at a mouse click? What 'tools of the trade' do we refer to? Are commercial translation memory[1] packages the hot tools for translators, the one and only?

1.1. Tools …AND resources, please!

Up to the late 20th century's information revolution, heavily characterized by the advent of the personal computer (PC), the so-called ICT[2], and the Internet, the translator's *tools* had primarily been pen and paper (without forgetting about the now old typewriter and the Dictaphone®). Of course, *paper* understood in its broad sense (different sizes, textures, colours…) as a means to **manually** catalogue, archive and, hopefully, retrieve – throughout the years – translation notes, bibliographical references, and laborious samples of terminographic work. Undoubtedly, these were extremely valuable (and praiseworthy) *self-made resources* under a not very convenient support.

Other conventional translators' *resources*, linguistic and non-linguistic, consist of printed dictionaries and reference materials (such as voluminous encyclopedias –now online[3]), as well as certain cultural and/or domain-specific knowledge, gradually acquired through reading, visits to libraries, travelling, life experience and, sometimes, long discussions with fellow translators and subject experts over a cup of coffee.

Although the latter still works for some translators to some extent, the newer generations normally resort to other (quick-access) information sources and data processing applications, usually computer (e.g. on CD-ROM or DVD) or Web based, in order to accomplish their translations. Not surprisingly, 'tools' and 'resources' often get listed as *useful links* in Web sites and other publications for the translator, without making much of a distinction between them. However, I would like to see these two concepts differentiated (despite their undeniable affinity – and even interdependence[4] – in today's translation workflow),

[1] *Translation tools* have become the buzzword in translation educational and work contexts. By and large, they are usually identified with translation memory (TM) packages, the apparently ideal solution for a cost-effective and consistent translation. Yet, apart from these tools managing and reusing previously translated repetitive input, translators also ought to get to know about tools that allow them to create, retrieve, exploit, interconnect, and exchange…*language resources* (LR) – simply because LR are their most precious resources.

[2] Acronym of 'Information and Communication Technologies'.

[3] E.g. *Encyclopaedia Britannica* (http://britannica.com).

[4] If a translator uses a terminology management program to manage their terminology records, then the program itself would be the *tool* whereas the resulting records would be the

since this paper will concentrate upon *resources*, rather than *tools*.

In essence, *tools* should refer to those instruments or equipment (e.g. ball-pen, computer, printer, software program, etc.) that translators use in their daily work or that they need for a particular job assignment (e.g. a concordancer[5] for automatic term extraction, the comment utility of a word-processing software for proof-reading, etc). But equally important are *resources* (e.g. corpora, dictionaries and reference materials, glossaries and terminological databases, etc.), especially *language resources* (henceforth LR), since these are useful elements in the translation process and contribute to enhancing the translator's professional profile.

1.2. LR and HLT applications – something to equip the language professional, too

Moreover, in the area of HLT[6], where translation technology indisputably has its place, LR can be essential *components*. Without them, many research and real life systems would not see the light. Godfrey, J. J. and A. Zampolli (1996) thus define LR as '…(usually large) sets of language data and descriptions in machine readable form, […] used in building, improving, or evaluating natural language (NL) and speech algorithms or systems. Examples of linguistic resources are written and spoken corpora, lexical databases, grammars, and terminologies, although the term may be extended to include basic software tools for the preparation, collection, management, or use of other resources.'

Apart from offering us an overview of LR, Godfrey & Zampolli stress the fact[7] that LR may be extended and used to elaborate other resources, then including or interacting with tools. This is an important aspect for translation work and research. LR are usually conceived with a purpose in mind, but they may serve other purposes later, by being expanded, tailored to the needs of another user-group or integrated in a system. For instance, a paper-based glossary is linguistically-enriched (i.e. annotated or marked-up) and transformed into electronic form to become available in an organization's intranet; a few navigation and edition tools are added to allow for rapid cross-referencing and regular content updates. Some time later, this and other LR are part of a new terminological workbench, also accessed by translators and domain expert validators working for the same organization. Since the time this resource gets digitized, its lifecycle varies dramatically according to its functions and targeted user-groups.

The *resourceful* language professional[8], interested in the advances of the profession, should thus be able to create, use, and evaluate those LR serving their job or area of specialisation needs better. Translation training programmes should then prioritize topics related to LR creation, manipulation, and evaluation.

2. Goal of the paper

This paper therefore aims at discussing the importance of resources, in particular LR, shaping every facet of translation (the training of translators, the profession itself, translation as part of global content production, etc.). Ideally, our translator will be conceived as an eclectically evolving, and qualified language professional, rather than as a word artist exclusively.

3. LR in the training of translators

In order to response to revolutionized translation work patterns, most translation training institutions have incorporated some technology-related elements within their syllabuses, but it still remains unclear whether they are sufficient and efficient enough. Whereas at the beginning much emphasis was given to introductory modules on IT[9], most recently some commercial translation memory packages seem to be getting all the attention.

In 1999, the LETRAC[10] commission reported that in the surveyed translation training institutions[11] across Europe, 'LE/IT [not expliciting the concept of LR, though] in translator curricula vary from nothing but basics in word processing to a broad range of sophisticated software tools (terminology management, translation memory, machine translation, Telecommunications / Internet, CD-ROM-based information systems...).' Also of interest are their

resource. But, obviously, given this interdependence between tool and resource, one might argue that there is a very fine line between the two.

[5] A *concordancer* is a software application aimed at retrieving *concordances* (an automatic display of a word or phrase occurrence/s, known as KWIC – key word in context, surrounded by left and/or right accompanying words) from a text or corpus previously loaded. As this tool allows for rapid linguistic insight of any word, it is of great value for the linguist, lexicographer, or translator. This is why most translator workbenches include now a concordancer among their growing panoply of utilities.

[6] Acronym of 'Human Language Technologies'.

[7] Fact also reported by OVUM (1995): 'In order to provide users with a working system adapted to their environments, […] linguistic resources may also include the ability to create other bi-lingual, multi-lingual or reversible dictionaries to provide terminology quickly in other language pairs'. The potential multi-user access is also highlighted.

[8] The term *language professional* is normally applied to translators, who do not perceive their professional activity restricted to translation in its traditional sense. It may also be applied to other professionals working with language, such as terminologists, proof-readers, cross-cultural multilingual advisers, content managers, etc. They all are key *language industry* players.

[9] Acronym of 'Information Technology'.

[10] LETRAC - *Language Engineering for Translators Curricula*. EU-funded research project that run from 1998 to 1999, whose aim was to survey best practices in the training of translators enhanced by language engineering (LE) components.
http://www.iai.uni-sb.de/LETRAC/home.html

[11] Reuther, U. (ed.). April 1999. 'LETRAC survey findings in the Educational Context', Deliverable D1.2.

observations[12] on how (the type of) training has a determining effect on translators' professional success:

- 'A translator does not only perform translation.
- Training in IT should be obligatory.
- Translators do not feel well prepared by their institutions for the real world of work.
- Translators gained their present LE/IT knowledge mainly from work experience, by means of "learning by doing".
- Among freelancers, two extremes can be observed: those translators who follow the principle *as little IT as possible*, and those who can cope with virtually all aspects of new technologies. The latter are those who do better economically.
- Most translated texts are LSP[13] texts; therefore specialised translation and terminology should be an essential element in curricula.
- There is a lack of qualified IT-specialists on the translation market. Translators with LE/IT-skills have far better professional prospects.'

These reflections show the big challenge for translation training institutions posed by global language market needs, described by Shreve (1998:5) as 'an evolution in fast-forward', highly dominated by the areas of multilingual technical communication and software/web localization.

3.1. LR in academic training

Plenty of translation scholars and researchers have advocated the use of corpora in the classroom, presented them as invaluable analytical resources in TS[14] (among others, see Austermühl 2001, chapter #8, Baker 1992/3/6/9, Bernardini & Zanettin 2000, Bowker 2000a/b and 2001, Kenny 1998, Laviosa 1997, Pearson 1996/8, and 2000, Tognini-Bonelli 2000, Ulrych 1997, Yuste 2000/1, Zanettin 2000/1 and forthc., as well as Hansen and Teich, Olohan, Zanettin, Maia, and Bowker, in order of appearance in this vol.), and also created tools for their exploitation or access (see Badia et al., and Barlow, this vol.). However, it appears that a generalized systematic inclusion of LR, mainly corpora, in translation training curricula still remains a necessity (Yuste, forthcoming), especially in places where English is not an official or a tuition language.

It is beyond the scope of this paper to advocate again for corpora in translation training scenarios. Yet, it is relevant to bear in mind that translators 'need, above all, to acquire a sound knowledge of the raw material with which they work: to understand what language is and how it comes to function for its users' (Baker, 1992: 4). This is better achieved through meaningful training activities whereby future translators look into authentic (against pre-fabricated) language instances in context. Besides, corpora allow the translator trainer to keep a steady balance between theoretical linguistic insights and practical applications.

Most importantly, one should not forget that many aspects of corpus linguistics (e.g. concordancing, alignment, parallel corpora) are present in current and future language/translation technology applications. Future translators should be made aware of the fact that the commercial TM package available in their lab contains such and such corpus linguistics features. It is only when modern tools for the translator are presented comprehensively and, if necessary, theoretically backed-up, that the translator can fully understand the mechanisms behind the tool. He or she is then also empowered to make the most out of the tools or applications at hand.

Tools such as translation and localization workbenches, knowledge and content management systems, to name but a few, are usually solutions which get constantly fed with linguistic data, i.e. LR such as corpora. Under such circumstances, it is important to promote research linked to market needs, e.g. fostering of LR *exchange*[15] *standards* or *reusability* (see Kübler, this vol.). An ideal first step is to get future language professionals involved in the creation and maintenance of resources, such as (DIY) corpora (see Zanettin forthc. and Zanettin, Maia, and Bowker, this vol).

In this line of work, it is important to follow *collaborative* (see Kiraly 1999/2000 and Yuste 1999/2001) and *project-based* training approaches, whereby future translators do not only learn about how to create or exploit shared LR but also get used to teamwork, project management, etc. – skills so highly appreciated in corporate and institution settings where cross-site language work is crucial.

3.2. LR in vocational or continuous training

Most technology-related vocational or continuous training courses on offer for future and practicing translators deal with TM systems or localization tools, sometimes with little reference to LR, such as corpora. Software tools producers (usually their marketing-oriented training departments), translation training academic departments (often postgraduate course modules devoted to translation technology, which may be opened to an external audience), and occasionally translators' societies or bodies organize these courses, whose training quality and price can vary considerably.

Their merit is mainly to aim at compensating for the lack of up-to-date technology-aided translation training in formal academic settings. These courses, heavily market-oriented, should nevertheless employ solid

[12] Reuther, U. (ed.). April 1999. 'LETRAC survey findings in the Industrial Context', Deliverable D2.2.

[13] Acronym of 'Language for Specific Purposes'.

[14] Acronym of 'Translation Studies'. Note that the impact of corpora in TS has lead to *Corpus-based Translation Studies* (CTS), with M. Baker as one of the main precursors.

[15] In that corpora, terminologies, language ontologies, output from TM systems, etc. may represent valuable LR not for the resource creator or first intended user-group only, LR have to be conformant to formats so that they can be exchanged, made accessible to other user-groups or integrated into other applications. For more information on recently agreed standards, such as TMX and TBX, see specifications drawn from the SALT Initiative and Abaitua (2001), Budin et al (1999), Budin & Melby (2000), Budin (2002), and Zerfass (this vol.).

training principles (see previous section) and real-life application scenarios (i.e. full description of interrelated components, usefulness of the tool within overall workflow, satisfaction and benefits for the translator, etc. instead of a mere exposition of reduction of costs).

3.2.1. Training on LR at the workplace

When the course takes place at the workplace, it is of utmost importance to analyze what the needs for LR (and any form of translation/language technology) are, not only for translators or linguists, but also for other staff members, such as resource evaluators and domain experts.

Similarly, it is advisable to look at LR from the *corporate language* (or even institution-wide language) perspective, and see how they may contribute to optimizing (global) multilingual documentation production. For example, to learn how to create corporate databases (product names, enterprise-wide terminology) helps reinforce a company's image, promoting clear, consistent communication and aiding cross-cultural understanding. *Controlled language* (see Fankhauser 2000) schemes (e.g. multilingual corporate style guides for written documents of all kinds) and *content management* (see Budin, this vol.) strategies may have to be implemented.

Finally, similar initiatives/solutions developed by other language industry players and organizations of the same sector will have to be carefully examined, not to reinvent the wheel. Ideally, language professionals (and other LR user-groups) will have to be able to maintain, customize and tailor existing LR, as budget controls may prevent them to create their own. Sharing and exchanging LR with other partners will be essential, and so it will be training focused upon LR exchange standards (see footnote #15).

4. Conclusion

Despite the length limit of the paper, we have attempted to discuss the relevance of language resources (LR) for the translator and the rapidly evolving translation profession in a comprehensive and up-to-date manner.

LR are crucial to transform the qualified translator into a *resourceful* language professional, able to respond to any challenge, and enhance any translation-related workflow. But, of course, nothing of this is possible without adequate and tailored LR training be it in an academic setting or at the workplace.

Abstract

We describe here the basic modules of a concept-oriented bilingual text-and-term-based knowledge management system (KB-NHH) to which students, teachers, researchers, domain experts, terminologists, linguists, translators and writers of various categories can turn for content learning, reference and documentation. The aim is to ensure that the interface between English and Norwegian is being handled with efficiency and consistency.

Primary user context of the implementation described here is an on-campus e-learning system.The aim is to facilitate the representation, learning, teaching and dissemination of relevant domain knowledge, to monitor changes in and development of the subdomain languages and to document all through authentic citations. Conceptual linkage of terms and authentic segments in the text bank allow source inspection and evaluation by user. Focus is on corpus-based term extraction, definitions, terminological representations, Norwegian-English equivalence problems and contrastive phraseology.

This paper makes a distinct contribution by proposing the integration of a conceptual knowledge-base with the textual manifestation of its underlying domain knowledge and its terminological representation in one or more languages, all in the context of a standard e-learning system. This should greatly facilitate learning by bridging the language gap experienced by native and non-native students alike in approaching a new knowledge domain.

1. The general problem

Communication in very specific domains of activity is crucially dependent on possession of specific domain knowledge and mastery of the specific domain language through which such knowledge is conventionally represented and transmitted. Whereas translation of general text between two national languages remains a general challenge for both human and machine translation, the translation of special domain text presupposes far greater proficiency in handling the content and representation of that domain knowledge.

Thus translation work undertaken along the interface between two special domain languages, each of which being entrenched in its respective national language, puts heavy demands on the translator's ability to control content and expression on both sides of the gap. Similarly a student of a specific domain faced with teaching or textbooks in a foreign language will have a dual problem: He or she will need to connect the technical terms and concepts encountered on the far side to equivalent concepts and terms on the near side, which in principle involves learning new content also in the native language. The need for a content and terminology management system at this point should be obvious, while the practical solution is not.

2. Specific obstacles

The potential problems arising in the contrastive language situation just described can be further aggravated if there are marked asymmetries between the two languages involved. In the domains referred to above English tends to be the source language for the overwhelming majority of communication involving bilingual text and terminology, and the pace at which new concepts and terms are created and disseminated can be quite hectic. This puts under considerable pressure a number of "lesser spoken languages", and particularly their cultural resilience and readiness for "terminological self defense". This makes it all the more important to compensate for the asymmetry by providing efficient and user friendly tools for managing the relevant language resources.

Fortunately the rapid development of information technology has placed tools within our reach which may enable even a lesser-spoken language such as Norwegian with 4.5m speakers to cope, partly at least, with such major challenges. We will describe here the basic modules of a concept-oriented text-and-term-based knowledge management system (KB-NHH) to which students, domain experts, terminologists, linguists, translators and writers of various categories can turn for content learning, reference and documentation. The aim is to ensure that the interface with English is being handled with efficiency and consistency.

The project described here is being developed in the context of the TERMINEC project, a three-year effort to establish the foundations of such a resource database for Norwegian and English special language as used in economic-administrative domains. What follows below is a description of a particular implementation of tools for bilingual data capture, terminology handling and application in a research and teaching environment dependent on economic-administrative communication. Due to space limitations the focus will be on modules involved in a web-based e-learning system.

3. The building blocks[1]

3.1. Data capture.

The foundations of the TERMINEC database are being implemented in the form of two parallel text corpora, one English, one Norwegian, of representative text from about

[1] "Modules" referred to in this section are shown in appended diagram

30 economic-administrative subdomains (see table 1), and a parallel term database whose contents are largely being derived from and dynamically linked to the text corpora.

One of the modules is thus a textbank (module 4 in appended diagram), a representative corpus of indexed full texts in the chief genres associated with didactic, expository and popularizing text types drawn from textual representations of the universe of subdomain knowledge (module 1).

Accounting and Costing, Capital markets, Corporate analysis, Corporate strategy and Ethics, Economic geography, Economic history, Economics, Economy systems and management, Finance, Investment, Information systems and management, Law (Corporate law, EU/EEA law, Tax law, etc), Macroeconomics, Management, Market communication, Market economics, Market research, Marketing, Mathematics and statistics, Microeconomics, Organization and management, Organizational behavior, Public economy, Quality management, etc.

Table 1: Tentative economic-administrative domains/subdomains

Typologically the text bank will contain English and Norwegian parallel texts both in the sense that they are original texts which share subdomain and genre, as well as in the sense of aligned translation pairs of source text and target text, which will increase the research value of the collections considerably.

3.2. Knowledge representation.

Terminological research is normally based on the onomasiological principle, the grouping of terms according to their conceptual meaning. Thus any knowledge subdomain can be characterized by a (partially) structured set of basic concepts which are represented linguistically through domain-focal terms (cf. Brekke, 2000). Establishing or extending conceptual systems (cf. module 8) becomes essential in achieving authentic representations of the knowledge which constitutes a given subdomain. This activity presupposes close cooperation between a domain expert and a trained terminologist (cf. "module" 2 & 3) in identifying and delimiting what the basic concepts are, conventional term usage, acceptable synonymy etc. The repository for their work is a termbank (cf. module 9) holding terminological units defined, classified as to subdomains, and mapped to their respective key concepts and conceptual hierarchies in module 8. Using the concept as a term record pivot (as is done in e.g. Trados MultiTerm, which is employed in the pilot project) facilitates the inclusion of other language equivalents (French, German and Spanish are obvious candidates for inclusion later on).

3.3. Term extraction (cf. module 5).

The slow time-honored techniques of "excerption" has long since been supplemented by increasingly sophisticated computational methods. Many of the results are impressive but have not allowed us to dispense entirely with the services of the domain expert in tandem with the terminologist. Given that the selection of input texts has yielded a representative corpus, it remains a sampling and thus very far from being exhaustive of the knowledge constituting a given subdomain. The problem is twofold: On the one hand, any automatically generated list of term candidates (cf. module 6) will reflect massive overgeneration of spurious combinations which will need to be pruned. On the other, no automatic term extractor will point out which basic terms are NOT represented in the sampled text, which takes an alert and knowledgeable human being.

The TERMINEC pilot project has allowed room for experimentation along these lines using SystemQuirk's suite of terminology tools. The point of departure is frequency lists followed up by selective concordance work. A typical subcorpus (of about 17000 words) yields the following (table 2):

90 internet	41 countries	31 investment
81 america	40 prices	30 companies
73 new	39 funds	30 capital
71 economy	37 years	30 fund
63 growth	37 economic	28 markets
60 productivity	32 technology	28 japan
45 firms	32 high	26 big
44 business	32 year	26 commerce
44 investors	32 risk	26 shares
41 market	31 share	26 pension

Table 2: Top of System Quirk's standard frequency list.

Some of these one-word units of fairly general scope can be identified as Economics terms, which is useful but of limited value. SystemQuirk provides two different functions for enhancing frequency lists to improve on our term enquiry.

3.3.1. Weirdness.

SQ exploits a "weirdness"-function based on a comparative ratio which expresses the likely occurrence of a given item in the text being scrutinized compared to the same for a large general corpus. Where the latter occurrence is zero the ratio will of course be infinite, indicating either a typo, a nonce word, or in fact a technical term, which is also indicated by a very high ratio. As a result a number of items occurring only once in a given text will be brought to the top of the frequency list, and such lists usually give significant inputs to the ensuing frequency studies. Table 3 (over) reveals a typical situation. It should be noted in table 3 that of the top 30 items on the list, 2/3 of them occur only once, which would effectively drown them out of the investigator's attention had not the "weirdness"-function been active (cp table 2).

While both tables contain terms which are immediately recognizable by an economist they only share one (*investment*), and those on the "Weirdness"-list are clearly of a more specific domain-related scope (and presumably less recognizable by a nonexpert). Table 3 has

12 inf!-terms, i.e. items not occurring in a large corpus of general English, while the remainder occur between 151 and 3 times more often than they would in that corpus. Thus their degree of specialization is approaching general usage.

3.3.2. Terms as strings of content words.

The other tool offered by SQ for sniffing out potential multi-word terms, aptly named Ferret, is based on a very simple algorithm: It takes a general list of function words as boundary signals and proceeds to identify any string of content words uninterrupted by such boundary signals as a term candidate. Table 4 displays the results obtained from examining the same text as above.

Frq	Match	SL/GL Ratio
10	capital markets	inf!
3	business cycle	inf!
2	annual report	inf!
2	central bank	inf!
1	new york stock exchange	inf!
1	dow jones industrial average	inf!
1	cost of capital	inf!
1	capital stock	inf!
1	european union	inf!
1	institutional investor	inf!
1	balance sheet	inf!
1	fiscal policy	inf!
1	solvency	151.2382
6	equity	88.5297
1	annuity	75.6191
1	takeover	75.6191
1	futures	50.4127
31	investment	35.1849
2	premium	32.7001
2	inventory	31.8396
1	liquidity	30.2476
1	diversification	27.4978
1	downstream	19.5146
1	revenues	10.2534
3	yield	8.0303
4	bond	7.8565
1	float	6.8745
1	commodity	5.5500
1	options	4.4482
1	margin	3.2700

Table 3: Top of System Quirk's frequency list with "weirdness"-function active.

For reasons which are unclear Ferret missed two of the occurrences of *capital markets*, and it does seem to invite some obvious refinements of its list of boundary signals, but otherwise the high end of the frequency list does throw up some promising term candidates.

3.3.3. Equivalence checking: Plugging the terminological holes.

In economic domains the terminological pressure from English has increased in proportion to the rapid globalization processes seen through the nineties and continuing unabated, while the readiness to invest in professional means for handling the textual interface has been lacking. Most of the recent efforts have gone into developing a speech interface, and the systematic monitoring and creation of suitable terminology for use in translating economic texts has been left to private initiative. Some subdomains thus appear well looked after, while others tend to end up with haphazard and ad hoc equivalents for newly formed concepts and terms from English-speaking

8 capital markets	7 pension funds	7 mutual funds
5 see chart	5 less than	5 life insurers
5 past decade	5 information technology	4 institutional investors
4 share prices	4 s economy	3 this year
3 on average	3 recent years	3 since america
3 point out	3 but there	3 this survey
3 other countries	3 retail sales	3 but even
3 cost savings	3 poorest countries	3 world bank
3 foreign aid	3 emerging economies	3 supply chain
3 short term	3 b2b e	3 s gdp
3 hedge funds	3 state street	3 an annual average

Table 4: Ferreted strings

cultures. Since the two languages have very close historical and lexical affinities, one should not be surprised to encounter a variety of terminological misfits, from simple (and humorous) "folk translations" through cognate shifts to serious "false friends" which may create hazardous and expensive mistakes.

Cognates constitute a rich quarry for terminological misfits. Consider the following examples:

*1. Federal Reserve Bank of Minneapolis President Gary Stern warned on Friday against the ``**moral hazard**'' that may prompt banks to undertake too much risk amid excessive confidence of government safety nets.*

Anyone connected professionally with hedging and insurance will recognize the special term (in bold). While each member of the phrase has a cognate with several

meanings in Norwegian, it is rather obvious that the connotations they bring along are quite different from the English ones. Nevertheless the temptation to use the "direct method" is clearly irresistible, as the following sample (from a sizable collection) will show:

*2. Kombinasjonen av usikrede lokale banker, **moralsk hasard** i utlandet, av kortsiktige utenlandske kapitalplasseringer og Pengefondets innstrammingspolitikk, ga kraftige negative utslag.*

A linguistically sensitive person familiar with the concept underlying the original expression in 1 (including their use as separate English words) will realize that the "calque" in 2 creates undesirable connotations. Unfortunately many will fail to see the problem, which allows the emergence of a Norwenglish (quasi-Norwegian) terminology lacking professional and cultural quality assurance. Arriving at the Norwegian equivalent "**åtferdsrisiko**" requires professional handling, time, and relevant domain knowledge (another subdomain prefers "**subjektiv risiko**"). It also requires an efficient dissemination channel to ensure its adoption and use.

Equivalence checking is thus serious and important business for anyone purporting to traverse the knowledge gap as well as the language gap through translation or related forms of text production. It appears to be one stage of the bridge building which cannot easily dispense with the bilingual human expert/terminologist or their term creation principles, be they linguistically, politically or culturally motivated. In other words, the bridge heads on either side must be anchored in their respective professional context, and the quality of work assured through a content and terminology management system. Only then can our efficient computer-based tools for processing and dissemination come into their own.

4. Dissemination and use.

At the outset the material held in the KB-NHH database will form the basis for student oriented bilingual domain glossaries with definitions, as well as genre-related material for learning and teaching. Both textbank and termbank will be SGML conformant, adhering as far as possible to the TEI guidelines, which allows interactive access via a Web-browser or ftp downloading. In addition all or parts of the termbank may be distributed on CD-ROM. Printed versions are possible, but the main emphasis will be on interactive use via electronic networks. This will take full advantage of the dynamic aspects of electronic media, allowing e.g. fuzzy matching of any search to the nearest form.

The diagram referred to in Appendix outlines the current architecture of KN-NHH, a "proof-of-concept" implementation of the e-learning oriented application of TERMINEC. The student enters the e-learning system (cf. module 11, a "Blackboard"-type system) via a standard web-browser (cf. module 10), accesses the course catalog and proceeds to the description/presentation of the course content in either English or Norwegian. All domain focal terms have active links to the central conceptual system. At this point the student may follow the link to the relevant term record in the desired source language, study definitions etc. and go from there into the text bank to inspect authentic text samples illustrating usage, phraseology etc. This is particularly useful for a non-native student. Alternatively the student may proceed directly from conceptual system to the text samples, and from there via clickable text-embedded terms across to the full term-bank representation of the desired concepts to study definitions, synonyms, acronyms etc.

Students approaching a new knowledge universe will easily detect concepts not adequately covered or explained. All searches will be logged to allow a study of user behavior and user needs, with a view to enhancing the intuitiveness of the user interface. Following an unsuccessful search the user will be asked (through automatic routines) to report unfound terms and submit a relevant text segment with source reference, and will have a chance to include responses or comments. It will be considered whether users also should be invited to join an «official» discussion group. Success in engaging the user in such dynamic interaction will not only provide a way of monitoring a continuous growth of the collection but may also create greater user identification with the KB-NHH, which in turn may have a standardizing effect.

5. Maintenance and development.

New concepts are constantly being created in the professional community and migrate towards general usage, sometimes even grabbing front page headlines: *unit-link*, *derivatives* and *hedge funds* have recently enjoyed such instant attention. At the time of writing *e-business* is very much in vogue (along with almost any noun with an *e-* prefix), and *creative accounting* is already a cliché in the financial headlines.

This implies that simply registering the constitutive concepts of a given domain, including their manifestation through the terminology of one or more national languages, is not done once and for all. What is required is a more or less continual monitoring of the entire life cycle of any given term, from creation through extension and expansion to disuse and eventual death. The above are random examples of an ongoing process which is in fact quite normal, although the speed and intensity may vary with the times and the subdomain. Ideally the new or altered terms would need to be absorbed by writers, their underlying concepts defined and systematized by domain experts and terminologists, standardized by professional bodies, and their usage documented through carefully vetted citations. At the receiving end of this process would be speakers of other languages (be they experts, journalists or textbook authors) who would ideally have to establish procedures for finding or creating equivalent terms and determine proper usage.

6. Outlook

This paper makes a distinct contribution by proposing the integration of a conceptual knowledge-base with the textual manifestation of its underlying domain knowledge and its terminological representation in one or more languages, all in the context of a standard e-learning system. This should greatly facilitate learning by bridging the language gap experienced by native and non-native

students alike in approaching a new knowledge domain. A well documented and web-accessible clearinghouse for English-Norwegian economics text and terminology as envisaged here would also establish a significant point of reference for empirically based term-formation and possibly standardization, thus providing Norwegian export-oriented corporations with a much needed quality assurance of the linguistic interface. The same would hold for Norway's administrative and political cooperation with the outside world, as well as for the global language industry, which depends on the availability of multilingual databases and some form of translation. The realism in trying to stem the flood of English usage in conducting the professional affairs of people whose normal mode of communication is something other than English is highly debatable, but the virtue of avoiding linguistic domain losses in Norwegian is not.

Creating a Term Base to Customise an MT System: Reusability of Resources and Tools from the Translator's Point of View

Natalie Kübler

Intercultural Centre for Studies in Lexicology
University Paris 7
2, Place Jussieu, 75251 Paris Cédex 05, France
kubler@ccr.jussieu.fr

Abstract

This paper addresses the issue of combining existing tools and resources to customise dictionaries used for machine translation (MT) with a view to providing technical translators with an effective time-saving tool. It is based on the hypothesis that customising MT systems can be achieved using unsophisticated tools, so that the system can produce output of sufficient quality for post-translation proofreading. Corpora collected for a different purpose, together with existing on-line glossaries, can be reused or reapplied to build a bigger term base. The Systran customisable on-line MT system (Systranet) is tested on technical documents (the Linux operating system HOWTOs), without any specialised dictionary. Customised dictionaries, existing glossaries completed by adding corpus-based information using terminology extraction tools, are then incorporated into the system and an improved translation is produced. The dictionary will be augmented and corrected as long as modifications generate significant results. This process will be described in detail. The resulting translation is good enough to warrant proofreading in the normal way. This last point is important because MT results require specialised editing procedures. Compared with the time taken to produce a translation manually, this methodology should prove useful for professional translators.

1. Introduction

The growth in the volume of documentation for translation and the constant enhancement of tools have brought about great changes in the world of translation. Corpus linguistics has opened up new perspectives for both translation studies and the process of translating. As Baker (1993) pointed out as early as 1993, corpora can offer new insights into the theoretical and practical aspects of translation. The different stages in which various types of corpora can help in the translation process have been investigated by Aston (2000), while Varantola (2000) evaluates the use of dictionaries and specialised corpora, and other researchers investigate issues in the area of translator training, which is currently undergoing deep changes. The use of corpora and MT in the translation classroom has become a subject in its own right (Zanettin 1998; Yuste 2001, and Kübler forthcoming).

The translator is no longer seen as an isolated individual, working with a paper dictionary. A range of new resources are available for translators, particularly for translating technical documents[1]. However, there is a fear that machines, especially MT, will eventually replace translators[2]. MT has already changed the way professional translators work, but will not replace human beings. Today, it can be used as a tool to provide translators with quick on-the-fly versions that need thorough proofreading. The experiment described in this paper deals with the **next step**: Customising MT systems to provide translators with **a time-saving tool producing good quality results**.

We shall show how MT systems can be customised using existing resources, such as on-line glossaries and existing or self-made corpora, initially collected for a different purpose. A combination of resources, such as terminology extraction and conventional corpus linguistics tools, can be applied in the building of complete dictionaries containing sophisticated linguistic information. The recycled resources will be described, together with the tools used. The Systran user-customisable on-line MT system is then presented, with the linguistic features that can be integrated. The methodology applied in the creation of new dictionaries is detailed, and samples of improved translations are provided. A time-based evaluation of manual and MT outcome is included. The conclusion points to some work that remains to be done.

2. Resources

The project was carried out by **recycling** existing language resources, and using on-line Web-based resources. The tools that were used are simple to implement and do not require specific programming knowledge. The language resources that are readily available for assembling dictionaries can be divided into three categories:

- on-line bilingual technical glossaries;
- monolingual and parallel technical **corpora**;
- the Web as a corpus[3].

In this computer-science-based project, all three types of language resource were used .

2.1. Bilingual glossaries

On-line Web-based bilingual glossaries generally propose aligned lists of English terms and equivalents in French. These dictionaries are normally small, containing a few hundred headwords, usually with few verbs, adjectives or multiword units. They do provide useful lists

[1] Translation memory, term extraction tools, term base management software can all help when translating Languages for Specific Purposes (LSP), including Web sites, user manuals, help files, and financial documents.

[2] *Ouaibe et traduction: que craindre du Systran?* http://www.geocities.com/aaeesit/art21.html

[3] i.e. making linguistic queries with search engines, and search tools like WebCorp (see section 2.3. below).

of bilingual entries in the specialised area of computing, though they partly have the same headwords. Three glossaries were selected initially, because they contain terms that do not cross LSPs because they are domain-specific. They were downloaded, corrected, and formatted, to be compiled as customised dictionaries in Systranet. Here is the list of selected glossaries and the number of headwords for each:

- The HOWTO translation project glossary[4]: a small glossary of 200 words discussed and agreed upon in the project discussion list .
- Netglos Internet Glossary[5]: a multilingual glossary of Internet terminology compiled in a voluntary, collaborative project, containing 282 terms.
- The RETIF[6] site glossary. This short glossary contains 73 terms approved of by the French Governmental Terminology Commission for Computing and the Internet.

2.2. Corpora

Corpora make up the core resource exploited by the Systran team. Smaller corpora, exploited with simple tools, produce interesting results on a more individual scale. The smaller corpora used in the experiment had been collected to teach computer science English to French-speakers (Foucou & Kübler 2000). The texts used are highly technical and freely available on the Web:

- Internet RFC[7]: 8.5 million words: monolingual English corpus. This corpus consists of the Internet Request For Comments available on the RFC documentation site.
- Linux HOWTOs: English to French aligned corpus, ca. 500 000 words. The English HOWTOs and their translations in several languages are available on the Linux documentation site[8].

The above-mentioned corpora are embedded in a Web-based environment that can be accessed on our Wall[9] site.

2.3. The Web

The Internet has become a necessary resource for linguists, lexicographers, translators, and other language researchers, providing them with on-line dictionaries, reference documents, newsgroups. The Web can also be considered as an open-ended, unstructured corpus which can be queried using search engines, though these are not tailored for linguistic search. A specific linguistic search tool is Webcorp[10] (Kehoe & Renouf, forthcoming), which provides users with concordances, collocates, and lists of words found on Web pages; we have used this for a variety of purposes. A Web-based search strategy should be used in conjunction with the off-line, finite, corpus-based approach, since they yield complementary information.

[9] http://wall.jussieu.fr
[10] http://www.webcorp.org.uk

2.4. Tools

The first tool used is an on-line concordancer featuring perl-like[11] regular expressions, which gives access to aligned paragraphs of French and English texts from which a concordance has been extracted. Another on-line tool is a tokeniser, which allows the user to sort the words of a text in alphabetical order, or by frequency.

As the general philosophy of this experiment was to use simple tools, a commercially available term extraction tool was selected: Terminology Extractor[12], which works for French and English. It uses a dictionary to lemmatise the vocabulary of a text and produce four different output types:

- *Canonical forms:* recognised by the program and sorted by alphabetical order or by frequency; the most frequent forms are to be considered as potential terms.
- *Non words*: not recognised by the system; most of them are specialised terms.
- *Collocations*. Collocational extraction is based on a very simple principle: any sequence of at least two -- and at most ten -- words, that is repeated at least once is considered as a collocation. Stop words are discarded to avoid sequences, such as *sauvegarde de la* [save the], in which *la* is a determiner preceding the second part of the term, as in *sauvegarde de la configuration* [save the settings]. Collocates are good candidates for technical terms.
- *KWIC (key word in context):* for the combined three lists. This feature is used to extract lexico-grammatical information, on verb structures, for example.

3. Systranet: customisable dictionaries

Systran MT has been much improved in recent years (Sennelart et al. 2001). Systranet is an on-line service offered by Systran. Users have access to a dictionary manager which allows them to create and upload their own multilingual linguistically-coded dictionaries into Systran, in order to improve translation results. These multilingual dictionaries contain a list of subject-specific terms that are analyzed prior to using Systran in-house dictionaries. This feature is based on the assumption, demonstrated by Lange & Yang (1999), that domain selection and terminology restriction are beneficial to translation results.

Linguistic information, such as part-of-speech, number and gender, subcategorisation, or low-level semantics can be added to the user's dictionary entries. Once the dictionary has been compiled, its accuracy and linguistic coverage can be tested by translating subject-specific texts.

The translation results can be improved by modifying the dictionary, a recurrent process which can be continued so long as the modifications produce significant improvement. Systranet offers specific features that allow

[11] Perl is a particularly appropriate programming language for handling word strings or finding language patterns.
[12] http://www.chamblon.com

the user to see which terms have been translated using customised dictionaries, and which terms are not recognised at all. It allows the user to check whether the dictionary entries have really improved the translation results as expected. Another feature used to complete the dictionary is the non-word feature: all the words that have not been recognised by Systran or the user's dictionaries appear in red. They can then be integrated into the user's dictionary.

4. Experiment and methodology

We chose technical documents written by experts for experts, the Linux HOWTOs, which are the user manual of the Linux operating system. This experiment is part of a larger project that consists in translating all the new HOWTOs using MT. HOWTOs are documents of various size, describing the way to install the system and software related to it. Existing software is constantly updated and augmented, so the corresponding documents are updated and new documents are written with each new program. These documents have been translated into several languages by the various Linux communities. The French Linux community has developed a translation project[13] in which the translation is usually done by non professional, voluntary translators. People choose the document they want to translate and do the job. Today, most HOWTOs have been translated, which makes it possible to align the French translations with the English source and use them as a parallel corpus.

The task set for the experiment was to provide a complete and appropriate dictionary to translate the remaining untranslated Linux HOWTOs. This is based on the assumption that the initial dictionaries will be augmented in the light of each new text to translate. Since a comparative study of the translation results -- with and without customised dictionaries -- had to be established, each text was first translated without using any specific dictionary.

4.1. Creating the dictionaries

The methodology is a combinatorial approach, recycling data and using terminology extraction tools.

First, the three glossaries mentioned above were downloaded and converted into dictionary files, augmented with linguistic information, giving more than 500 entries. These glossaries were selected when translating a HOWTO. Then, a more complete and corpus-based approach was applied. It produced two types of dictionary: *step-one dictionary* and *step-two dictionary*.

4.1.1. Step-one dictionaries

The step-one dictionaries were created using term extraction software, corpora, and a concordancer. This sort of dictionary can be produced using large corpora, but the most efficient solution for the individual user is to apply it to the texts to be translated.

The candidate texts were processed using Terminology Extractor. Initial candidates for headwords in the dictionaries were selected from the non-word and collocation lists. Unlike the existing glossaries, Terminology Extractor outputs do not provide French equivalents for the English words. On-line term banks, such as *Le Grand Dictionnaire Terminologique*[14] or *Termium*[15] proved insufficient for translating most terms. A corpus-driven approach was adopted to find French equivalents: the RFC corpus was used to find more information about context, the aligned HOWTO corpus was queried with the regular expressions concordancer (Wall) to find appropriate translations, as illustrated below.

The term README in the computing context is used as a noun, as shown in the following context, in which the term is the head of a subject NP:

links which Linus describes in the **README** are set up correctly. In general, if a

Figure 1. The noun *README* in context

The term *addon* was in the non word list, but by using the HOWTO corpus, we found contexts and a French translation:

The FWTK does not proxy SSL web documents but there is an **addon** for it written by Jean-Christophe Le fwtk ne route pas les documents web SSL, mais il existe un **module complémentaire** écrit par Jean-

Figure 2. The noun *addon* and its French translation

This stage was necessarily completed by using Web search engines to verify some translations found in the HOWTOs, or to deduce new translations from indirect queries. Since the documents are translated by various people who are usually not professional translators, but computing experts, the French versions of the HOWTO are not homogeneous. This means that one English term can be translated by several different words that are true synonyms in French. Only one equivalent must be chosen for the MT dictionary. Another problem is the case of borrowings. In spoken computing French, the English term is often used. Even in written texts, and especially in translations, usage leads translators to keep the English term and give the French equivalent once at the beginning of the document.

When no answer can be found in the HOWTO corpus, WebCorp can provide solutions. By looking for collocates and concordances for an English term in French language documents, possible translations can be traced back to the French sites. The collocates of *network* in French-speaking sites, for instance, allowed us to trace back *home network* and the French *réseau domestique* (Kübler, forthcoming).

4.1.2. Step-two dictionaries

Once a set of dictionaries has been produced for each HOWTO, it must be tested not only to correct possible

[13] http://www.traduc.org

[14] http://www.granddictionnaire.com

[15] http://www.termium.com

errors in the entries, but also to add the new words that are neither in Systran's nor in the customised dictionaries. The more HOWTOs are translated, the fewer words have to be added until the dictionaries are saturated, i.e. no new word can be added to improve translation results.

Step two is illustrated with the Home-Network-Mini-HOWTO, one of the not yet translated HOWTOs. Below is an example of translation results with and without customised dictionaries:

Source text	This page contains a simple cookbook for setting up Red Hat 6.X as an internet gateway for a home network or small office network.
Without cust. dict.	Cette page contient un cookbook simple pour le chapeau rouge 6X d'établissement en tant que Gateway d'Internet pour un réseau à la maison ou le petit réseau de bureau.
With cust. dict.	Cette page contient un cookbook simple pour l'établissement ***Red Hat 6.***X en tant que ***passerelle Internet*** pour un ***réseau domestique*** ou un petit ***réseau de bureau***

Fig. 3: Comparing translation results with and without customised dictionaries

In the next table, the customised dictionaries were completed with the words badly or not at all translated with the first version of customised dictionaries.

Source Text	This page contains a simple ***cookbook*** for ***setting up Red Hat 6.X*** as an ***internet gateway*** for a ***home network*** or small ***office network.***
Step-one dict.	Cette page contient un **cookbook** simple pour l'établissement ***Red Hat 6.***X en tant que ***passerelle Internet*** pour un ***réseau domestique*** ou un petit ***réseau de bureau***
Step-two dict.	Cette page contient ***des recettes*** simples pour ***l'installation Red Hat 6.***X en tant **que** ***passerelle Internet*** pour un ***réseau domestique*** ou un petit ***réseau de bureau***.

Fig. 4: Comparing translation results with step-one and step-two dictionaries

4.2. Translation outcome

Comparing the translation outcome with and without customised dictionaries shows encouraging results. Testing existing customised dictionaries on another text in the same subject area demonstrates that the text-based dictionaries can be reused, and that fewer headwords have to be added. Little by little, translators can add to their own dictionaries in various LSPs.

Obviously, as in any translation process, those translation results must be proofread. However, the points that need correcting are quite different from a translation done by a human being. If the MT errors are obvious and often serious, they have the advantage of always occurring in the same context. Most errors in this particular MT system are due to the same syntactic failures and can easily be corrected by the translator, once recognised.

Conjunction and disjunction are two of the main problems in MT systems that have yet to be solved. The garbled translation is however easily corrected, since the errors are similar each time a conjunction or a disjunction appears in an NP context:

Source text	*Translation result*	*Correct transl.*
Your internal and external networks	votre interne et des réseaux externes	vos réseaux interne et externe
a fulltime Cable or ADSL connection	une connexion en continu d'AADSL	une connexion en continu par le câble ou l'ADSL

Fig. 5: Conjunction and disjunction in an NP context

Another characteristic of MT systems is the overgeneralisation of transfer rules which leads to errors. Again, it is quite easy to check and correct those errors, for instance, the system translates a zero article in English by a definite article in French, although, in most cases, it should be the indefinite article:

Source text	*Translation result*	*Correct transl.*
decoded by specific individuals	décodé par les individus spécifiques	décodé par des individus spécifiques

Fig. 6: An example of transfer rule overgeneralisation

4.3. Human vs machine?

We selected two HOWTO totalling 9357 words in English. The expansion coefficient (15% in French) brings the total up to 10 750, i.e. ca. 36 standardised pages. This should take a professional translator from 5 to 7 days, depending on the tools used. Systranet took less than two minutes to produce an outcome. Professional translators assess the proofreading necessary at ca. 2 days. MT can therefore be included in the set of tools professional translators can actually use.

5. Conclusion

It has been demonstrated that the quality of translation can be significantly improved by importing customised dictionaries. Individual translators can thus create their own customised dictionaries with user-friendly and publicly available resources and tools.

These dictionaries recycle already existing resources, and their upgrading is corpus-driven. Translators working in LSPs can take advantage of a customised MT system because they can obtain quickly translated texts, and proofread them in a short time, as the errors generally have similar morpho-syntactic patterns. Although considerable work needs to be done in the beginning, after processing a few documents, the dictionaries are more or less saturated, and just a few words have to be added.

Further work will focus on reusing customised dictionaries to translate cross-LSP texts, such as digital cameras. More testing on the coding of Systranet customisable dictionaries is currently being done with students to improve coding rules and their applications.

Evaluating Translation Memory Systems

Angelika Zerfass

Holzemer Str. 38
53343 Wachtberg
Germany
azerfass@debitel.net

Abstract

Since the mid 1980s, translation tools have taken over more and more of the daily lives of translators and translation project managers. But a lot of time now has to be spent on evaluation, training and administrative tasks.
Translation tools were designed to make the translator's work easier, faster and more efficient. They range from conversion utilities to terminology management, translation memories, machine translation as well as workflow and project management systems.
They were developed with the aim to reduce repetitive translation work, but on the other hand they add different tasks to the workload, like administrating databases and the like.
This presentation will give an overview of one area of translation tools - the different translation memory systems on the market today and the technologies they use. It includes a comparison of common basic features like word count, analysis/statistics function and pre-translation, some tools' specialities as well as the description of data exchange possibilities between the systems by use of the TMX format.
As there is no "one best tool" for everything, the aim of this workshop is not, to recommend one tool, but to provide some guidelines for evaluating translation memory systems according to individual requirements.

1. Translation Memory Tools - Overview

Translation memory systems, as the name implicates, "memorise" the translations made by a human translator. Most translation memory systems (often also called "TM-systems"), consist of a database that stores the original text along with its translation - a database of segment pairs.

"Segment" here indicates that the units that is being translated and stored to the database can range from a single word (for example a heading or an item in a bulleted list) to phrases, complete sentences or even whole paragraphs. The tools recognise a segment by a set of internal rules that define, for example, that a segment ends with a full stop or a paragraph mark.

During translation itself, the tool will automatically look up every new source language segment to be translated in that bilingual translation memory. If the same segment is found in the database, the system will offer the translation that was saved with this segment as a suggestion to the translator for reuse. If it does not find the very same segment, it will start looking for similar segments. These are the so-called "fuzzy" matches, as the source language segments (in the document and in the database) only match to a certain percentage. When the translator gets such a fuzzy match from the database, they can decide if and how much of it can be reused for the current translation. Usually the translator can even set the level of "fuzziness", that is the percentage of similarity, so that the system will only offer translations that can be reused without having to make too many changes to the suggested translation.

Thus the use of a translation memory system can increase consistency and it cuts the time for writing a translation. This is especially true for the translation of repetitive documents like technical documentation, manuals, instructions and updates of already translated material.

Translation memory tools are usually the main component of a tools' suite. These suits also offer recycling tools, so called alignment systems. These are used to prepare translations made without translation memory systems for reuse in such a translation memory tool. They read in the source and the target language files, display them in parallel and propose connections of the source language segments to the corresponding target language segments. A translator will then review these connections. Then, the segment pairs can be imported into the translation memory. From now on they can be used just as if they had been translated interactively with the system itself. Another component of such a tools' suite is the terminology management system - another database that stores single terms (or phrases) together with their translation(s) into the target language(s). The translation memory database and the terminology database work together during translation. The translator will not only get suggestions for the translation of whole segments but also a list of all the terms within that segment that were found in the terminology database. Other components of such a tools' suite could be workflow or project management systems as well as filters and utilities for file format conversion.

Translation memory systems also start to be customisable for use with document or content management systems and some are even programmable via an API (application programming interface - programming commands that enable the user to call the translation memory system from other applications).

2. Translation Memory Tools Basic Principle

Basically all translation memory tools were developed with the same goal in mind: Something that has been translated before should not have to be translated again from scratch. It should come out of the database or reference material so that the translator only has to decide whether the previous translation can be reused or needs to be modified.

The technologies used to achieve this are different. Some tools use a model of referencing the files of a previous project, The referencing model uses those previously translated files (original source language files and translated files) as the source for suggestions of new translations. This model works especially well for projects with many updates containing a lot of small changes.

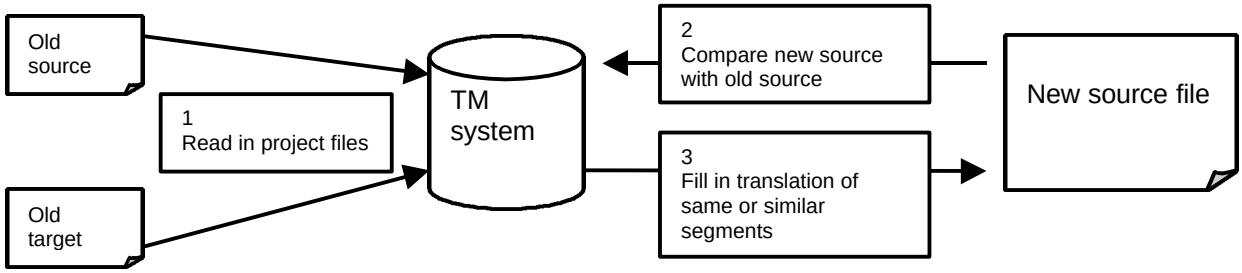

Figure 1. Reference Model

The database model on the other hand stores all translations ever made in one database, independent of context, which is useful if the same or similar segments appear in different projects and document types. Most of the commonly used translation memory systems are able to work with any language installed on the user's machine and they usually also allow the user to add project or user specific information to each translation.

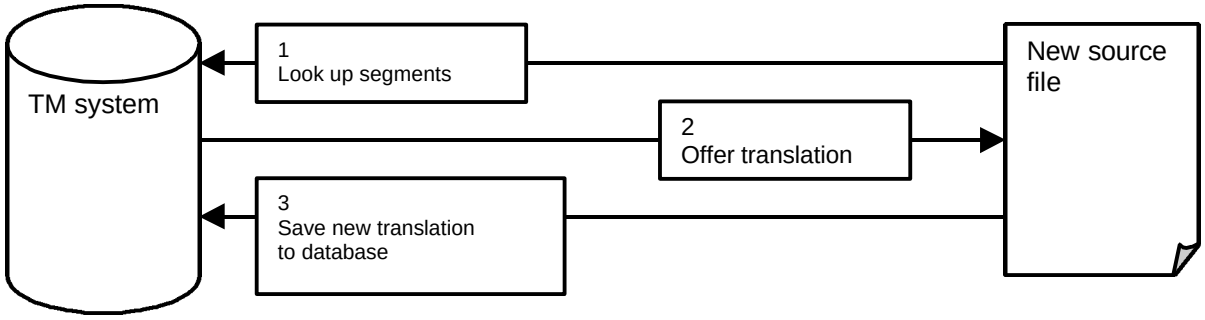

Figure 2. Database Model

3. Translating with Translation Memory Tools

The text to be translated consists of smaller units like headings, sentences, list items, index entries and so on. These text components are called "segments". Translation memory systems are equipped with a set of rules, which enables them to recognise, where a segment starts and where it ends. When translating with a translation memory system, the system goes through the text segment by segment, offering each of them to the translator together with any translation for this or a similar segment that has been stored in the database or can be found in the reference material. The translator decides whether to reuse the proposed translation, to adapt it or to create a new translation and then saves it to the system. Thus the translator builds up a store of segment pairs that can be referenced for future translation.

This store of segment pairs can also be used for analysing new files to determine the rate of recycling that can be achieved. Or it can be used to run a pre-translation, which creates files that contain segments with more or less matching translations already in them. This is very useful when working on a large batch of files or preparing files for other translators who are not working with a translation memory tool.

To be able to use translation memory tools on different file formats, from common Word files to DTP (desktop publishing) files, for example FrameMaker or Interleaf or files for the web in HTML, XML or SGML, some of these formats need to be converted to a format that the translation memory tool can work with. This happens either by use of separate conversion tools or filters integrated into the translation memory systems. Selecting a TM system therefore also depends on what file formats have to be worked on and how much time and effort needs to be spent on preparing and converting them to a usable format for translation and back to the original format afterwards.

Also, when it comes to software localisation for example, different tools have to be used for different parts of the project. The project might consist of text within the software from the user interface (GUI) to dialogs and messages as well as online-help files, documentation, packaging and marketing material and so on. And here different types of text require the use of different tools. GUI, software dialogs and messages are best translated with a software localisation tool, that is a translation memory tool that can read those special software file formats. They usually also contain testing features to check for consistent use of hot keys for example, or length related problems that might arise, if the translated text does not fit the button space it is supposed to appear on. But those systems are mostly specialised on the software itself.

For translation of the documentation, another translation memory tool is needed. And here the question arises how those tools for translating software and documentation interact, because what has been translated for one part might also be reusable in the other (this will be covered in the section about data exchange further down).

Online-Help files for example, could be translated with either a software localisation tool or with a translation memory system for documentation as both system types support this format.

4. Feature Comparison

All translation memory tools offer basic functionalities like word count or an analysis of recycling potential (how many of the segments in the file to be translated are present in the database or reference material as 100% matches or as similar, fuzzy matches). They also provide features for automatic pre-translation, search functionalities within the segment database, as well as access to terminology management components during translation. But each and every tool also has its specialities. These are the features that can influence the choice of tools.

Most translation memory systems read the files to be translated into the system itself, converting them into a table where one column contains the source language segments and another column that will be filled with the respective translation. Others connect to Microsoft Word so that any file that can be opened in Word does not have to be converted before translation and can be worked on in a WYSIWYG (what you see is what you get) mode. The translators can work in an environment that they are used to. Other file formats, for example DTP formats or so called tagged file formats like XML, HTML or SGML, are either converted or displayed in a separate editor. Colours are used to mark text to be translated as well as tags that make up the structure and formatting of the file.

More and more developers are enhancing the functionalities of the translation memory tools by adding new features like context sensitive pre-translation or machine translation-like components (for segments that have no match from the translation memory) as well as project management components.

5. Data Exchange between Translation Memory Systems

For some time, translators did not have the possibility to bring the data from one translation memory system into another system for reuse. A situation that was alleviated to some extent by the tools manufacturers by adding export functionalities for some proprietary formats of other manufacturers. But it was not feasible for each tool to support all export/import formats of all other tools - especially with new tools being developed and marketed all the time.

Now, the tool manufacturers have agreed to use one standard format for representing the data in their systems or at least to offer this format as one of the export formats. This allows an easier transfer of translation memory data from one system to another - even though the results are not always completely satisfactory. This standard is called TMX - Translation Memory Exchange format. It is an XML based representation of the data stored in a translation memory system.

5.1. Example of data representation in TMX format:

Segment pair:

This is a test. (English segment)
Dies ist ein Test. (German segment)

TMX representation:

```
<tu>
    <tuv lang="EN_US">
    <seg>This is a test.</seg>
    </tuv>

    <tuv lang="DE_DE">
```

```
        <seg>Dies ist ein Test.</seg>
        </tuv>
</tu>
```

Each segment pair is represented with a <tu> and </tu> tag that denote beginning and end of the segment pair. ("tu" stands for "translation unit", as those segments pairs are often called.) Then come the individual languages of the segments and the textual contents. This format could be produced and read by any translation memory system that works with TMX.

There are three levels of TMX compliance today. The first level only represents the text itself. The second level is able to represent the formatting information as well. And level three would be used to represent additional tool specific data like user IDs, project names and everything else the user has specified. Today, most tools comply at least to TMX level 1 or even to level 2.

6. Conclusion

Before investing in any translation tool, it is necessary to list the individual user requirements. This includes the file types that are to be translated. As most translation memory tools rely on structural and formatting information in the file, to segment and display the text, it should be tested if the way the files for translation are constructed, work well with this or that translation memory system. It could even mean to adapt the way of writing the documents in the first place, so that, at the translation stage, the tools that are used can handle the files more easily.

Another point is the networkability and the list of supported languages as well as the different supported file types.

Pricing for licenses, training and support should also be taken into consideration.

Then the tools should be tested for some time with real life examples to be able to evaluate, which tools answer the user's requirements best. Most tool manufacturers offer a trial period of about 30 days or a limited demo version of the software or, in case a longer evaluation period is needed, an extended trial with the full version of the software. This usually includes the need to buy a training session as well, to prepare the people who will be evaluating the software in the best possible way.

Language Resources at the Languages Service of the United Nations Office at Geneva

Marie-Josée de Saint Robert

United Nations Office at Geneva
1211 Geneva 10
mjdesaintrobert@unog.ch

Abstract

The language staff at the United Nations makes a very selective use of language technologies. So far no computer-assisted translation software has been installed on translators" workstations even though tests have been conducted for several years on the two major computer-assisted translation (CAT) systems at United Nations Headquarters in New York, for instance. The aim of this paper is twofold : 1) to show why CAT systems are not considered as potential sources of improvement of quality nor quantity in translation work at the United Nations, and 2) to present the kind of language resources that are considered essential for the adequate rendering of content in any of the six official languages of the United Nations (Arabic, Chinese, English, French, Russian and Spanish). This paper analyzes the particular linguistic and technical constraints specific to an international setting and argues in favour of a selected number of language resources used at the United Nations other than translation tools readily available on the market. Among such language resources, one finds search engines, government and research institutions" websites, and, in a not too distant future, institutional knowledge bases.

1. Introduction

In an international, multilingual environment such as the United Nations, surprisingly enough, translators and language staff in general are not considered on the same footing as substantive departments, which prepare reports and organize conferences. Wherever technological innovations are designed and developed, the primary concern is the diplomatic community or the international community at large, not the language staff. Although translators do have a major role to play in the preparation of parliamentary documentation, their needs, such as prompting automatic alignment of two language versions of the same document whenever desirable, are very seldom taken into consideration by United Nations designers and developers. This low profile for linguists may well explain why so few technological innovations have made their way through to the translator and the terminologist. More reasons can be found in the very nature of the translation process in multilateral diplomatic settings where linguistic and technical constraints play an important role.

2. Linguistic Constraints

Several linguistic constraints are obstacles to the straightforward application of language technologies to translation work. Some are quite obvious, while others are specific to international organizations.

2.1. Word Choice

Translation cannot be reduced to the mechanical substitution of one set of terms in one language by a similar set in another language.

2.1.1. Semantic Adequacy

The sentence starting with (1) should not be translated into French by (2) no matter how common that phrase is but by (3):

(1) the report shows
(2) le rapport montre que
(3) il ressort du rapport que

Also, the correct rendering in French of the English phrase (4) is not (5) but (6):

(4) abusive sexual practices that may affect very young girls

(5) pratiques sexuelles abusives qui peuvent affecter les très jeunes filles

(6) pratiques sexuelles dont peuvent être victimes les très jeunes filles

It is not always clear with CAT whether faulty phrases such as (2) and (5) would be offered by the system, as it may only keep the first instance found and disregard other instances of the same phrases found subsequently, and whether the translator in haste may not accept the phrases in (2) and (5) since both look correct from the grammatical point of view but are incorrect from the semantic point of view[1]. Maybe more accurate information on what CAT systems do is needed. Yet it remains to be seen whether distributed management of translation memories can be efficiently organized on a large scale, with fifty translators having the right to update the translation memory on a permanent basis in each language pair.

2.1.2. Lexical Variety

Translations serve the purpose of a specific communication need and should not be considered as models for translators to replicate across the board. Such is also the case for terminology in any target language. Mere electronic bilingual dictionaries or glossaries cannot

[1]In (2) an inanimate noun is used with an animate verb; in (5) it is as though sexual practices would be divided into two categories: abusive and non-abusive, which is wrong in the case of very young girls.

satisfactorily capture variation, not only in the original language but also in the target language, if based upon the assumption that a notion corresponds to a term in English and one or several terms in French, for instance. Names given to human rights are a case in point. A terminologist would very happily collect the names of all rights, starting with the right to food, to adequate housing, and to education, while a translator would resent it. Such rights are indeed referred to under different names by different speakers, and a too rigid list of rights would miss the needed subtleties while discussions are still under way. Should "adequate housing" be rendered in French by "logement convenable," "logement adéquat," "logement suffisant," or "logement satisfaisant," all four equivalents being found in United Nations legal instruments or resolutions, and not by "bonnes conditions de logement" or "se loger convenablement" when the context allows or requires it? Translators want to preserve flexibility, when present-day translation systems propagate rigidity and, as a lurking consequence, poverty of style and vocabulary. For Fernando Peral (2002), a translator at the International Labour Organization: "The main operational problems of "semi-automatic" translation [i.e., translation with the help of translation memory systems] are linked to the quality of the output and to a process of "de-training" of the translator, who becomes less and less used to the mental process of searching for proper solutions in terms of functional equivalence and relies more and more on the machine"s decisions, which inevitably affects professional development and job satisfaction."

2.2. Linguistic Insecurity

Document originators at the United Nations are nationals from over a hundred and twenty countries. In most cases their native language is not one of the official languages of the Organization, and document drafters erroneously think they have to use English, which may prevent them from using their main language, even when it is an official language, and produce better originals. Documents may also be submitted to the United Nations by officials or experts working for Member States that do not have either any of the official languages of the Organization as their main language. Syntactic, semantic and morphological mistakes are therefore not rare in documents, and in most cases only translators are in a position to detect mistakes and rebuild faulty sentences in the original text. Only they are required to work in their native language that is one of the official languages. Due to lack of resources at the United Nations, only a small portion of all documents is edited prior to being translated (e.g., documents prepared by the Commission on Human Rights). Translators consequently do act as filters for grammatical correctness and language consistency as they work on the texts to be translated. As a result, they often improve original texts whenever the drafters or submitting officers accept their changes in the original documents. A translation memory processing straightforwardly a document to be translated prior to the perusal of a translator may not detect inappropriate use of terms or syntactic errors in the original language. Even when an automatic term-checking system is appended to the translation memory, it may not be as efficient as a human eye either. The fear therefore is that a computer-assisted translation system may add more mistakes to the original ones, which will then be even harder to detect and correct.

2.3. Different Stylistic Rules

Document drafters use a variety of writing rules and styles to convey meaning. For instance, among writing styles one can mention the fact that repetitious words are not considered as poor style in English but are definitely considered poor style in French. The English sentence (7) presents a repetition of the word "aircraft" which the French rendering in (8) would avoid:

(7) the shooting down of civil aircraft by a military aircraft

(8) la destruction d'aéronefs civils par un appareil militaire

2.4. Functional Adequacy

Each Committee or Body has specific ways of expressing an idea in order to reach a consensus within its respective audience or circle. Underlying references to protagonists, former meetings, earlier decisions discussed by Committee members but not explicitly mentioned in the text play an important role in translation. Sometimes the reasoning of a *rapporteur*, a speaker or an author, or an amalgam of lengthy sentences couched in simple terms that are perfectly unintelligible to the outsider, i.e., someone who has not participated from the beginning in the discussions, has to be left untouched in the original. Acceptability of a translated text does not come solely from its grammatical and semantic well-formedness. It must also be appropriate within the United Nations context. A translated text must, like its original, follow a highly standardized path: it must convey the impression of having been written by a long-time member, perfectly familiar with the background in which the text has been drafted, even if it is deliberately vague or obscure. In fact most United Nations texts cannot be interpreted without prior knowledge of the particular political framework in which they appear. The sociopolitical motivation and rationale behind a text are part of the unwritten constraints imposed on communicative competence at the United Nations. Developments in artificial intelligence are not perceived to have reached this level of refinement. As Fernando Peral (2002) puts it: "translation is based on finding "functional equivalences" that require linguistic, intertextual, psychological and narrative competence; only human beings are capable of determining "functional equivalences"; productivity in translation is therefore intrinsically linked to the capacity of the translator to find the adequate functional equivalence, i.e., it is based on the quality of the translator."

These constraints conflict with the concept of translation reuse for translation purposes on which most commercially available alignment tools and translation memory systems are based, especially when document traceability (i.e., the capacity of retrieving the complete document from which a sentence is extracted by the translation memory system) is not guaranteed.

3. Technical Constraints

Quality requirements are not always met in translated documents for technical reasons.

3.1. Time Constraints

Non-respect of deadlines for document submission results in not allowing translation to be performed in the required conditions. Feeding translation memories with texts that have not been properly revised for lack of time appears to be useless, even when such texts are considered as basic texts in an area. The underlying assumption is that basic texts can be improved over and over as they are cited in other texts, but no one can guarantee that it will indeed be the case, as translators are more and more required to work under emergency conditions, keeping revision at a very low level.

This explains why most documents are not considered by translators as authoritative sources for official denominations either in the source or in the target languages. Most official names of international and national organizations, bodies and institutions are referred to under several names in various documents and sometimes even within the same document. Alignment tools and translation memories that would provide precedents in two languages to translators might perpetuate the number of variants and confusion rather than helping translators to use the right equivalent, unless quality assessment is performed, which is a rather slow and uneconomical process looked down upon in an era of search for productivity gains. The problem is even more complex when it comes to designating a body whose name may be official in one or two languages but not in other languages. Chances are that transliterated names in English, French or Spanish rarely reappear again under the same denomination unless a rather time-consuming compilation is done to provide the best possible equivalents across official languages that would be used by translators. Yet as George Steiner (1975) rightly puts it: "Languages appear to be much more resistant than originally expected to rationalization, as well as to the benefits of homogeneity and technical formalization." Languages resist because human beings resist.

3.2. Digital Divides

Other technical constraints make the use of CAT systems difficult: 1) non-submission of documents in electronic form: many documents are submitted on paper with last minute written corrections – linguistic insecurity or a changing appreciation of political requirements being the main causes of last minute changes; 2) non-availability of reference corpora: some official references may exist in one or two languages, and have to be translated into other languages – reference documents that are considered as authoritative in one language pair may not be so in another, thus the task of building translation memories is labour-intensive, language pair by language pair; 3) scarcity of digitalized language resources in some languages: translators cannot completely switch to ready-made technological innovations – expertise in conventional research means should be kept.

3.3. Lack of Preparedness

CAT tools are known to be most efficient with repetitive texts. So far, since at the United Nations not all texts are available in electronic form, it is hard to assess the amount of repetition to be able to ascertain whether or not CAT is an efficient tool in this environment.

Proper training also has to be given to translators to make certain they know how to utilize the tools that they are given. The fear is that translators are no longer assessed only for their linguistic and narrative competence and performance, but by their computer skills.

Finally, equipment used in an international organization has to be compatible with the equipment required by a particular CAT software.

4. Tools for Translators

Translators at the United Nations make use of internal glossaries and terminologies developed within the specific institutional constraints.

4.1. In-house Glossaries

A dictionary look-up tool commonly used by translators at the United Nations provides a list of equivalents to remind translators of all possible synonyms as is the case for "significant" in English and its possible renderings into French:

"Significant - Accusé, appréciable, assez grave/long, caractéristique, certain, considérable, de conséquence, d'envergure, de grande/quelque envergure, digne d'intérêt, d'importance, de poids, de premier plan, distinctif, efficace, élevé, éloquent, explicatif, expressif, grand, important, indicatif, instructif, intéressant, large, louable, lourd de sens, manifeste, marquant, marqué, net, non négligeable, notable, palpable, parlant, particulier, pas indifférent, perceptible, plus que symbolique, positif, pour beaucoup, probant, qui compte, qui influe sur, réel, remarquable, représentatif, révélateur, sensible, sérieux, soutenu, significatif, spécial, substantiel, suffisant, symptomatique, tangible, valable, vaste, véritable, vraiment; a significant proportion: une bonne part; in any significant manner: un tant soit peu; not significant: guère; the developments that may be significant for: les événements qui peuvent présenter un intérêt pour; to be significant: ne pas être le fait du hasard." [2]

Access to validated and standardized terminology is considered more important than access to tools for document reuse other than the basic cut and paste function from documents carefully selected by the translator and not automatically provided by the system. Dictating sentences afresh, once proper terminology has been identified, also is considered a less time-consuming process than reading and correcting all or a selection of all possible renderings of a sentence found in previously translated documents by a context-based translation tool. Language resources used by United Nations translators thus are primarily terminology search engines that facilitate the search for adequacy given the specific

[2] Organisation des Nations Unies (2000).

context in which the document has been drafted, rather than any previous context.

4.2. Web resources

Language resources used by translators also include online dictionaries and government and research institutions" websites that translators have learned to identify and query for information extraction and data mining. Portals have been designed to help translators locate best language and document sources on the Internet.

4.3. Alignment Tools

Additional tools are document alignment tools by language pairs. Indexing of large text corpora for retrieval of precedents are felt preferable to tools that provide text segments, be they paragraphs, sentences or sub-units with their respective translations, but without any indication of date, source, context, originator, name of translator and reviser to assess adequacy and reliability in an environment where many translators are involved.

4.4. Knowledge Base

The construction of a knowledge base is envisaged to help translators perform their task in a more efficient manner. Ideally it would capture all knowledge generated by United Nations bodies and organs and various organizations and institutions working in related fields (i.e., any subject from outer space to microbiology tackled by the United Nations), and the knowledge and know-how of an experienced translator well trained in United Nations matters and that of an experienced documentalist knowing which documents are the most referred to. Such knowledge base would, for instance, predict instances where "guidelines" should be translated in French by "directives", as given by most dictionaries, and where "principes directeurs" would be a more appropriate translation. In statistical documents at the United Nations, one finds "recommendations," a term which is translated by "recommandations" in French and refers to rules to be followed, and "guidelines", translated as "principes directeurs," which are mere indications to be taken into consideration. If the term "directives" would be used in such context, it would convey the meaning of a document of a more prescriptive nature than "recommandations" would, which are actually more binding. Such instances of translation are best captured by a knowledge base that refines contexts and provides best reference material on any topic in the text to be translated. The knowledge base would provide not only adequate referencing and documentation of the original, but also the basic understanding of any subject that arise in a United Nations document.

Such knowledge base ideally would reduce the choices offered to the translator rather than list all possibilities. The easier it is for the translator to make the decisions he or she needs the faster he or she delivers.

The knowledge base would offer the translator with past alternatives, too, as in the case of "sexual harassment", translated into French by "harcèlement sexuel". Other French equivalents were tested before this rendering was coined and accepted. They may arise in a French original to be translated into other languages and thus should be retrievable: "assiduités intempestives," "avances (sexuelles) importunes," "privautés malvenues," "tracasseries à connotation sexuelle". The knowledge base would refer, too, to associated terms: "attentat à la pudeur," "outrages."

5. Conclusion

In conclusion, United Nations translators are very cognizant of the limitations of automated tools for translation and are more inclined to rely on easily accessible, structured information concerning the history and main issues in a particular subject matter in order to be completely free to choose the best translation equivalents.

Global Content Management – Challenges and Opportunities for Creating and Using Digital Translation Resources

Gerhard Budin

University of Vienna
Department of Translation and Interpretation
Gymnasiumstraße 50, A-1190 Vienna
gerhard.budin@univie.ac.at

Abstract

In this paper the concepts of content management and cross-cultural communication are combined under the perspective of translation resources. Global content management becomes an integrative paradigm in which specialised translation is taking place.

1. Convergence of content management and cross-cultural communication

Two different paradigms that have previously developed independently of each other have converged into a complex area of practical activities: cross-cultural communication has become an integral part of technical communication and business communication, and content management has become a process that is complementary to communication by focusing on its semantic level, i.e. its content. Specialised translation as a form of cross-cultural communication is a content-driven process, thus digital translation resources become a crucial element in content management that takes places in a globalised marketplace.

Content management has recently emerged as a concept that builds upon information management and knowledge management with an additional focus on content products, such as databases, electronic encyclopedias, learning systems, etc. Due to globalised commerce and trade, such products are increasingly offered on multiple markets, therefore they have to be adapted from a cultural perspective, which also includes the linguistic viewpoint. We will have a closer look at the concept of content, its transcultural dimension, and the role translation resource management plays in this area.

2. Reflections on concurrent trends

Economic globalisation had been a re-current development during several phases in modern history and several industrial revolutions and has been one of the crucial driving forces in the development of modern engineering, in particular computer technology. Together with rapid advances in telecommunications it was the basis for building databases and global information access networks such as the Internet. Visualisation techniques and constantly increasing storage capacities led to multimedia applications.

This increasingly powerful technology base has then been combined with terminology management practices in the form of termbases, with multilingual communication and translation requirements as well as with cultural adaptation strategies in the form of localisation methods. Language engineering applied to translation in the form of computer-assisted translation, translation memory systems, and machine translation have recently been combined with localisation methods and terminology management for creating integrated workbenches.

On the economic level, international trade and commerce have increasingly required cross-cultural management and international marketing strategies tailored towards cultural conventions in local markets. This trend towards customisation of products has now generated personalised products and services that are based on specific user profiles, customer satisfaction and quality management schemes. The emergence of information and knowledge management systems has been another key development in recent years. Computerisation and economic globalisation are the key drivers in a complex context of the information society, leading to interactive processes between linguistic and cultural diversity, professional communication needs in economic and industrial processes and technological developments. As a result, cross-cultural specialised communication and content management have emerged, both complex process themselves, as a dynamic and integrative action space in society.

3. What is Content?

While terms such as *data*, *information*, *knowledge* have been defined many times so that we can compare and ideally synthesize these definitions, the term content has not been defined so often. But since this term is essential for our discussion here, and since it is used so often in terms such as *content management*, *eContent*, *content industry*, etc., we have to take a closer look at what this term actually means.

In a modest attempt at distinguishing the different conceptual levels, an iterative and recursive value-adding chain emerges:

data + interpretation = information + cognitive appropriation = knowledge + collective representation and utilization = content

Each higher level of complexity integrates diverse elements of the lower level. Usability aspects are most important on the content level. All lower levels remain crucial on the higher levels, e.g. data management is still an important part of content management.

Looking at the generic concept behind the word content, we would say: *Content* is what is *contained* in a written document or an electronic medium (or other

containers of such types). We would expect, that any content has been created by humans with certain intentions, with goals or interests in their minds. So we can say that content is usually created for specific *purposes* (such as information, instruction, education, entertainment, arts, etc.).

Content is often created in specific *domains* (arts, sciences, business/industry, government, social area, education, etc.). When specific content that was originally created in a science context, for instance, it will have to be adapted and re-organised, in order to be able to re-use this content in other contexts, e.g. in secondary education or in industry.

Discussing the term content, we cannot avoid dealing with related terms such as data, information, and knowledge. In fact it is essential to have a clear distinction between the meanings of (the concepts behind) these terms. From an economic or business perspective, 'data is a set of particular and objective facts about an event or simply the structured record of a transaction' (Tiwana 2000: 59f). We derive information by condensing (summarising, eliminating noise), calculating (analysing), contextualising (relating data to concrete environments, adding historical contexts), correcting (revision of data collections on the basis of experience) and categorising data (Davenport/Prusak 1998).

Data management has always been a fundamental activity that is as important as ever. Data repositories and data sharing networks are the basic infrastructure above the technical level in order to facilitate any activity on the levels above, i.e. information management and knowledgement. The transition from information to knowledge can also be described from a systems theory point of view: a certain level of activities has to be reached, so that knowledge 'emerges' from information flows. Many knowledge management specialists warn companies not to erroneously equate information flows to knowledge flows. In order to legitimately talk about knowledge, a number of conditions have to be met:

- *Cognitive appropriation*: knowledge is always the result of cognitive operations, of thinking processes. Yet knowledge is not limited to the personal, individual, subjective level. When people consciously share knowledge on the basis of directed communication processes, it is still knowledge, either referred to as collective or shared knowledge, or as interpersonal, intersubjective, or objective knowledge. In theories of scientific knowledge, the term 'objective knowledge' was mainly explicated by Karl Popper (1972) and is the result of regulated research processes such as hypothesis testing, verification, proof, etc., and that is written down in science communication processes. This is the justification for libraries to talk about their knowledge repositories in the form of books that contain this type of knowledge, i.e. objective knowledge – but as mentioned above, this knowledge has once been subjective knowledge in some persons, in this case scientists, that had thought and communicated about it before.
- *Complexity*: the level of complexity is another factor in the transition from information to knowledge. The same processes as on the previous emergence level, from data to information, are relevant: condensation of information (summarising), analysis and interpretation of information gathered, contextualisation (relating information to concrete problem solving situations, embedding and situating information in historical contexts and drawing conclusions from that, correcting (revision of data collections on the basis of experience) and categorising knowledge accordingly.
- *Life span:* the validity of knowledge has to be checked all the time. Again we are reminded by Karl Popper that all knowledge is unavoidably hypothetical in nature and that no knowledge is certain for eternity. Therefore we constantly have to redefine the criteria by which we evaluate our current knowledge for its validity. Another metaphor from nuclear physics is used for knowledge, especially in scientometrics: the 'half life'of knowledge is constantly decreasing, due to the increase in knowledge *dynamics*, not only in science and technology, also in industry, commerce and trade, even in culture, the arts, government and public sectors, the social sector, etc.

In knowledge management, three basic steps in dealing with knowledge are distinguished (Nonaka/Takeuchi 1998, Tiwana 2000: 71ff, etc.):

- *Knowledge acquisition*: learning is the key for any knowledge management activity
- *Knowledge sharing*: the collaborative nature of knowledge is the focus
- *Knowledge utilization*: knowledge management systems have to allow also informal knowledge to be dealt with, not only formalized knowledge (this is a crucial factor in evaluating knowledge technologies for their suitability in knowledge management environments.

The focus and the real goal of knowledge management is actually on *content*, i.e. not on the formal aspects of computing, but on what is behind the strings and codes: the concepts and the messages. When knowledge is then packaged as a product for a certain audience, presented in certain media presentation forms, then we can speak about *content*, which also has to be managed in specific repositories and to be processed for publishing purposes, for instance.

As soon as we introduce another dimension, that of culture and cultures, communicating content across cultural boundaries becomes a crucial issue. Since we talk about *localization* as the process of culturally adapting any product to a market belonging to another culture than that of the original market of a product, content also needs to be localized when it should be presented to other cultures. Translation, as a part of the complex process of localization, is one crucial step in this process, but not the only one. Content localization may very well involve more than translation in the traditional sense, i.e. we might have to re-create part of that content for another culture, or at least change fundamentally the way this content is presented to a certain culture.

Since 'content' is a relational concept, we have to ask ourselves, what contains something, i.e. what is the container, and what is in this container. A book (with its table of *contents*), for instance, is such a container, or a database with the information entered in the records as the content. A text or a term can also be containers, with the semantics of sentences and the meaning of the term as the

content. But this distinction between container and content cannot be made in a very clear-cut way. We are faced with a semiotic dilemma. Form and content always interact. The medium we choose to present certain information will have some impact on this information, the structure of the information will also lead us in the choice of an adequate medium. Usually we cannot completely separate the container from the content, the form from the content, the term from the concept, the semantics from the text, the medium from the message, etc. Despite the heuristic validity and necessity of an analytical separation, we need a synthesis in the sense of a dynamic interaction, an interactive complementarity. At the same time we also might want to transform one form of knowledge representation into another one, for certain purposes and tasks, and then have to be sure that the content of each knowledge representation does not change – a difficult task.

Similar to typologies of data, information, and knowledge, we also need a content typology. There are different criteria for distinguishing types of content:

the domain where specific content is created in: any field of scientific knowledge, a business branch, a profession, a form of art, a type of social activity, etc. For this type of distinction, we may also differentiate different degrees of specialisation (highly technical and scientific, monodisciplinary or multidisciplinary, popularised, etc., depending on the audience targeted);

the form of representation: text, picture, personal action, etc. or the medial manifestation: web site content, the 'story' of a film, of a video, a piece of music recorded, a digitized scroll, etc.

Here we see again that the form of representing content and the medium chosen to do this is constitutive for distinguishing types of content.

First of all, the purpose of the content: instruction, education, research, aesthetic and artistic purposes, etc. Secondly, the kind of content product that is designed for a particular target audience (e.g. a multimedia CD-ROM for 6-year old children to learn a foreign language, e.g. English). In addition to a content typology, we also have to look at the structures of content. In this respect, and regardless of the content type, we can make use of terminology engineering, and, more recently, also ontology engineering. Terminologies and ontologies are the intellectual (conceptual) infrastructures of content, both

- implicitly (in the form of personal or subjective knowledge of the content generator), or
- explicitly (as objective knowledge laid down in a specific presentation form).

So we can conclude that concepts are content units (conceptual chunks) and that conceptual structures (the links among concepts) are the structures of concept. Again we have to remember that the multi-dimensional content typology will determine the concrete structures of content that users will encounter in specific products.

4. Global Content Management

After having investigated a little bit into the concept of content, we can now look at content management and how cultural diversity determines this practice. Since the target audience of any content product is always culture-bound, i.e. belonging to one or more cultures, with we can simply state that content management always has to take into account cultural factors in content design and all other processes and tasks of content management. The language(s) spoken by the target audience, social and historical factors, among many others, are examples of criteria for concrete manifestations of content management. Also the meta-level of content management, i.e. those who are content managers, are also culture-bound. Those who have designed and created content products, such as multimedia encyclopedias on CD-ROM, have to be aware that they themselves are belonging to at least one culture (in most cases, there will be one pre-dominant culture in such content management teams), and that this very fact will unavoidably determine the way the content of the product is designed.

Now we look at a list of key processes of content management:

- Design and creation of content
- Processing of content, such as

Analysis of existing content structures, segmentation of content into units, aggregation of content units into structures, condensation of content (summarization, abstracting, etc.), expansion of content into more detailed forms, transformation of content, etc.

- Presentation of content in different media and knowledge representation forms (see above)
- Dissemination of content on intranets or other web structures, on CD-ROMs, but also more traditionally in the form of books, etc.
- Sharing content in collaborative workspaces
- Using content for various purposes

Taking into consideration the differentiation between data, information, knowledge, and content (see above), we can make a parallel distinction between data management, information management, knowledge management, and content management. It is important to note that each management level is based on the one underneath, i.e. information management is impossible without data management, knowledge management needs both, data management and information management, and content management relies on all three levels below. The following figure shows different levels of complexity and levels of integration. As a result of combining these two dimensions, degrees of usability can be differentiated: data management is usually not user-oriented, since it is an internal process at an infrastructural level. Content management, on the other end, is most user-oriented.

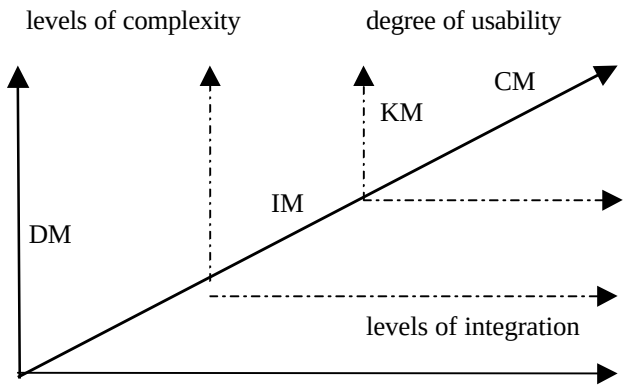

Figure 1: Levels of complexity and levels of integration, and degrees of usability as emergence levels of data management (DM), information management (IM), knowledge management (KM), and content management (CM)

Now we should return to the aspect of cultural diversity and the way it determines content management. Global content design, accordingly, is an activity of designing content for different cultures as target groups and is cognizant of the fact that content design itself is a culture-bound process, as shown above.

From the field of cultural studies we can benefit when looking at definitions of what culture is: a specific mind set, collective thinking and discourse patterns, assumptions, world models, etc.

Examples for types of culture are corporate cultures, professional, scientific cultures, notably going well beyond the national level of distinguishing cultures.

Cultural diversity is both a barrier and at the same time an asset and certainly the raison d'être for translation, localization, etc.

The following model shows the various dimensions of Global Content Management discussed above. The term element 'global' stands for all the cross-cultural activities such as translation, localization, but also customization, etc. 'Content' includes terminologies and ontologies as its infrastructures, products and their design, user documentation, but also pieces of art, etc. And the management component includes all the processes such as markup and modelling, processing, but also quality management, communication at the meta level, etc. Usability engineering is crucial for all these components:

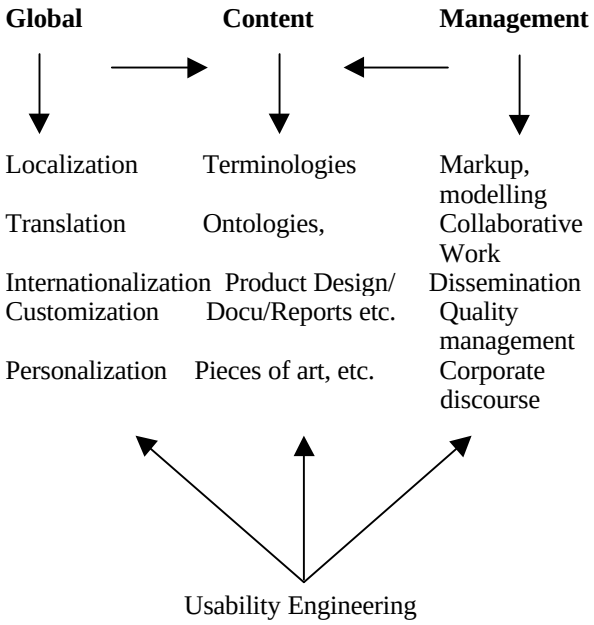

Figure 2: the three components of global content management with individual processes and components, all three nowadays determined by usability engineering imperatives

5. Pragmatic Issues in Global Content Management

Content management processes cannot do without appropriate knowledge organization and content organization. Terminological concept systems are organized into Knowledge Organization Systems (KOS) that can be used for this purpose of content organization:

- Thesauri, Classification Systems, and other KOSs, also conceptualized as (extrinsic) ontologies
- (Intrinsic) Ontologies (language-related, e.g. WordNet), domain-specific (medicine, etc.)

In order to establish and maintain the interoperability among heterogeneous content management systems, federation and networking of different content organization systems are necessary in order to facilitate topic-based content retrieval and exchange of content in B2B interactions.

Global Content Management may have very different manifestations. In the area of Cultural Content Management, for instance, cultural heritage technologies have developed in order to build up digital libraries, digital archives and digital museums.

Other applications of Global Content Management systems are:

- ePublishing (single source methodologies)
- eLearning (managing teaching content
- Cyber Science (Collaborative Content Creation)
- Digital Cities and other Virtual Communities projects.

On the pragmatic level of maintaining content management systems we observe similar problems as on the level of knowledge management, that a corporate

culture of knowledge sharing has to be developed and nurtured, that special communicative and informational skills are needed to share knowledge across cultures and that the dynamic changes in content require a management philosophy that is fully cognizant of the daily implications of these constant changes.

Translation resources such as translation memories and other aligned corpora, multilingual terminological resources, reference resources, etc. are typical examples of content that needs to be managed in such global action spaces.

6. Outlook

On the technological level a number of enabling technologies for global content management have emerged that are converging into Semantic Web technologies. Intelligent information agents are integrated into such systems. They are combined with knowledge organization systems (in particular multilingual ontologies). Semantic interoperability has also become a major field of research and development in this respect.

In the field of the so-called content industry different business models have developed that could not be more diverse: on the one hand open source and open content approaches are rapidly gaining momentum, also facilitated by maturing Linux-based applications. On the other hand national, regional and international legislation concerning intellectual property rights is becoming more and more strict and global players are buying substantial portions of cultural heritage for digitisation and commercial exploitation that might eventually endanger the public nature of cultural heritage.

Epistemological issues of global content management will have to be addressed, as well as best practices to be studied in detail in order to develop advanced methods for these complex management tasks. Managing cultural diversity in a dynamic market with rapidly changing consumer interests and preferences, with new technologies to be integrated, also requires a strategy for sustainable teaching and training initiatives (based on knowledge management teaching and training initiatives) in this fascinating field.

Terminology and Data Categories of Language Resources

Klaus-Dirk Schmitz
University of Applied Sciences, Cologne, Germany

Terminology Standards

Two meanings of "Terminology Standard"

- "Vocabularies" are terminology standards that contain subject-field-specific concepts and terms produced by terminology sub-committees on national, regional and international level
- Terminology-principles-and-methods standards produced by specific committees on national and international level (ISO/TC37, DIN-NAT, ...)

TC 37

Contents

3 Vocabulary

3.1 Language and reality

3.1.1
object
anything perceivable or conceivable

NOTE Objects may be material (e.g. an engine, a sheet of paper, a diamond), immaterial (e.g. conversion ratio, a project plan) or imagined (e.g. a unicorn).

3.1.2
subject field
domain
field of special knowledge

NOTE The borderlines of a subject field are defined from a purpose-related point of view.

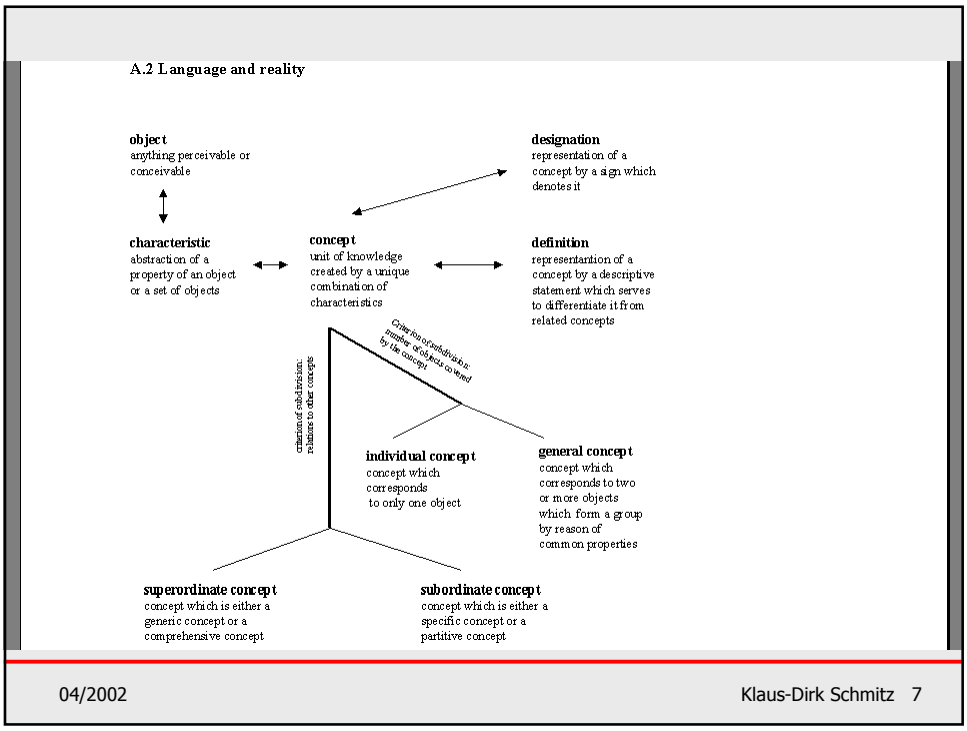
3.1.3
special language
language for special purposes
LSP
language used in a **subject field** (3.1.2) and characterized by the use of specific linguistic means of expression

NOTE The specific linguistic means of expression always include subject-specific **terminology** (3.5.1) and phraseology and also may cover stylistic or syntactic features.

3.2 Concepts

3.2.1
concept
unit of knowledge created by a unique combination of **characteristics** (3.2.4)

NOTE Concepts are not necessarily bound to particular languages. They are, however, influenced by the social or cultural background often leading to different categorizations.



A.2 Language and reality
object
anything perceivable or conceivable
designation
representation of a concept by a sign which denotes it
characteristic
abstraction of a property of an object or a set of objects
concept
unit of knowledge created by a unique combination of characteristics
definition
representation of a concept by a descriptive statement which serves to differentiate it from related concepts
Criterion of subdivision: number of objects covered by the concept
criterion of subdivision: relation to other concepts
individual concept
concept which corresponds to only one object
general concept
concept which corresponds to two or more objects which form a group by reason of common properties
superordinate concept
concept which is either a generic concept or a comprehensive concept
subordinate concept
concept which is either a specific concept or a partitive concept

Concept Orientation

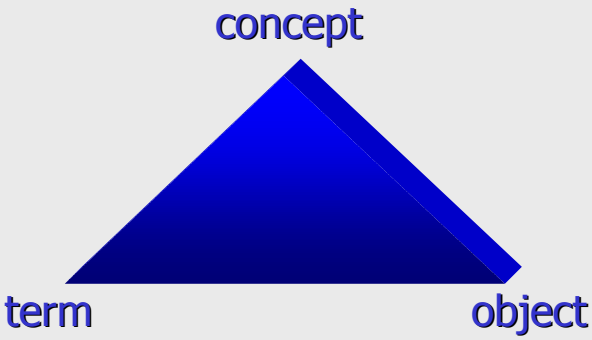
term object

04/2002 Klaus-Dirk Schmitz 10

Concept Orientation



Concept Orientation

object — Any part of the perceivable or conceivable world
Objects may be material (e.g. engine) or immaterial (e.g. magnetism)

concept — Unit of thought made up of characteristics that are derived by categorizing objects having a number of identical properties
Concepts are not bound to particular languages. They are, however, influenced by social or cultural background

term — Designation of a defined concept in a special language by a linguistic expression
A term may consist of one or more words

Concept Orientation

- All terminological information pertaining to *one* concept including all terms (designing this concept) in all languages and all descriptive and administrative data must be handled as *one* terminological unit.

Concepts in the Lexicon: Introduction
John F. Sowa
The lexicon is the bridge between a language and the knowledge expressed in that language. Every language has a different vocabulary, but every language provides the grammatical mechanisms for combining its stock of words to express an open-ended range of concepts. Different languages, however, differ in the grammar, the words, and the concepts they express. The differences arise from three kinds of variation:
Accidental. The most obvious differences result from arbitrary choices of sounds, such as hand in English and mano in Italian. Other variations depend on arbitrary choices of where to draw boundaries. In English, hand refers to the part of the body from the fingertips to the wrist. But in Russian, the corresponding word ruka extends all the way to the elbow.
Systematic. The grammar of a language determines how the conceptual structures are linearized as strings of words in a sentence. English and Chinese, for example, put the subject first, the verb in the middle, and the object at the end for an SVO word order. Irish and Biblical Hebrew are VSO languages that put the verb first. Latin and Japanese are SOV languages that put the verb at the end. The grammar also determines how the units of meaning, called morphemes, are combined to form words. Chinese is an extreme example of an analytic language in which almost all the morphemes can be used as stand-alone words. German is an agglutinative language, which forms compound words like Lebensversicherungsgesellschaftsangestellter (life insurance company employee). Old English was an agglutinative language like German, but as it evolved into modern English, it became almost as analytic as Chinese.
Cultural. The concepts expressed by a language are determined by the environment, activities, and culture of the people who speak the language. Since French, Chinese, and Indian cuisines are based on very different ingredients, methods of preparation, and cooking utensils, the people who cook and eat each kind of food use words for it that have no counterparts in the other cultures. The specialized concepts, however, can be transferred with the culture whenever a cook opens a new restaurant in a foreign land. Cultural and conceptual shifts occur across time as well as space. A book on science or business, for example, is easier to translate from modern English to modern Japanese than from modern English to the language of Shakespeare.
Grammars and words belong to the province of linguistics, but the concepts they express belong to the extra-linguistic knowledge about the world. For each language, the lexicon must provide the links that enable a language processor to carry messages from one province to the other.
Besides accommodating the idiosyncracies of each language, the lexicon must support all the possible uses of language. Each use has a different purpose, which

part of speech

Identifying and Definitional Attributes

Data Element ID:	ISO12620A020201 **Version No :** 1
Data Element Name:	part of speech
Type :	Data Element
Status :	Current 12-DEC-1999
Admitted Name:	
Non-admitted Name 1:	grammatical category
Non-admitted Name 2:	word class
Definition:	A category assigned to a word based on its grammatical and semantic properties.
Source-related Comment:	
Concept-related Comment:	
Example:	
Dictionary ID :	A.2.2.1

Relational and Representational Attributes

Datatype :	Plain Text (or user-defined picklist)
Representational Form :	??
Representation Layout :	??
Minimum Size :	
Maximum Size :	
Guide for Use :	In a given database, it is wise to configure this category as a user-defined picklist in order to avoid the proliferation of alternate forms, etc. For a global interchange format, however, it is important to specify this item as plainText because it is impossible to predict all the possible options that might occur in all possible language combinations
Validation Rules :	

Data Domain Details

Examples of parts of speech commonly documented in terminology databases can include:

Permissible value	Domain Meaning Definition Text	Example
noun	A word that refers to a person, place, thing, event, substance or quality.	'Doctor', 'tree', 'party', 'coal' and 'beauty' are all nouns.
verb	A word or phrase that describes an action, condition or experience.	The words 'run', 'keep' and 'feel' are all verbs.
adjective	A word that describes a noun or pronoun.	'Big', 'boring', 'purple', 'quick', 'obvious' and 'silvery' are all adjectives.
etc.		

TC 37 / SC 4

- It is important to develop a standard for data categories used in typical "SC 4 applications"
- May-be with different parts for different types of language resources (NLP lexica, texts, speech etc.)
- Data analysis material: language data collections
- Data analysis method/tool: (mod.) SALT's DCS-Editor

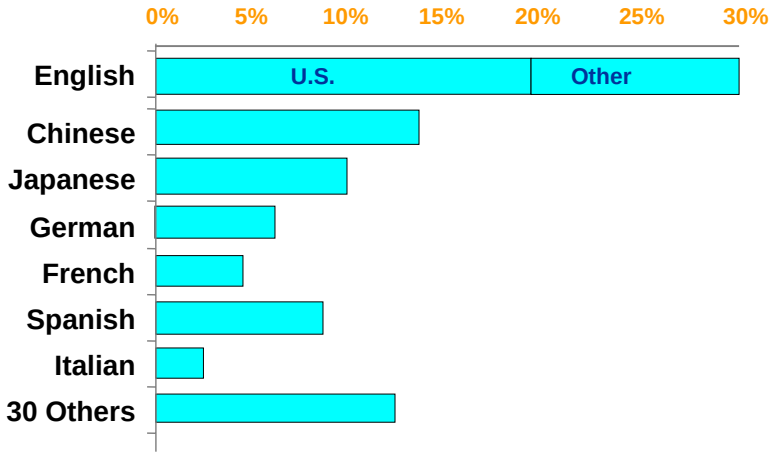
Language Resource Representation and Management Standards for the Localization Industry

Alan K. Melby
<akm@byu.edu>

ttt.org -translation, theory & technology-

Tidbit: Internet Users by Native Language - 2005



Source: IDC Internet Commerce Market Model, V7.1 (c/o Rose Lockwood)

Overview of Presentation

A. Definition of localization as part of GIL
B. Brief history of LISA and OSCAR
C. Layers of Localization standards
D. XLIFF for text and source code
E. TMX for translation memory exchange
F. TBX and OLIF for terminology
G. Unresolved issue: segmentation

[A] GIL

- Globalization (G11N)
- Internationalization (I18N)
- Localization (L10N)

[A.1] Globalization

- Globalization (G11N)
  - Globalization is the business process of taking products and services into various new markets around the globe
  - A locale is the geographic region and language of a particular market
- Internationalization (I18N)
- Localization (L10N)

[A.2] Internationalization

- Globalization (G11N)
- Internationalization (I18N)
  - Internationalization is the engineering process of generalizing a product or service so that it can handle multiple languages and cultural conventions

Localization (L10N)

[A.3] Localization

- Globalization (G11N)
- Internationalization (I18N)
- Localization (L10N)
  - Localization is the cross-cultural communication process of preparing locale-specific versions of a product or service and consists of translation of textual material and adaptation of non-textual material.

[B] Brief History of LISA and OSCAR

- LISA (Localization Industry Standards Association) – see http://www.lisa.org/info/about.html
- OSCAR (Open Standards for Container/content Allowing Re-use)
- OSCAR is a LISA special interest group for language resource data standards

Localization-related Technologies

- Text Representation (Unicode and XML)
- Translation/Localization Container (TLC)
- Translation Tools (specialized)
  - Segmentation, alignment, encapsulation
  - Termbase setup or enrichment
  - Translation memory and machine translation
  - Terminology lookup
  - Missing segment and markup check
  - Term check (consistency, false friends, and variants)

[C] Layers of Localization Standards

- Unicode
- XML (including language/locale ids)
- XLIFF
- TMX
- TBX and OLIF

[D] XLIFF

- XLIFF is a format to store extracted text and carry the data from one step to another in the localization process
- see http://www.opentag.com/xliff.htm for more information

[E] TMX

- The purpose of TMX is to allow easier exchange of translation memory data between tools and/or translation vendors with little or no loss of critical data during the process.
- See http://www.lisa.org/tmx/ for more information

[F] TBX and OLIF

- TBX and OLIF allow the representation and exchange of terminological data, with a focus on human-oriented and NLP-oriented data, respectively
- See http://www.lisa.org/tbx/ for more on TBX
- See http://www.olif.net/ for more on OLIF

[G] Unresolved Issue

- Segmentation of words, sentences, and other linguistic units has not yet been standardized for the localization industry
- This means that word counts are not standard
- This also means that translation memory lookup may not detect some matches

OpenNetTerminologyManager- a Web and Standards based OpenSource Terminology Management Tool

Klemens Waldhör*

* Friedrichstr. 17, 90574 Roßtal, Germany, dr.klemens.waldhoer@waldhor.com

Abstract

OpenNetTerminologyManager is a privately started Open Source project which aims at developing a freely available pure web based concept terminology management system. It runs with any browser supporting JavaScript. The server side requires MySQL, Apache Web Server and Perl. The system is currently available through sourceforge.net at http://openwebterm.sourceforge.net. OpenNetTerminologyManager supports different terminological models. A version which is based on MARTIF has been implemented.

1. Introduction

Through the years the world has seen the attempt to establish several different terminology standards starting from MARTIF, Geneter to TBX, XLT (SALT), TMF (ISO 16642) and so on. The author himself was part of one of the older efforts which started 1990 where within the MULTILEX project a first try was made to create a standard exchange description for areas like mono- and multilingual dictionaries, machine translation etc. The basic idea there was to use SGML as the description language. This was followed up in projects like EAGLES, Otelo (OLIF) etc. In parallel other attempts have been made like Geneter. Sometimes one is really puzzled how creative the terminology community is in inventing new ideas and standards. Often it is really hard to follow what is going on. This is the one side of the coin. On the other side the industry uses "**quasi standards**" like the export format used in MultiTerm™ from Trados™. Several products of competitors like TermStar™, UniTerm™ and others provide import and export features from and into the MultiTerm™ format, simply because MultiTerm™ is the market leader in this area. Otherwise getting into this application field for new systems is nearly impossible as most customers either use MultiTerm™ or at least provide their data in this format.

Interestingly enough Open Source terminology software was never really part of the terminology game, in contrast to other areas like web servers where open source software like Apache is the dominating software (60 % of the world web server market). If one searches for "open source terminology management" in Yahoo and inspects the returned results in detail there are only two other relevant matches, the ForeignDesk and OpenGALEN match. In the last half year Lionbridge has made its software **ForeignDesk** available through open source. Another notable effort is **RosettaWerks** which deals implementing a set of tools for the localisation process.

But what is really missing is a terminology tool which is available on several operating systems (not just Windows™) and can be used through the web and itself is built on free available software. This is not the place to discuss the advantages of the open source model. A lot of discussion is going on this area, but I just want to add that one clearly has to distinguish the open source model from models which are offered by software suppliers where one can get the executables for free, but has no access to the source code. Several providers of terminology software supply down-graded or full versions of their tools – mainly viewers - e.g. UniLex™ from Acolada GmbH, but this does not bring any advantage to the user as he still relies on the provider to fix bugs etc. In addition it is hard to check if there are any hidden traps in the software. As professional terminology management contains company or customer information security aspects and the ability to check this will be an important aspect of choosing a system in the future. Based on this observations – and being also a fan of the open source community - I started developing a terminology management software which should fill this gap.

2. OpenNetTerminologyManager Terminology Model

The basic idea of the system architecture is the capability to support **different terminology models**. The user should have the option either to create his own model or to adapt an existing model by sub-classing it or adding his own fields. It should also be possible to keep track with on-going changes in the standardisation community. This has been realised in the system in the following way: attributes (elements) of the terminology model are not directly mapped to database tables, but this information is kept in a specific column where the structure can be freely defined. The actual mapping of these content of this column to attributes is defined in **model files**. Each database represents one model. The advantage of this approach is a) that it keeps the number of databases tables to a minimum, b) as a result the system is quite fast in searching and reading entries and c) adaptations of attributes can be made easily.

The basic OpenNetTerminologyManager approach is **concept oriented** as it used in most modern terminology systems. In this approach a concept corresponds to one meaning of a word. The language specific parts of a concept are called "**language terms**" or simply "**terms**". Each concept is tagged with an unique identifier, while each term related to the concept uses the concept identifier plus a language identifier and an internal term counter as identifier.

Example: The German term "**Birne**" (three meanings: Glühbirne, Frucht, Kopf = bulb, pear, nut) will be represented by creating three concepts (Figure 2):

a) one with the meaning of "Frucht = fruit" and

b) one with the meaning of "Glühbirne = bulb" and

c) one with the meaning of "Kopf = head".

The **kernel** of OpenNetTerminologyManager consists of several tables:

a) A **MONOTERM** table which holds all relevant information for a term including term attributes

b) A **MULTITERM** table which links entries in the MONOTERM table to a concept and also also stores concept related attributes.

c) A **DETAILS** table which contains links from attributes to terms and concepts. This table is only used to optimise the speed when searching with attributes.

d) A **LINK** table which establishes links between either concepts or term (e.g. in order to express a relations like "synonym").

Different terminology models are now mapped to the kernel model in a **model file**. This model file defines:

The **names** (e.g. "Gender") to be used for the **attributes** of the terminology model into an internal name. This association differentiates between concept related and term related attributes.

The **values** and **forms** to be associated with a such **names**. As an example associate the attribute "Gender" with three possible values ("male", "female", "neuter") and display them in the browser as a select box.

Table 1 shows a simple section for the MARTIF model. Models can further be differentiated into two classes: "**full models**" and "**sub-models**". A sub-model is defined as a subset of attributes of a full model. This is mainly necessary if for a given model (e.g. MARTIF) only specific attributes should be shown or if specific restrictions may apply for attribute values. The system contains some additional fixed attributes like the owner of the concept, read and write accesses etc.

3. OpenNetTerminologyManager Features

The following functions are currently supported:

- Constraints between attributes can be realised with JavaScript
- New models and sub-models can be created by the user (see Figure 1).
- Attributes can be defined by the user.
- Different types for attributes like option fields, text fields, select etc. are supported.
- Multiple databases; multi-user read/write support (locking at concept level). Different right combinations can be used. Databases are either private (with user and password protection) or public.
- Partial Unicode support. Unicode characters above Ascii 255 are stored as SGML entities in the database. This will be removed once MySQL supports directly UTF8 or a similar Unicode encoding scheme. Languages like Arabic, Chinese, Japanese etc. can be used through this approach. Once a Unicode implementation of MySQL is available this representation will be changed to an internal Unicode character set.

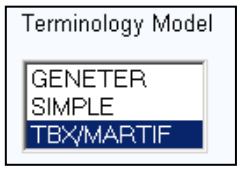


Figure 1: Models

Currently one terminology model based on MARTIF has been (partially) implemented. It normalises the XML definitions into the relational (table based) approach defined above. Others like Geneter are under way.

```
opwdetail40=Grammatical Gender
opwdetail41=Term Type
opwdetail44=Grammatical Number
…
 <tr>
   <td>
     <fieldset>
       <legend>Grammar</legend>
       <table>
         <tr>
           @tdopwdetail43=Part Of Speech?10<select!noun|verb|adjective|other
           @tdopwdetail40=Grammatical Gender?10<select!na|feminine|masculine|neuter|other
         </tr>
         <tr>
           @tdopwdetail41=Term Type?10<select!...|variant
           @tdopwdetail46=Valency?10<input
         </tr>
         <tr>
           @tdopwdetail44=Grammatical Number?10<select!na|dual|mass|other|plural|singular
           @tdopwdetail45=Animacy?10<select!animate|inanimate|other
         </tr>
       </table>
     </fieldset>
   </td>
 </tr>
```

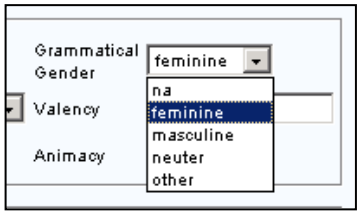

Table 1: OpenNetTerminology Manager GUI description

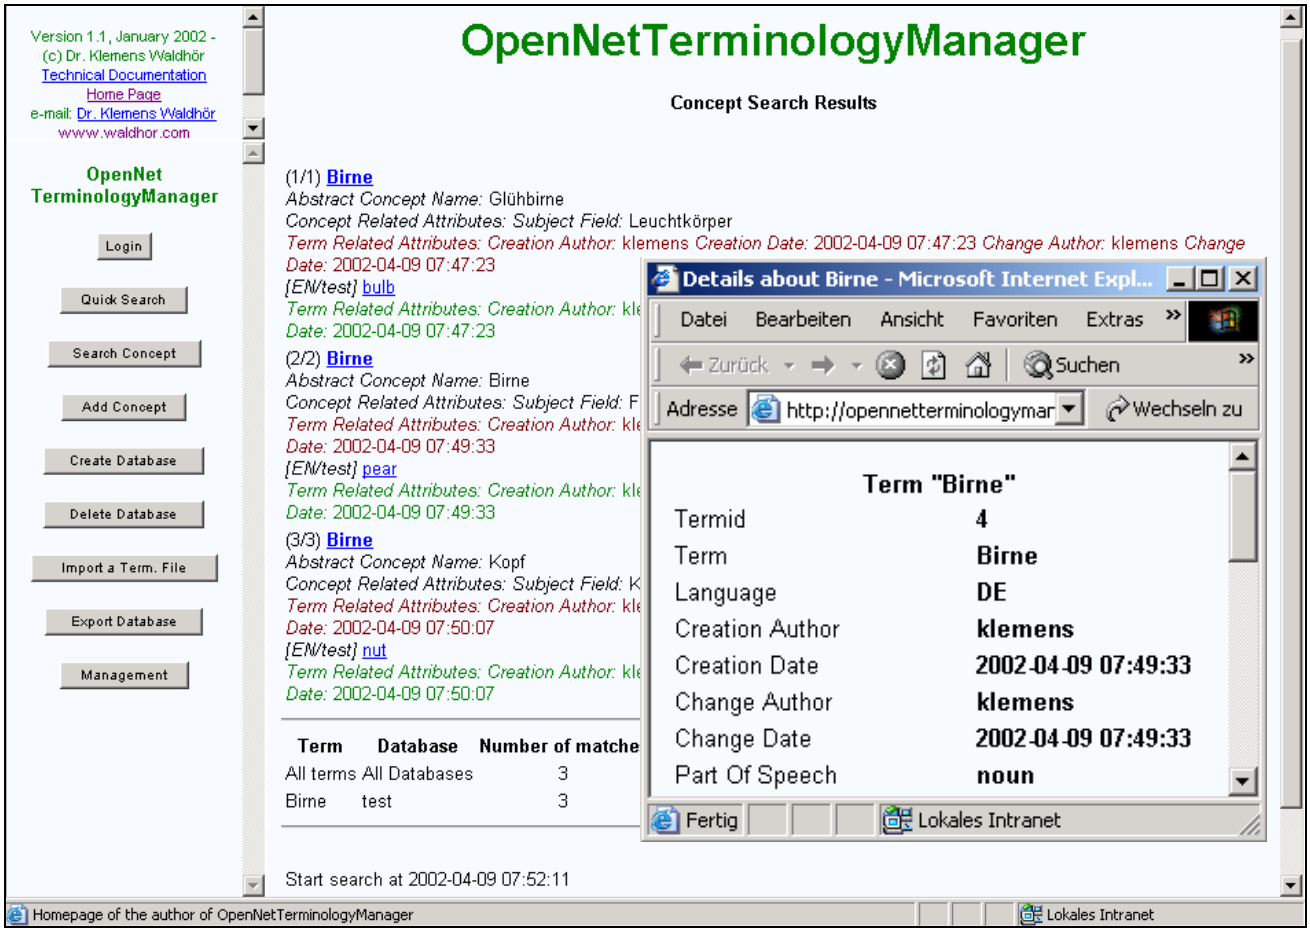

Figure 2: OpenNetTerminology Manager User Interface

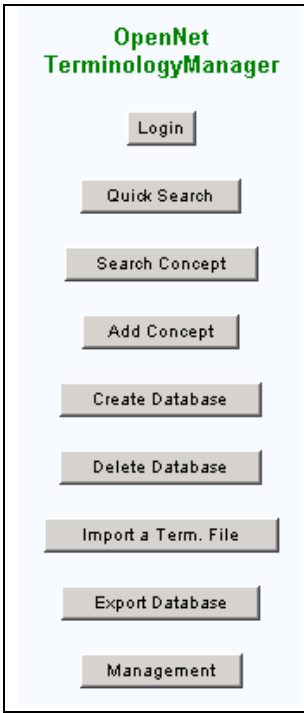

Login allows the user to define default values like his preferred databases, languages, attributes to be displayed for a model, how search results should be displayed etc.

Quick Search offers a simplified search mode which simply looks up the database for a specified term independently of the language.

Search Concept supports more detailed search options like languages to be searched and displayed etc. Through this item the user also can edit concepts in the database.

Add Concept adds new concepts to the database.

The user can create new databases using **Create Database** where he also specifies the model and access rights for the database.

Databases can be deleted using **Delete Database**.

Import Term File allows existing terminology files to be imported in various formats supporting double detection during import,

while **Export Database** exports databases into various formats.

Management is mainly intended to give an overview of current system settings and databases. It also supports recreating the database structure.

Figure 3: OpenNetTerminologyManager Commands

4. The Basic User Interface of OpenNetTerminologyManager

Figure 2 shows the basic web based user interface. It consists of a main window where the results of queries etc. are shown and a navigation window (left). Optionally additional concept or term related information can be displayed in a separate browser window. Figure 3 describes the basic functions of the navigation window.

Concepts can be edited by first searching them with the **Search Concept** function and using the "Edit Mode" (not choosing "Dictionary View" option). See figure 4. Results are then displayed in a tabular like format (figure 5). Clicking on "Edit" will then display the full entry (figure 6) in an editable format. Results can also be displayed in a "Dictionary View" mode (figure 7). In this mode concepts found with the same name for a given language may optionally be collapsed into one output entry. This displays the entry in a similar way as they are show in printed dictionaries. Depending on the user search result display settings attributes will be displayed either directly in the main window as part of the entry or the term name is realized as a hyperlink and when clicking on it is displayed later in a separate browser window (figure 2). In addition the user can configure for each database which attributes should be shown. The query itself supports various search options like full text search, regular expressions, the LIKE operator etc.

5. Software requirements

OpenNetTerminologyManager requires the following software components: Perl > 5.0 (with some additional modules installed), Apache Web server or a compatible server, MySQL and a JavaScript enabled Web Browser. Tests have been done with Internet Explorer 5.0, 6.0®, Netscape® and Opera® . The system has been tested both on Windows (NT® and 2000®) and LINUX.

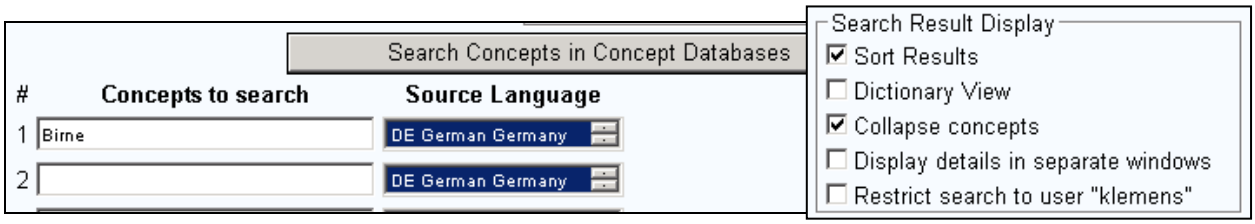

Figure 4: Searching concepts

No	ID / Concept	Source Language DE	Translation Term	Language	Database	Operation
1/1	316071404	Birne	nut	EN	meine	Edit Delete Copy Concept
2/2	284021368 Glühbirne	Birne	bulb	EN	meine	Edit Delete Copy Concept
3/3	312237593	Birne	pear	EN	meine	Edit Delete Copy Concept

Figure 5: Searching result display

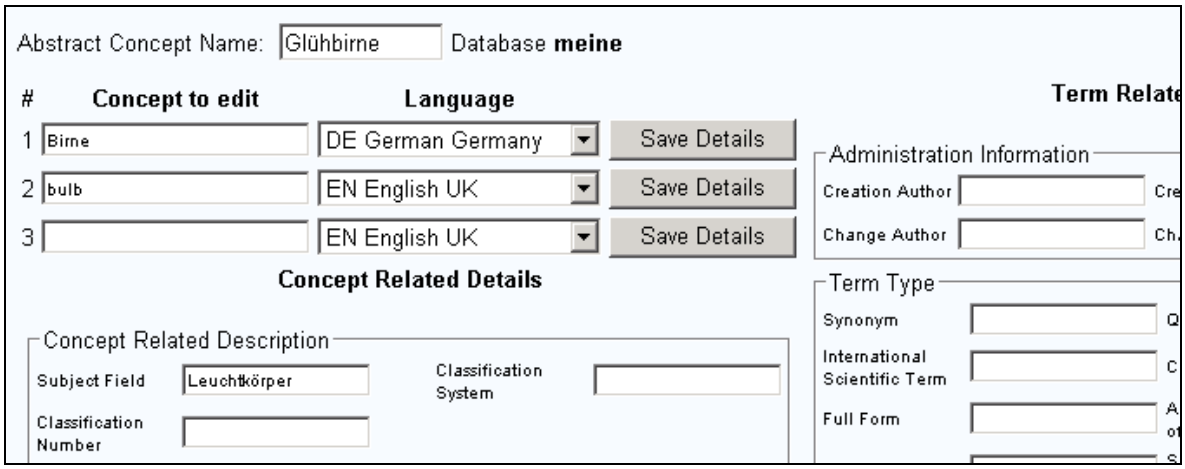

Figure 6: Editing concepts

Figure 7: Dictionary View display with no attributes displayed searching for "Planet%"

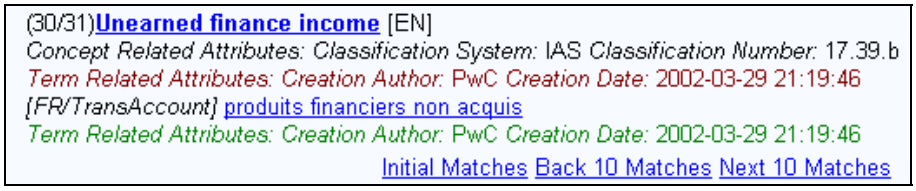

Figure 8: Result of a TransAccount terminology database full text query (searching for the term "finance") with attributes displayed.

6. Application Scenario

The TransAccount project (MLIS 5016) deals with the need for a multilingual translation system allowing the translation and interpretation between the annual accounts of a member state of the European Union (France) and IAS (International Accounting Standards) statements. Within this project the XBRL (eXtensible Business Reporting Language) IASCF taxonomy has been translated from English to French by one of the partners. The resulting 2000 concepts have been imported into a TransAccount terminology database. In addition about 2000 other general financial terms have been converted from a Geneter based format which have been produced by another partner at the start of the project. An example of the results of a query is shown in figure 7.

7. Next Steps

An important feature which is currently under development is an advanced link concept. This link concept will not only support links in the way as TBX defines them but will allow to create complex typed links between concepts and terms and databases. This will allow the user to search the databases not only as a simple term-lookup tool but to browse through it in a kind of semantic net and to find related concepts.

A concept is also developed which supports "similarity queries". It is intended to introduce a "stemming based index" by applying the Porter stemming algorithm to terms for some languages automatically (Porter, 1980). Other developments concern additional import / export formats and simplified form handling for attributes.

As there are several opens source project on mapping xml to relation databases on the way (e.g. XML-DBMS) I am currently also looking into replacing the internal structure of the database by a full xml database approach. This will heavily depend on the access speed compared to the current implementation.

An XML Markup Language Framework for Lexical Databases Environments: the Dictionary Markup Language.

Mathieu MANGEOT-LEREBOURS **Frédéric ANDRÈS**

Software Research Division, NII
Hitotsubashi, 2-1-2 Chiyoda-ku
101-8430 Tokyo, Japan
mangeot@nii.ac.jp

Introduction

Lexical data resources are growing rapidely thanks to the Internet. Unfortunately, despite numerous existing standards like TEI, MARTIF, GENELEX, EAGLES/PAROLE, etc. each resource has its own format and own structure. Furthermore, the existing lexical data is generally developed for a specific purpose and can't be reused easily in other applications.

In this paper, we intend to define a complete framework for developing multilingual lexical database for multipurpose. The framework is generic enough in order to accept a wide range of dictionary structures and proposes for manipulating heterogeneous dictionaries a set of common pointers into these structures.

We will first present the organisation of Dictionary Markup Language (DML) framework.

Then we will describe more precisely the DML language based on XML schemata.

Next, we explain how to describe dictionary macro and microstructures with the DML.

Lastly, we will explain our concept of common pointers defined in a Common Dictionary Markup (CDM) set.

1. Presentation of the DML Framework

The DML Framework described first by Mangeot-Lerebours (2001) is a complete framework for the consultation of heterogeneous dictionaries, cooperative construction of new dictionaries and communication with other lexical databases or lexical data client and supplier applications. The framework is completely generic in order to manage heterogeneous dictionaries with their own proper structures.

The consultation of heterogeneous dictionaries is possible as soon as they are encoded in XML, consultation of other resources via remote servers through API, possibility of adding pre-consultation help modules such as spell checking and morphological analysis before consultation or post-consultation modules like syntethisers, conjugation of verbs, learning drills, etc. Possibility of automatic consultation of the database via client API.

The construction of new dictionaries can be done by a community of contributors and validated by a group of head lexicographers specialists.

The management of user profiles, preferences and weights for consultation, annotation and edition of lexical data with inheritance and sharing possibilities among groups of users is also handled by the framework.

The `<database>` element describes a lexical database and lists the dictionaries that are stored in it.

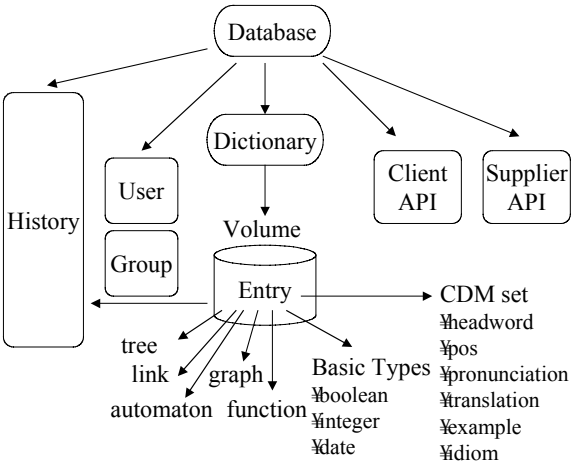

Figure 1. Logical Organisation of a Lexical Database

The `<dictionary>` element describes the metadata linked to ther dictionary. It links all the volumes of the dictionary.

The `<volume>` element describes a dictionary part. The content is principally a list of dictionary entries. For example, a bilingual bidirectional French-English dictionary will be described by only one `<dictionary>` element. The French->English entries will be in one `<volume>` element and the English->French entries in another `<volume>` element

2. The DML Language

2.1. The DML Namespace

To describe the structure of all the documents, elements, attributes and XML types, we use an XML namespace [XML Namespaces]. Our namespace is called DML for Dictionary Markup Language. The

namespace URI points to an XML schema [XML Schemas] describing the contents of the namespace. It is available online[1] to allow users to edit and validate their files online with an XML schema validator.

```
<MyElement
xmlns:dml="http://www-clips.imag.fr/
geta/services/dml">
  ...
  <dml:MyDescendant/>
  ...
</myElement>
```

Figure 2: Usage Example of the DML Namespace

2.2. DML Common Types and Attributes

For some information, we define type and attributes common to all DML elements. It allows to standardize the data. The XML schemata have originally simple predefined types. We selected and reused some in our definitions.

2.2.1. Dates and Time

Dates are represented by the `date` DML attribute of the XML schema type dateType taken from the extended format of the ISO 8601 standard.

2.2.2. Response Delay

The `delay` DML attribute of an element indicate the response delay when a request has been launched on this element.
This delay is a duration of the XML schema `durationType` type. For example, 5 seconds and 10 cents will be indicated : "5.10S".

2.2.3. Unique ID

The `id` DML attribute of an element is a unique ID in all the lexical database. It allows to create links between elements. It redefines the XML schema ID simple type.

2.2.4. Modifications History

The modifications history of an element has a unique ID. The element links to its history thanks to the DML attribute `history` that gives the value of the history ID. The type redefines the XML schema ID simple type.

2.2.5. Languages Notation

To note the various languages, we use the ISO-639-2/T (T for Terminology) [ISO98] standard that defines a 3 letter code for each language (French->fra; English->eng, Malay->msa, etc.). It is far more complete that the two letters code standard ISO-639-1. We also add our proper codes like "unl" for the UNL language. This codes list represents the lang DML type. The `lang` DML attribute is from this type.

[1] http://www-clips.imag.fr/geta/services/dml/

2.2.6. Documents Encoding

To note the encodings of the various documents in the database, we define the `encodingType`. DML type. The values are those described by the IANA (Internet Assigned Number Authority) for the encodings. These are also the values used for MIME types (Multipurpose Internet Mail Extension). Among the most used, we find ASCII on 7 bits, ISO-8859-1 on 8 bits for latin languages, Shift-Jis on 8 or 16 bits for the Japanese, UTF-8 on 8 bits for UNICODE characters, etc.

2.2.7. Status of an Element

The `status` DML attribute is used to indicate its status. The values can be among others `auto` if the element has been obtained automatically, `rough` if the element has not been revised and `revised` if so, etc.

3 DML Architecture

3.1. Macrostructure Definitions

To describe the macrostructure of our dictionaries as well as our lexical database, we use XML elements. We principally based our definitions on the LEXARD language defined by Serasset (1994) and added some information

3.1.1. Description of a Lexical Database

To describe a lexical database, we use the `<database>` element formally described inthe DML schema.
The modifications of the `<database>` element and its descendants are stored in a document linked with the `history-ref` atttribute.
We add to LEXARD the possibility to define various users and groups in the database. At the beginning three groups are predefined : `universe` contains all the users of the database, `administrators` contains the administrators of the database and `lexicologists` contains the users in charge of the control of the data.
The information relative to each user are stored in another element referenced by the `<user-ref>` element.
All the dictionaries of the database are referenced by pointers on XML documents that describe them. The pointers are the `href` attributes of the `<dict-ref>` elements grouped in the `<dictionaries>` element.

3.1.2. Description of a Dictionary

To describe a dictionary, we use the `<dictionary>` element. The modifications information is stored in a document pointed by the `history-ref` attribute.
We indicate meta-information on the resources.
The elements `<category>`, `<type>` and `<links>` describe the dictionary macrostructure.

The <category> element indicates the dictionary type (monolingual, bilingual, multilingual, interlingual). The <type> element indicates if the dictionaries are unidirectional, bidirectional or pivot based.
The <links> element indicates the links between the volumes of the dictionary. For example, if a dictionary is pivot based with 3 languages English, French and Malay, it contains 4 volumes Interlingual, English, French and Malay linked as follows:

```
<links>
  <link from="English"
to="Interlingual"/>
  <link from="French"
to="Interlingual"/>
  <link from="Malay"
to="Interlingual"/>
</links>
```

The dictionary volumes are referenced by their unque name. The <volumes> element gathers all the reference to the volumes files noted with the <volume-ref> element.
The source and target languages are indicated with the 3 letter code DML lang type.
The <content> element describes the content of the dictionary. The <domain> element indicates the domain covered by the dictionary (general, medecine, computer, etc.)
We indicate also the size of the dictionary in bytes by <bytes>, and the headword number by <hw-number>.
For the version management, we indicate the version number (<version>), the creation-date of the dictionary (<creation-date>) and the date of the integration of the dictionary into the database (<installation-date>).
For the non-DML resources, we need to indicate the file format (<format>) and the encoding (<encoding>). The encoding values are determined by the DML type encodingType.
We also indicate meta-information on the dictionary like the resource supplier (<source>), the owner (<owner>), the responsible at the database level (<responsible>), the rights attached to the dictionary (<legal>) and miscellaneous comments (<comments>).
The CDM (see chapter 4) elements list (<cdm-elements>) is stored with for each element, its real name in the resource and the maximal response delay. The (<corpus>) element is special, it allows to indicate that we search a string anywhere in the dictionary.

3.1.3. Description of a Volume

The <volume> elements gathers dictionary entries with the same source language. The modificaitons history is referenced with the history-ref attribute.

3.2. Microstructure Definitions

To represent dictionary microstructures, we propose to redefine in XML the structures defined with LINGARD (see serasset (1994).

3.2.1. Trees

To represent a dependance tree associated to the sentence "Le chat mange une souris.", for example, we can use a “decorated node” <dn> with attributes corresponding to the grammatical variables.

```
<dn ul="manger" time="present"
aspect="imperfectif">
  <dn ul="chat" determ="defini"
gnr="masc" pos="-1"/>
  <dn ul="souris" determ="indefini"
gnr="fem" pos="+1"/>
</dn>
```

3.2.2. Links

The definition of a link is done with the xlink standard [XLink 1.0]. We alslo add our attributes:

- The attribute type="bidirectionnal" or type="oriented" indicates if the link is bilingual or not;
- The attribute id is of the DML id type. It allows to attribute a unique id for each link;
- The content text of the element allows to tag the links.

Here is a link example:

```
<link type="oriented" id="l001"
href="example.xml#xpointer(//node[xl
:label='n002'])"/>
```

The reference to the external element is done with the href attribute. The reference is noted as a URI. If the object does not have a unique id (id), the link is described with the [XPointer] standard. Otherwise, it is pointed as follows:

```
<link type="oriented" id="l001"
href="example.xml#n002"/>
```

3.2.3. Graphs and Automatons

The xlink standard [XLink 1.0] is used to describe arcs. The arcs type is oriented type="oriented" or bijective type="bijective". The source and the target of the arc are noted with the node identifiers from="n001" and to="n002".
The definition of an automaton follows the definition of a graph. The starting node is noted with the xl:title="starting-node" attribute. The ending nodes are noted with the xl:title="ending-node" attribute.

3.2.4. Functions

The following example represents the lexical function [lambda]x1 ($CausOper_1$x0x1). The results of its application to the French lexie DÉSESPOIR are the following: pousser, réduire quelqu'un au désespoir,

jeter quelqu'un dans le désespoir, frapper quelqu'un de désespoir. The function is noted in XML as follows:

```
<function name="CausOper1">
  <arguments>
    <first value="desespoir"/>
  </arguments>
  <valgroup>
    <value>pousser</value>
    <value>réduire [qqun au
désespoir]</value>
    <value>jeter [qqun dans le
désespoir]</value>
    <value>frapper [qqun de
désespoir]</value>
  </valgroup>
</function>
```

3.2.5. Feature Structures

If the features are typed, the type is noted with an attribute. If the feature has several values, the element is duplicated.

```
<feature1
type="type1">valeur1</feature1>
<feature1
type="type2">valeur2</feature1>
```

3.2.6. Sets and Disjonction

Sets and disjunctions are defined directly at the XML schema level with the two elements <xsd:choice> and <xsd:sequence>

3.2.7. Basic Types

The basic type of an XML document is the character string. Thanks to XML schemata, we can use many other basic types like boolean, entity, decimal, float,etc.

4. The Common Dictionary Markup Subset

We defined a subset of DML element and attributes that are used to identify which part of the different structures represent the same lexical information. This subset is called Common Dictionary Markup (CDM).

4.1. Definition of the Subset

The DML framework may be used to encode many different dictionary structures. Indeed, two dictionary structures can be radically different. So, in order to handle such heterogeneous structures with the same tools, we need a common formalism. Standards like TEI [Ide95], MARTIF [Melby94], [ISO99]; GENELEX/EAGLES [GENELEX93] and [GENETER] aim to be universal but very few resources implement them.

We made a more pragmatic work with identifying the information in the existing resources as well as their meaning and naming them ina unique way in the DML namespace

This hierarchized subset is called Common Dictionary Markup and comes principally from the detailed examination of the FeM, DEC, OHD, OUPES, NODE, EDict, ELRA-MÉMODATA dictionaries and the 12th chapter of the TEI about dictionaries. It contains the most frequent elements found in these resources like the headword, the pronunciation, the part-of-speech, the examples, the idioms, etc. These elements have always the same semantics. For example, <dml:entry> always refer to a dictionary entry and <dml:headword> to the headword.

For some elements with closed lists of values, we define a list representing the intersection of the values and conversion rules for each resource. An example is the list of parts-of-speech for each language.

This set is in constant evolution. If the same kind of information is found in several dictionaries then a new element representing this piece of information is added to the CDM set. It allows tools to have access to common information in heterogeneous dictionaries by way of pointers into the structures of the dictionaries. The table 1 lists a first version of the CDM subset.

<CDM tag>	**(TEI equivalent)**
<entry>	(entry)
<headword hn="">	(hom)(orth)
<headword-var>	(oVar)
<pronunciation>	(pron)
<etymology>	(etym)
<syntactic-cat>	(sense level="1")
<pos>	(pos)(subc)
<lexie>	(sense level="2")
<indicator>	(usg)
<label>	(lbl)
<definition>	(def)
<example>	(eg)
<translation>	(trans)(tr)
<collocate>	(colloc)
<link href="">	(xr)
<note>	(note)

Table 1: CDM Elements Subset

4.2. CDM Correspondance Examples

When a resource is recuperated, a correspondance table is established between the original element names and CDM elements. The table 2 has been used for the FeM, OHD and NODE dictionaries.

CDM	FeM	OHD	NODE
<entry>	<fem-entry>	<se>	<se>
<headword>	<entry>	<hw>	<hw>

<pronunciation>	<french_pron>	<pr><ph>	<pr><ph>
<etymology>			<etym>
<syntactic-sense>		<sense n=1>	<s1>
<pos>	<french_cat>	<pos>	<ps>
<lexie>		<sense n=2>	<s2>
<indicator>	<gloss>	<id>	
<label>	<label>		<la>
<example>	<french_ sentence>	<ex>	<ex>
<definition>			<df>
<translation>	<english_equ> <malay_equ>		<tr>
<collocate>		<co>	
<link>	<cross_ref _entry>	<xr>	<xg> <vg>
<note>		<ann>	

Table 2: Equivalents of the CDM elements in the FeM, OHD and NODE

Conclusion

This framework has been extensively used for the Papillon project (see Serasset & Mangeot-Lerebours (2001)) of mutualized construction and consultation of a pivot multilingual lexical database. This experiments allowed us to correct and adapt some parts of the DML.
Nevertheless, the framework need to be opened to the public in order to receive feedback and comments. We plan to open a web site dedicated to the DML soon.

TOWARDS A GENERIC ARCHITECTURE FOR LEXICON MANAGEMENT

Cristina Vertan
Walther von Hahn,
University of Hamburg, Natural Language Systems Department
Vogt-Kölln-Straße 30, 22527 Hamburg, Germany
cri@nats.informatik.uni-hamburg.de, vhahn@nats.informatik.uni-hamburg.de

Abstract

In this paper we propose an architecture for a lexicon management tool MANAGELEX. This tool aims at a general environment for reading, updating and combining lexicons in different formats. The starting point is the already existing lexicon models MULTILEX and GENELEX. Each functionality (reading, updating and combining) is based on a corresponding model, which can be configured and maintained coherently.

1. INTRODUCTION

A large amount of lexical resources was developed during the last 15 years. Unfortunately, in the absence of a standard each application produced and used its own lexicon in a specific format and a specific model, according to particularities of language, system functionality and available physical resources. Reusable lexical resources, however, could noticeably reduce the cost of development of NLP applications. Moreover, during research projects, lexicon requirements may change over the run time of the project, and maintaining a suitable lexicon is expensive and time-intensive work.

The problem of standardization appeared as an absolutely and urgent necessity, and several projects were carried out in this sense (v.Hahn 2000). The task is quite difficult because it implies at least two components : standardization of the format and standardization of the model. Moreover, these two components are not completely independent. For the former it is general agreed today, that the starting point is a SGML –based format. Several SGML-lexicon standard formats were already proposed (EAGLES, OLIF, SALT) (Lieske & al. 2001, Melby 1999). It is, however, necessary that we have not only a standard set of tags but also a standard model of a lexicon representation. As a result of this insights, several projects tried to develop a standard and general model for lexicons. The most well-known formalisms after this phase are GeneLex and Multilex.

2. STANDARD LEXICON MODELS. STATE OF ART

Although having many architectural features in common, Genelex is abstracted basically from a French monolingual lexical model, whereas the Multilex architecture is genuinely designed as a multilingual language-independent general structure, trying to include all language specific models (EAGLES 1996). At least, as quoted in one of the final reports (Praprotté & al. 1993), Multilex *"is based on a consideration of the following languages: English, German, French, Spanish and Italian, and to lesser degrees Dutch and Greek"*. Compared to the multitude of (at least) European languages we observe that the Slavonic family was not taken into consideration, and also a lot of other languages which bring in new linguistic features (for example Romanian, although it belongs to the Latin languages, it has several important characteristics, due to the Slavonic influence).

The MULTILEX architecture presented a generic model for a lexical entry, which can be used as a starting point for further developments. However MULTILEX, as other similar projects *"imposes constraints on the linguistic level. Each of these projects imposes its own notion of 'lexical unit' (lemma, word-sense, concept) and its own logical structure (Typed Feature Structures, Entity-relationship model, automata, trees,...)"* (Sérasset 1996).

With these constraints, a user at the moment cannot use the same system to manipulate two lexicons coming from different places. Some steps in this direction were done in MULTILEX, which originally proposed the development of tools to convert lexicons into MULTILEX format. The proposal was not further developed because, quoting the same final report (Praprotté & al. 1993) *"copyright problems, problems in converting and correcting dictionary data, a lack of consistency in the data"* made this proposal unreachable.

Much lexical work from completed projects cannot be used in follow-up projects because of one of the following reasons:

- The lexicons were produced with the help of systems that are not any longer maintained; thus nobody can provide an export facility.
- In some cases, lexicon definitions contain procedural elements, which cannot be used without the hosting system,
- Lexicons may contain too rich features, which are too expensive to remove from the files.
- Experimental lexicons may be inconsistent or contain entries with different granularity,
- Lexicons may be stored in a data base, whereas others are plain files and the export formats do not match,
- Lexicons differ in their linguistic classes, i.e., there is a more-to-more mapping between feature classes.

From another point of view the use of a specific format (for example MULTILEX) means to adapt a posteriori other systems' processes to read and work which such external formats. This is usually quite cost-expensive.

The situation is much more critical for small languages, and languages from Central and East Europe, for which

lexical resources were developed quite ad hoc as they were needed for a certain project.

Although a lot of resources after a few years may be linguistically and technically outdated, about 60% of a dictionary with approx. 80 000 entries comprises the lexical core of very high and rather high frequency words, which remain stable in their syntactic and semantic properties over a long period of time. The other part (especially terminology) from time to time must undergo revision, updating or even replacements.

3. MANAGELEX A GENERIC LEXICON MANAGEMENT MODEL

Following the above considerations, we assume that for a rather long time from now, NLP applications will still have to deal with manipulations of non-standard lexical resources.

However, this is only possible with rather general lexical management tools for acquisition, comparison, manipulation and validation of lexicons, based on several abstract models.

In this section we propose a new architecture for a lexicon management tool (MANAGELEX), a tool, which is able to read, convert and combine lexicons, independent of their format, language or system requirements.
The general architecture of such a system includes (as shown in figure 1) 3 levels of abstraction (which follow the ANSI(1999) data modeling specifications): the meta model level, the model level and the real world level.

- The real world level identifies real (present), distinct objects, their concrete features, and the actual relation among them. In figure 1 this corresponds to the encoded lexicons (DocA, DocB) and their structure (StructA, StructB)

- The model level groups real world objects and present features into object and attribute classes and recognizes possible relationships among object classes. On this level our architecture has 3 tools:
  - A tool for reading and updating a lexicon (acquisition and editing tool),
  - a tool for encoding and decoding (encoding / decoding tool) and
  - a tool for mapping two lexicons, possibly with different structure (mapping tool)

- The meta model level, classifies types of elements appearing on the model level and the abstract relations among them, situation independent. Accordingly, we propose

  - A generic lexicon model (LexMod) which provides a rather rich model of possible lexical information. Here, every linguistic feature, with their possible values which may occur in a set of languages (at least European) are specified (MULTILEX together with the MILE (Calzolari & al. 2001) model (defined in the frame of the ISLE project) are a good starting point). A flexible formal specification will be provided for this model. The model will also allow for new categories, joining as well as splitting of existing categories.

  - A generic encoding model (Encod), which specifies the way of combining the linguistic information in a specific entry and lexicon structure. The model should also include options for encoding files in the new generally agreed SGML-standards as OLIF or SALT (Lieske & al. 2001; Melby 1999).

  - A mapping model (MAP), that specifies modalities of combining two lexicons and takes into account problems like mutual gaps and complex categories.

Given this architecture, we now explain the functionality of the envisaged system in three situations:

1. Building / updating a lexicon.

Input: Lexicon definition from LexMod, Encoding Model Encod,
Output: Lexicon interface, lexicon file

The operation is mainly performed by the acquisition/editing tool. The interface of this tool is built automatically according to the characteristics selected from LexMod for this particular lexicon. The output of this tool is a data structure recording the structure of the lexicon LexA. The encoding / Decoding Tool uses this data structure and the Encoding module and produces and encoded lexicon DocA.

2. Reading a lexicon.
Input: Lexicon file, Encoding Model Encod,
Output: -

This operation requires first the identification of the encoding and the generation of the corresponding linguistic structure (StructB). Responsible for all these is the encoding tool

3. Join of two lexicons (LexA and LexB)
Input: General Lexicon definitions from LexMod, lexicon definitions from StructA and StructB, mapping models MAP
Mapping models MAP
Output: Lexicon file

This is the most challenging operation. The mapping tool has to use not only the structure of the two lexicons (StructA and StructB) and the mapping model (MAP) but also the generic lexicon model (LexMod). This is required for example in case of different names for the same linguistic feature. The resulting structure contains data consistent with both lexicons. Furthermore a new lexicon can be encoded as described above.

4. CONCLUSIONS

In this paper we described a model of a possible lexicon management tool, which can deal with frequent problems in lexicon acquisition / maintenance. The presented architecture is still in prototyping phase. We envisage to develop it in the frame of an European project. How ever for the moment we will take into account the European languages. Extensions to other language should be possible one the system reaches a stable version. The system is not intended to replace the actual already defined standards, but to supply the use and reuse of the already developed non-standard lexical resources

Management of Language Resources using Metadata

P. Wittenburg, Daan Broeder

Max-Planck-Institute for Psycholinguistics
peter.wittenburg@mpi.nl

Abstract

Technology development allows many more researchers than before to create language resources especially with multimedia extensions. This creates a resource management problem that exceeds the boundaries of established resource centers. Metadata environments such as the one proposed by IMDI that offer a metadata set and also tools to operate on them have a strong potential to help the individual researcher to carry out his resource management tasks. In addition, it allows him to easily integrate his resources into a large distributed domain of resources. The work at the Max-Planck-Institute for Psycholinguistics to establish a large multimedia language corpus helped to understand the needs and requirements. Due to this experience the IMDI environment has reached a state of maturity, but still some important features have to be added.

1. Introduction

Researchers and developers in the area of language resources are faced with four very dominant trends in the recent years: (1) The number and complexity of language resources stored in digital archives is growing fast, (2) there is an increasing acceptance of the need to improve the availability of the resources, (3) the Internet now connects many archives storing such resources and this asks for interoperability and (4) for many language resources need to be stored in archives for a large period of time due to economical and ethical reasons.

An impression about this explosion of resources can be given by the example of the multimedia/multimodal corpus at the Max-Planck-Institute for Psycholinguistics where every year around 40 researchers carry out field trips, do extensive recording of communicative acts and later annotate the digitized audio and video material on many interrelated tiers. The institute now has already more than 7000 annotated sessions - the basic linguistic unit of analysis - and we foresee a continuous increase. It was usual that researchers managing their resources with individually designed Excel-Sheets eventually were not able to keep control of them and that the institute effectively lost all access to resources when a researcher left. Thus the individual researcher as well as the institute was both faced with a resource management problem. It is known that in other research centers, universities and also in industry similar situations occur.

The increase of the amount of resources was paralleled by an increase in the variety and complexity of formats and description methods. Moving from purely textual to multimedia resources with multimodal annotations caused this. Media can include not only several audio and video tracks, but also increasingly often other information such as for example from eye trackers, data gloves and brain image recorders.

In many areas resources were seen as the private capital of a researcher or a specific project that served only to investigate a limited number of research questions. Therefore, the need to make resources available for other research was not seen. However, researchers now understand the potential of modern technology to immediately access the raw material, which enables for example re-coding, or incremental annotation procedures that can be part of collaborations. These opportunities increase the individual researchers willingness to share his resources and to invest time to create publicly available descriptions. We clearly recognize a trend towards making the resources themselves available via the Internet or at least indicating what resources exist by creating structured descriptions available on the Internet.

The usage of the Internet demands for interoperability on various levels. Therefore new technologies devoted to the special requirements of the Internet such as RDF (Resource Description Framework), XML and UNICODE are have been developed to improve the exchange and re-usage of data. The usage of open standards is even more important when repositories of language resources have to support long archive periods. The Internet also adds another dimension of complexity since people want to create distributed repositories where the resources of a corpus can be scattered over different locations, nevertheless requiring transparent access to them.

Summarizing we can say that a much broader group of researchers besides the experts who have always handled expensive resources are now involved. They are managing larger amounts of more complex structured resources, making them available in standardized formats and descriptions via the Internet. Now that resource creation has become much more easy many individual researchers are also coping with resource management problems pushing the management task beyond the experts at large data centers.

2. Resource Management

The increased relevance of resource management can best be seen in the document domain by the emergence of various sorts of commercial Content Management Systems. It is widely understood that only improved management concepts will allow us to prevent a chaotic situation where we will have an increasing amount of data on our storage devices, but don't know about them nor know how to access them.

We can identify at least four different groups of people involved in resource management each one with their own views: (1) the computer system specialists have to be able to manage data on a physical level. They allocate physical resources, define structures in file systems and take care of redundant copies for secure data storage. (2) The producer of resources wants to integrate his resources into the repository in an easy way and describe them easy and correctly to facilitate retrieval. (3) The user wants to deal with data on a domain-oriented level, i.e. a level where the

well-established concepts and terminology of a domain are used. He is not interested in file system details. This view includes distributed scenarios where the user wants to combine resources from different institutions without having to know where exactly the resources reside. Often the producer is himself a user. (4) The archive manager acts as an interface between system specialists and producers and also prefers to manage data at the level of domain concepts. At least he has to know how the system managers handle the resources since he has to draw the links between logical and physical structure and influence for example the policies for protecting the data. In many cases the producer/user is also the archive manager, since there is no support stuff. Management has to consider all views.

The following is a non exhaustive list of points to be addressed by modern resource management (resource discovery is in general seen as being a component of resource management, but in this paper we will mention it, but not focus on it).

- How to store resources such that they can survive for many years independent from technology changes.
- How to protect resources against unauthorised access
- How to create personalized views on resource repositories to facilitate easy and optimised navigation
- How to offer easy and immediate access to resources after access is approved?
- How can descriptions of sets of resources be modified easily?
- How to easily integrate new resources into the distributed resource repository?
- How to keep track of old versions?
- How to make such a management scheme available to interested parties.
- How to easily move groups of resources to other locations transparent to the user/producer?
- How to achieve hardware and operating system independent operation within the resource domain?
- How to easily integrate different data types that belong together and allow access while hiding the complexity?
- How to inform people about the existence of a resource and its major characteristics?
- How to easily discover resources in a distributed scenario from a conceptual perspective?

In this paper we will focus on the resource manager and user views. This although many important problems such as for example the problems of long-term archiving of digital media are not at all solved.

3. Pillars of Management

As already indicated, industry delivers a wide range of software solutions that are meant to cover documents of all sorts. In this paper we will not discuss Document Management Systems although they may deliver much functionality, but focus on the key pillars of open distributed solutions aimed at our specific environment and data types.

3.1. Standards

Open standards are very important to achieve interoperability, to build up long-term archives and to produce long-term available tools. Especially in the domain of computer-based language resources, however, we are faced with an extremely dynamical situation. This means we are confronted with a multitude of standards making many people turn over to use the word “best practice guidelines” instead. For multimedia resources for example we are confronted with a long list of media compression methods (MPEG1/2/4, Cinepak, Sorensen, MP3, ATRAC etc) all emerging within the last decade. Each having its advantages and disadvantages dependent on the field of application. For an archive one has to decide about major backend standards (such as MPEG2) which allows creating other representations for specific applications on the fly.

Referring to the earlier questions we need a couple of standards. We claim that many of the management problems can be solved with the help of establishing a suitable metadata environment existing of a metadata element set and appropriate tools. Tools themselves are not subject of standardization per se, since it is good to have competing solutions. With respect to the metadata set, however, we need agreements on various levels. The metadata elements are the dimensions of how to characterize a resource and it is clear that each choice for a set of dimensions limit the expressiveness for other groups of users. Therefore, we can expect that there will be different sets of dimension to describe multimedia/multimodal language resources. Important for the community is that we have open accessible definitions of the elements such that schemes can refer to them. They should be described as Data Categories if this will be the common practice for terminology repositories.

In addition, in the case of non-orthogonal spaces as the one we need to describe, these dimensions can only be defined appropriately by specifying suitable controlled vocabularies. They are the values that a specific dimension can take. Also these controlled vocabularies have to be openly accessible and should be defined in the same way. Both elements and their controlled vocabularies, have to be known exactly to achieve interoperability. Of course, it makes sense to use just one controlled vocabulary for example for language codes, but also here we are faced with different (quasi) standards such as ISO 639-2, the Ethnologue list from SIL[1] [1,2] and the various lists handled by specific projects. Also here we must accept that different vocabularies will exist.

Consequently, we are faced with mapping problems on different levels. RDF will be the primary language to try and bring all the different pieces of the mosaic together. This problem has not been tackled yet with the exception of a few cases such as in the Harmony project and in the mapping proposal from IMDI[2] to DC[3]/OLAC[4]. MPEG7[5] categories were mapped on Dublin Core categories in a very restricted way and the element relations are described

[1] Summer Institute of Linguistics
[2] ISLE Metadata Initiative
[3] Dublin Core Metadata Initiative
[4] Open Language Archives Community
[5] MPEG7 is the standard for media annotation within the family of MPEG standards in the film and media industry

with the help of the RDF formalism. Such a formal framework has not yet described the IMDI to OLAC mapping. At the moment we don't know which expressional power the community will need to accomplish the big task to create such a mapping for the language resource domain. The emergence of DAML/OIL [3] indicates, however, that RDF itself will probably not be sufficient.

It is assumed here without further comment that XML is our common language, i.e. all definitions and frameworks to be used should be based on XML.

3.2. Metadata Descriptions

The usage of metadata descriptions for improving the management of documents is not a new concept. Librarians are used to describe their documents with cards since many years. Linguists and speech engineers were used to describe characteristics of their resources and put these in file headers - mostly project specific formats. The community learned a lot from the TEI [6] work about standards for resource headers (later adopted by the CES[7]) and it is still used as a reference to look at. Also in some projects such as CGN[8] the TEI recommendations were followed to a certain extent.

TEI is a comparatively exhaustive descriptor set meant to describe the characteristics and structure of a resource. Newly developed metadata sets do not want to describe the resource in a too great detail, but address the problem of easy discovery primarily, i.e. a resource would be described sufficiently well, if a user manages to find it. Metadata sets such as DC, OLAC and IMDI follow this approach. DC tries to address the discovery problem with 15 sloppily defined categories ordered in a flat structure. In doing so DC allows the user to describe resources about steam engines as well as resources about Sign Language both on a very general level. For many DC categories it is not clear how they can be applied to different domains, therefore refinements are defined as was done by the OLAC initiative. The "DC:Type" element that defines the resource type is refined by the characteristic "CPU" to describe the type of CPU a NLP tool can run on. The semantics of such an element are stretched extremely.

MPEG7 and IMDI followed another approach since they started with studying the domain specific requirements. For MPEG7 it is essentially the production process of movies that has to be covered to later be able to retrieve relevant segments that are covered by the metadata set in addition to the ordinary elements such as "Creator". The basis of IMDI was an extensive survey of the different ways in which linguistic resources in all their variety have been described. Often this was done in the form of a proprietary "file-header" that contained metadata information about the annotation as a whole such as for instance the CHAT file format [4]. CES (being TEI compliant with respect to corpora) suggestions were applied were useful for discovery, however, we have not found sufficient support for other types of linguistic data than text. TEI/CES also mixes metadata and content in the same way as MPEG7. IMDI has favored a physical separation of metadata and content allowing uncomplicated protection schemes which is important for some groups of users. It also allows separate management of resources and metadata, usefull because the integration of legacy data formats has to be supported.

3.3. IMDI

3.3.1. Session Concept

The IMDI set was especially targeted at multimodal/multimedia resources and their inherent complexity, i.e. basis is in general the existence of media recordings. This led to the development of the "Session" concept. For linguists a session is defined as the basic unit of linguistic analysis and covers a coherent type of linguistic action or performance. From a corpus organization point a session is the leave in the tree. A session is in general associated with a bundle of tightly related resources: a video recording of a native speaker, a set of pictures of that persons house, some field notes about this scene and afterwards some multimodal annotations. The IMDI definition of the term "session" covers this bundling from an access and management point of view.

In DC one would have to use the "DC:Related" element to describe the relation between these resources that is associated with much overhead. This was described in more detail in the IMDI-OLAC mapping document [5].

From a management point of view the session concept makes sense since accessing or extracting subcorpora implies accessing resp. copying of complete sets of related information.

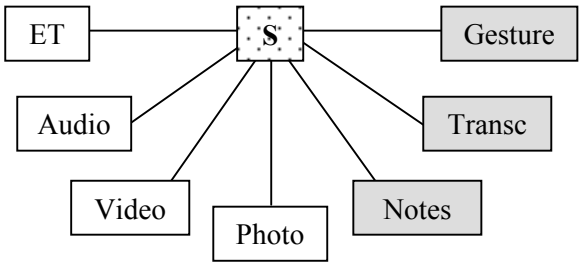

Figure 1 shows a typical session with its related resources all referring to the same linguistic event. It covers different types of recordings and different annotations.

In IMDI its the structured metadata set which describes this relation, i.e. there is only one metadata description (if the user decides to do it that way) with different sub-blocks describing the characteristics of the individual components. This way allows a user to ask questions such as "give me all resources which have eye movement recordings and a phonetic transcription of what was spoken"

3.3.2. Browsable Domain

Next to the "Session" concept, IMDI introduced the idea of structuring corpora in a conceptual space by having hierarchies of (sub-) corpora where description nodes representing a certain level of abstraction with respect to other (sub-) corpus nodes culminating eventually in pointers to session nodes (see figure 2). Each level represents a certain abstraction layer that is meaningful to the resource manager or user.

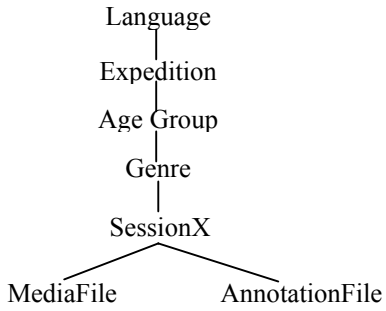

Figure 2 shows a typical hierarchy from field linguistics

Since corpus nodes create logical structures several parallel hierarchies can be created to structure the same (sub-)corpus and to express different interests of users. This allows each user to establish his own preferred view on the distributed resource domain and by also using bookmarks to create his own conceptual space (see figure 3). These parallel hierarchies can also be used to support versioning. Of course, there is no reason for the user to not create cross-references. For management purposes such cross-references are of course difficult to handle, i.e. the resource managers preferably would work with just the canonical tree.

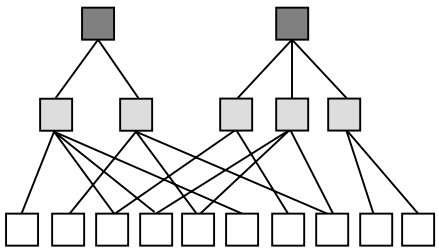

Figure 3 shows two user defined hierarchies referring to the same set of session nodes that are at the bottom level. One view could make a sex distinction, another one by age groups.

The mechanism by which the (sub-) corpora nodes refer to each other is to use URL's. This has the advantage to support distributed corpora frameworks and create a unique namespace for all resources.

3.3.3. Data Type Integration

Such a browsable domain as indicated is of course very useful for integrating various data types that we find in complete corpora. We already described the integration on the session level. For many data types however it only makes sense to associate them with higher nodes in a corpus tree. Such a node represents an abstraction with respect to a number of metadata elements (for example sharing the same language). Lexica can be related to a sub-corpus associated with a language or a set of recordings for a language (lexicon of a 3 year old child). Field notes and comments about dialect variants in general can appear on all levels of a corpus. In general many of these data types do not have any definite structure, but are just prose texts in some general format such as DOC, HTML or PDF. Corpus management has to provide mechanisms to include such descriptions in a flexible way. IMDI allows the resource manager to do so, but of course, will exclude proprietary formats such as DOC.

3.3.4. Practical Considerations

A strong concern was and still is how one can enforce creators and managers to adhere to standards with all its consequences as described above. The stricter the rules are such as full adherence to the chosen controlled vocabulary of a certain element, the more sensitive these procedures will become. Although the IMDI type of operations are now in operation for 3 years we cannot claim that a "standard" such as IMDI for describing language resources will not undergo changes. In IMDI for example we expect changes with respect to the dimensions and vocabularies that describe the resource content.

It was found - and this experience is nothing new - that it is very important to support the creators and managers with professional tools. Within IMDI it was always tried to have a balance between the development of the metadata set and an editor that supports the creation of IMDI descriptions. The IMDI editor now supports

- All metadata elements including their controlled vocabularies in a dynamic way, i.e. if the definition in the repositories change the editor will adapt its representations
- Sub-blocks which allow the user to save and reuse reoccurring information such as participant or project information

Version changes in the metadata set can of course lead to severe problems for corpus management and metadata usage. There efficient tools are of the greatest importance to modify all whole sets of existing metadata descriptions. Currently, a script allows the resource managers to change the values of the elements for a whole set of metadata descriptions. Of course, such operations are very sensitive and such a script may not be given to the general user. The intention is to include such an option in the editor such that all changes are conforming to the actual IMDI definitions.

The browser offers the same feature as the editor in so far that it also uses the actual vocabulary definitions from the repository. Further, the browser offers the following management relevant features:

- A user can create new (private) nodes and therefore define his own view on a sub-corpus
- It is possible to start the editor from the browser environment to modify metadata descriptions
- It is possible for the users (managers) to associate tools with individual or bundles of resources such that when a (set of) useful resources was found immediately a tool can be started to operate on the resources.

Both tools will have to provide for version conversion in case they find metadata descriptions in an older format. They should not however work with old versions without forcing (if possible) an update.

In the future the editor has to be extended to be able to create formatted lists (Spreadsheet type) of the content of a range of metadata descriptions for easy check and input to for example statistic programs. This is a favorite view on metadata of many users. The user has to be able to select the elements he wants to see. One complication is

given through the fact that some elements can occur several times such as participants, i.e. the number of entries for the spreadsheet can only be computed by first reading all selected metadata descriptions.

3.3.5. Difference to Normal HTML Domains

Of course, the basic organization principles sound very familiar, since we use the same for designing web pages. Instead of creating XML based descriptions one could create HTML pages and include all information and data types as hyperlinks in the usual way. Some archives are operating this way. Metadata descriptions could be included in the headers of the HTML files to support element-based search.

The IMDI team did not choose for this way for the following major reasons:

- HTML is basically a way to describe how documents should be displayed and not to describe data structures.
- Using HTML would not have made sense without also using HTTPD servers and browsers. Otherwise HTML is just a much less powerful version of XML. The current HTML browsers however are not suited to perform all computation tasks required of a metadata browser such as making intelligent choices for tools to work on resources.
- We needed a format to transfer information. Tools should be able to interpret this information either to display parts of it or to offer the user a choice of tools to work on referenced resources.

4. Conclusions

Based on 3 years of experience with a multimedia/multimodal corpus which covers already more than 7000 metadata descriptions and a showcase application including sample corpora from 6 European institutions we can draw some conclusions.

1. All questions raised in chapter two are addressed by the IMDI environment with two exceptions: (1) Version handling of resources and metadata description schemes are not yet supported by the tools by the tools. (2) The tool for extracting complete sub-trees of a corpus is not yet available.
2. The need to apply the definitions and tools to such a big and heterogeneous corpus as for example the MPI corpus was a useful and necessary enterprise. It made us understand the underlying processes and requirements to establish an environment such as IMDI.
3. Corpus management was performed during the development phase of the IMDI environment. This meant that frequent updates of the metadata schema took place that required frequent transformation of the metadata files.
4. We now have an environment where it is comparatively easy to integrate or build up IMDI based archives that supports the creator, the user and especially the resource manager with suitable mechanisms and tools.
5. Since all definitions are open everyone can create his own set of tools to work on the metadata descriptions, i.e. improve the search engine or write another browser.
6. Using a file oriented framework for storing metadata only appears as an advantage when distributing or integrating small (personal) archives or making extractions of sub corpora on portable media for off-line use. It does however create confidence of the linguists that they can take their metadata descriptions with them on a floppy and are not dependent on server bound DBMS's.
7. Using metadata in a uniform, controlled and structured way is a new experience for our linguists. It did and still costs a large persuasion effort to have them input their metadata. It has only be since a short time that they themselves can reap the benefits by using for instance metadata search, since a critical mass is necessary and since the improvements for resource management had to become apparent.
8. The introduction of a complete and operational metadata environment was the first experience for the development team of this sort. Often the practical experience guided us in designing and improving the tools, since we did not foresee all aspects of efficient resource management beforehand.

Finally, it seems to be appropriate to add a statement about future perspectives. We see metadata for language resources still in its beginning phase, since there are not so many resource repositories which already created the appropriate files. Especially there are only few attempts to do resource management with the help of metadata environments. We have shown their great potential but also the difficulties involved. Especially the inclusion of metadata element and vocabulary definitions in open repositories and the formulation of their relations with the help of Semantic Web compliant mechanisms such as RDF will motivate more groups to contribute and participate. Interoperability between different metadata sets will also be facilitated by applying these agreed standards.

The soon to be started INTERA project is aiming to realise and work at the above mentioned points.

1. Introduction

Multimodal interfaces, combining the use of speech, graphics, gestures, and facial expressions in input and output, promise to provide new possibilities to deal with information in more effective and efficient ways, supporting for instance:

- the understanding of possibly imprecise, partial or ambiguous multimodal input;
- the generation of coordinated, cohesive, and coherent multimodal presentations;
- the management of multimodal interaction (e.g., task completion, adapting the interface, error prevention) by representing and exploiting models of the user, the domain, the task, the interactive context, and the media (e.g. text, audio, video).

An intelligent multimodal interface requires a number of functionalities concerning media input processing and output rendering, deeper analysis and synthesis drawing at least upon underlying models of media and modalities (language, gesture, facial expression of user or animated agent), fusion and coordination of multimodal input and output at a semantic level, interpretation of multimodal input within the current state of the interaction and the context, and reasoning about and planning of multimodal messages. This implies an architecture with many components and interfaces; a reference architecture of an intelligent multimodal dialogue system was established at the workshop `Coordination and Fusion in Multimodal Interaction' in Dagstuhl, Germany, November 2001 (see Bunt, Kipp, Maybury and Wahlster, forthcoming, and http://www.dfki.de/~wahlster/Dagstuhl_Multi_Modality). The communication between many of the components in a multimodal interactive system rely upon an enabling syntax, semantics and pragmatics. A multimodal meaning representation plays central stage in such a system, supporting both interpretation and generation. Such a representation should support any kind of multimodal input and output, and should, in order to be useful in a field which is still developing, be sufficiently open to support a range of theories and approaches to multimodal communication.

The present document is intended to support the discussion on multimodal content representation, its possible objectives and basic constraints, and how the definition of a generic representation framework for multimodal content representation may be approached. It takes into account the results of the Dagstuhl workshop, in particular those of the informal working group on multimodal meaning representation that was active during the workshop (see http://www.dfki.de/~wahlster/Dagstuhl_Multi_Modality, Working Group 4).

2. Scope

To delineate the task of formulating objectives, constraints and components of multimodal meaning representation, we must first have a shared understanding of what is meant by *meaning* in multimodal interaction. We propose to define the meaning of a multimodal `utterance' as the specification of how the interpretation of the `utterance' by an understanding system should change the system's information state (taken in a broad sense of the term, including domain model, discourse model, user model, task model, and maybe more - see e.g. Bunt, 2000). While formulated with reference to input interpretation only, this definition can also be related to the generation of multimodal outputs, by assuming that an output is generated by the system in order to have an effect on the user through the interpretation of that output by the user. (The generation of appropriate outputs thus depends on the system having an adequate model of what its outputs may mean to the user – which is exactly as it should be.)

A multimodal meaning representation should support the fusion of multimodal inputs and the fission of multimodal outputs at a semantic level, representing the combined and integrated semantic contributions of the different modalities. The interpretation of a multimodal input, such as a spoken utterance combined with a gesture and a certain facial expression, will often have stages of modality-specific processing, resulting in representations of the semantic content of the interactive behavior in each of the separate modalities involved. Other stages of interpretation combine and integrate these representations, and take contextual information into account, such as information from the domain model, the discourse model and the user model. A multimodal meaning representation language should support each of these stages of interpretation, as well as the various stages of multimodal

output generation. Since we are considering inputs and outputs from a semantic point of view, the representation of lower-level modality-specific aspects of interactive behavior, like syntactic linguistic information or morphological properties of gestures is not a primary aim, but some such information may percolate as features associated with a meaning representation, especially at intermediate stages of interpretation, where their relevance for semantic interpretation may not have been fully exploited. At the other end of interpretation, where understanding is rooted in information structures like domain models and ontologies, a multimodal meaning representation language should support the connection with frameworks for defining ontologies and specifying domain models, such as DAML + OIL.

While supporting the linking up of meaning epresentations with ontologies and `low-level' modality-specific information, the design of multimodal meaning representations is to be clearly distinguished from the design of domain model representations, linguistic morphosyntactic representations, representations of facial expressions, etc., which do not fall within this scope. Also, meaning representations should not represent the underlying processes by which they are constructed and manipulated, although it may be important that they are `annotated' with administrative information relating to their processing, such as time stamps.

3. Objectives

The main objective of defining multimodal meaning representations is to provide a fundamental interface format to represent a system's understanding of multimodal user inputs, and to represent meanings that the system will express as multimodal outputs to the user. This interface format should thus be adequate for representing the end result of multimodal input interpretation, and for representing the semantic content that the system will present to the user in multimodal form. It should therefore allow dialogue management, planning and reasoning modules to operate on these representations. In order to be useful for this purpose, this interface format should support the interfaces of these as well as other modules that form part of the system, and thus be adequate not only for representing the end result of semantic interpretation but also intermediate results. Something similar holds for generation. This is a second objective that follows almost immediately from the first.

Another objective in defining a well-defined representational framework for multimodal communicative acts is to allow the specification and comparison of existing application-specific representations (e.g. the M3L representation used in the SmartKom project) and the definition of new ones, while ensuring a level of interoperability between these.

Finally, the specification of a multimodal meaning representation should also be useful for the definition of annotation schemes of multimodal semantic content.

4. Basic Contrains

Given the main objective of defining meaning representations, the first and foremost basic requirements of a semantic representation framework are those that we may call `expressive' and `semantic' adequacy:

- *Expressive adequacy:* the framework should be expressive enough to correctly represent the meanings of multimodal communicative acts;
- *Semantic adequacy:* the representation structures should themselves have a formal semantics, i.e., their definition should provide a rigorous basis for reasoning (whether deductive, statistical, in the form of plan operators, or otherwise).

The second objective, of providing interface formats within a multimodal dialogue system architecture, means that `incremental' construction should be supported of intermediate and partial representations, leading up to a final representation or, if the construction of a final representation does not succeed, leading to negative feedback or another appropriate system action. This implies three further basic constraints:

- *Incrementality,* in the sense of supporting various stages of multimodal input interpretation, as well as of multimodal output generation, allowing both early and late fusion and fission;
- *Uniformity:* to make incremental processing feasible, where possible the representation of various types of input and output should be uniform in the sense of using the same kinds of building blocks and the same ways in which complex structures can be composed of these building blocks.
- *Underspecification and Partiality*: to support the representation of partial and intermediate results of semantic interpretation, the framework should allow meaning representations which are underspecified in various ways, and which capture unresolved ambiguities.

Finally, the representational framework should take into account that the design of multimodal human-computer dialogue systems is a developing area in which new research results and new technologies may bring new challenges and new approaches for the representation of multimodal meanings. This means that the representational framework should satisfy the following two constraints:

- *Openness:* the framework should not depend on a single, particular theory of meaning or meaning representation, but should invite contributions from different semantic theories and approaches to meaning representation;
- *Extensibilty*. The framework should be compatible with alternative methods for designing representation schemas (like XML), rather than support only a single specific schema.

5. Methodology

As a first step in the direction of defining a generic multimodal semantic representation form, we have to establish some basic concepts and corresponding terminology.

First, the action-based concept of meaning mentioned above, applicable to multimodal inputs in an interactive situation, means that the meaning of a multimodal `utterance' has two components: one that is often called `propositional' or `referential', and that is concerned with the entities that the utterance refers to and with their properties and relations that may be expressed in propositions, and a `functional' component that expresses a speaker's intention in producing the utterance: what effects does he want to achieve (using `speaker' in a broad, multimodal sense here)? This distinction is familiar from speech act theory, where the two components are called `propositional content' and `illocutionary force', and is also prevalent in other theories of language-based communication (see Bunt, 2000); it is often viewed as drawing a border line between semantics and pragmatics. In the analysis of multimodal interaction it is especially important to pay attention to both these aspects of meaning, since different modalities often contribute to each aspect in different ways; for instance, in spoken interaction the referential and propositional aspects of meaning are often expressed verbally, while gestures and facial expression contribute primarily to the functional aspects. The term `multimodal content' should not be confused with `propositional content', and should not make us forget that multimodal messages have meanings with functional aspects that are equally important as their propositional and referential aspects. In this document we use `multimodal content' as synonymous with `multimodal meaning', including functional aspects, and we use `semantic representation' as synonymous with `representation of meaning'.

A convenient term that has become popular in the literature on human-computer dialogue is *`dialogue act'*. This term is mostly used in an informal, intuitive way, or as a variant of `speech act; it has a formal definition in terms of the effects that a `speaker' intends to achieve through its understanding by the addressee (see Bunt, 2000), which makes it suitably precise for use in the analysis of the meaning of multimodal inputs and outputs. Without further going into definitions here, we will use the term `dialogue act' in the rest of this document. Definitions of other useful concepts can be found in Romary (2002).

As a second methodological step, we propose to distinguish the following three basic types of ingredients that would seem to go into any multimodal meaning representation framework. Each of these ingredients is discussed further in subsequent sections

1. *Basic components*: the basic constructs for building representations of the meaning of multimodal dialogue acts: types of building blocks and ways to connect them.
2. *General mechanisms*: representation techniques like substructure labeling and linking, that make the representations more compact and flexible.
3. *Contextual data categories*: types of administrative (meta-)data that do not, strictly speaking, contribute to the meanings of semantic representations, but that may nonetheless be relevant for their processing.

5.1 Basic Components

Initially, the following basic components can be identified to represent the general organization of any semantic structure:

1. temporal structures (*`events'*), to represent, for instance:
   - spoken utterances (input or output dialogue acts);
   - gestures (same);
   - noncommunicative action (like searching for information, making a calculation);
   - events, states, processes,.. in the discourse domain, representing meanings of verbs and possibly other linguistic expressions;
2. referential structures (*`participants'*), to represent, for instance:
   - the speaker of an input utterance, or the person performing a gesture;
   - the addressee of a system output dialogue act;
   - individuals and objects participating in a semantic event
3. *restrictions* on temporal and referential structures, to represent, for instance:
   - the type(s) of dialogue, act associated with an utterance;
   - a gesture type, assigned to a gesture token
4. dependency structures, representing *semantic relations* between temporal and/or referential structures, for instance:
   - participant roles (like SPEAKER, ADDRESSEE, AGENT, THEME, SOURCE, GOAL,..)
   - discourse/rhetorical relations
   - temporal relations.

It may be noted that linguistic semantic phenomena that have been studied extensively in relation to the needs of underspecific representation, such as quantification and modification, can also be represented with these basic components. For instance, a quantified statement like `Three men moved the piano' can be represented as a move-event involving a group of three men and a piano, where the collectiveness and the group size of the set of men that form the agent of the event are represented by means of restrictions on the event.

5.2 General Mechanisms

In addition to these basic components, certain general mechanisms are important to make meaning representations suitable for representing partial and underspecified meanings, to give the representations a more manageable form, and to relate them to external sources of information. Examples of such mechanisms are:

1. *substructure labeling*: assigning labels to subexpressions and allowing the use of these labels, instead of the substructures that they label, as arguments in other subexpressions;
2. *argument underspecification*: partial or underspecified representations can be constructed using labels in argument positions; restrictions on labels can represent limitations on the ways in which such variables can be instantiated by labels of substruct - ures elsewhere in the representation;
3. *restrictions on label values*: see previous mechanism. Alternatively, *disjunctions*, or *lists* of labels can be used to represent ambiguity or partiality;
4. *structure sharing*, as in typed feature structures, makes it possible to represent that a certain part of the representation plays more than one role, e.g. a participant may be both agent and theme in a semantic event, or may be the speaker of an utterance and the performer of a gesture, as well as the agent in a semantic event expressed by the multimodal dialogue act;
5. *linking to domain models* (types and instances) to anchor meaning representations in the domain of discourse;
6. *linking to lower levels*, such as syntactic structure, prosodic cues, gestural trajectories,.. is useful for tying a purely semantic representation to lower-level information that has given rise to it, and that may not yet have been fully interpreted.

5.3 Contextual Data Categories

Finally, meaning representations will need to be annotated with general categories of administrative information, both globally and also at the level of subexpressions, to capture certain information which is not found inside the elements of interactive behaviour, but which is potentially relevant for their interpretation and generation, such as:

1. Environment data, for instance:
- time stamps and spatial information (when and where was this input received, etc.)
2. Processing information, such as:
- which module has produced this representation; what is its level of confidence, etc.
3. Interactional information:

6. Technical Backgound: XML

At this stage, we should say a word about what appear to be the unavoidable technical choices for the definition of a multimodal content representation format that would be used, among other possibilities, to exchange information between processing modules within a man-machine dialogue system. As a matter of fact, XML, as defined by the World Wide Web Consortium, appears to be the best candidate so far (and probably for quite a long time) to represent information structures intended to be transmitted across a network. In the following section, we give a very brief overview of XML, which we will then use to illustrate some of the principles mentioned above by means of a concrete example.

XML (eXtended Markup Language) is a simplified (but also in some respects enhanced) version of SGML. It provides a syntax for document markup as well as for the description of the set of tags to be used in classes of documents (a so-called DTD, Document Type Definition). An XML document is made of three parts:

- An XML declaration, which, beyond identifying that the current document is an XML one, allows one to declare the character encoding scheme used in the document (e.g. iso-8859-1, utf-8, etc.);
- A document type declaration, which can point to a DTD. This section can be omitted;
- An XML instance corresponding to the actual data represented by the document.

XML makes an important distinction between a *well-formed* document, which only contains the XML declaration and a syntactically conformant instance, and a *valid* one, where the instance is also checked against the associated DTD.

Among other characteristics, we mention the following important properties of XML:

- XML is both Unicode and ISO 10646 compatible[1]
- XML comes along with a specific mechanism, called *namespaces*, allowing one to combine, within the same document, markup taken from multiple sources. This very powerful mechanism, which is in particular the basis for XSLT and XML schemas, allows more modularity in the definition of an XML structure and also to reuse components defined in another context;
- XML provides a general attribute 'xml:lang' to indicate the language used in a given element (see above).

The W3C also provides three very important recommendations for traversing XML documents, namely:

- XPath, which describes a syntax and associated mechanisms to move within a document instance;
- XPointer, which allows one to indicate a location within a document and is based upon the XPath recommendation;
- XLink, which allows one to combine and qualify a set of pointers to describe a link between them.

[1] The W3C has put pressure on both ISO and the Unicode consortium to make sure that they would not diverge in their parallel work on the definition of a universal character encoding scheme.

These three recommendations are important for instance when one wants to relate some information produced by a given processing level and the information that has been used as input for those processes.

Still, it should be noticed that the existence of such a widely recognized *metalanguage* as XML does not solve our problems for representing multimodal content. First, XML by itself does not come with a formal semantics for its tags, and thus does not satisfy the requirement of semantic adequancy. Second, the requirements of flexibility and extensibility forbid us to try to standardize once and for all a precise XML format, but rather think of providing concepts and tools for anyone to be able to design his or her own format, while preserving interoperability conditions with someone else's choices. This is the spirit in which work has already been done within TC37/SC4 for the definition of TMF (Terminological Markup Framework; ISO 16642, under DIS ballot) and which has recently been taken over to deal with morphosyntactic and syntactic annotation (see (Ide & Romary, 2001a and Ide & Romary, 2001b, respectively). The basic assumption that we make is that there exists an entire class of document formats that can be modelled by combining a *metamodel,* that is an abstract structure shared by all documents of a given type (e.g. syntactic annotation document), with a choice of the data categories that may be associated with the various levels of the metamodel. Such a description can be seen as a specification of the document format, which can be instantiated by providing XML representations for the metamodel and the data categories. In such a view, if a community of researchers and implementers agrees on the definition of a reduced set of metamodels for language resources, the actual choice of data categories is left to the responsibility of a specific application. In this framework, the interoperability between formats is ensured by providing a data category registry which gathers, together with precise reference and definition, the various data categories needed for a particular field.

In the case of multimodal content representation we thus advocate that, beyond agreement on the basic components and mechanisms for instance as described in this paper, which could go into the definition of an actual metamodel for content representation, one should not try to standardize a particular XML format more precisely (though we need to make specific choices to illustrate our approach with concrete examples, see below).

7. A simple example

In the following, we illustrate the possible combination of basic components, general mechanisms, and contextual data categories into a multimodal meaning representation. This representation exemplifies the general methodology that we suggested here, by taking up a sample semantic representation derived from an initial example expressed in the ULF+ format (ULF+ is a slightly updated version of a semantic representation language that was developed successively in the PLUS dialogue project, see Geurts and Rentier, 1993, and in the multimodal DENK project; see Bunt et al., 1998; Kievit, 1998).

In the XML excerpt below (corresponding to the sentence "I want to go from Paris to Stuttgart" uttered by a speaker named Peter), we have extended the original ULF+ representation to introduce the notion of dialogue act, whose participants are the speaker and the system. This example is intended to show how we can differentiate between three types of information in such a representation:

- The instantiation of the semantic content representation metamodel as an XML outline (shown in underlined characters), which organizes the general information layout of the data to be represented;
- The actual information units describing the various levels in the XML outline (shown in gray characters);
- The generic mechanisms used to combine events, participants, restrictions and relations (indicated in **bold characters**).

The specific choices made in this example to represent the metamodel or the data categories as XML objects are only one possibility among many, and this does not affect the formal semantics of the underlying information structure. More precisely, the following explanation may help to clarify the example:

- The <semRep> element corresponds to the semantic representation of one elementary utterance or dialogue act. It is identified uniquely by an id attribute;
- The <event> element is used in this example to represent both the dialogue act proper ("e1") and the event expressed by the corresponding linguistic content ("e2");
- The <participant> element is used to represent the various entities involved in the events. Events and participants being related to one another by means of <relation> elements (with source and target attributes pointing to the corresponding arguments of the relation.

The various levels are then further described by a number of data categories, chosen here to illustrate the wide variety of possible cases. Notice the use of an <alt> structure to illustrate the case where an ambiguity would remain at a given step of analysis, each possibility being associated with a certainty evaluation ('cert' attribute). In accordance with the methodology developed in TMF, the name of the corresponding XML elements and attributes should not be the object of standardization, data categories being defined by abstract properties.

8. Action Plan

The variety of existing theoretical approaches, as well as the wide number of factors to be considered makes it very difficult to devise from scratch a truly generic framework for multimodal content representation. As a consequence it is necessary to involve, beyond the possibilities offered by the definition of a working group on this topic in TC37/SC4, as large a community of experts as possible in the development of such a framework. This is why we suggest that the work shall be initially conducted within a dedicated working group of SIGSEM (Special Interest Group on Computational Semantics of the Association of Computational Linguistics), which would be, right from the beginning, a liaison with TC37/SC4. This group would prepare a working draft, which would then be submitted to ISO.

Doing so, it would also be easier to ensure a proper interaction with other interested communities, in particular the people working on multimedia representation (SIGMedia, in complement to the existing liaison between MPEG and TC37/SC4) and on discourse and dialogue (SIGDial).

The agenda would thus be the following:

- Refining the workplan on the basis of the present paper at the TC37/SC4 Preliminary Meeting in Jeju (Korea) in February 2002.
- Presenting a position paper at the LREC workshop on "International Standards of Terminology and Language Resources Management" in May 2002.
- First working group meeting in conjunction to IWCS-5 (5th International Workshop on Computational Semantics) in Tilburg, the Netherlands, in January 2003.

Abstract

Intelligent computer-assisted language learning—Intelligent CALL, or ICALL—can be defined in a number of ways, but one understanding of the term is that of CALL incorporating language technology (LT) for e.g. analyzing language learners' language production, in order to provide the learners with more flexible—indeed, more 'intelligent'—feedback and guidance in their language learning process. However, CALL, ICALL and LT have been three largely unrelated research areas, at least until recently. In the world of education, 'e-learning' and 'ICT-based learning' are the new buzzwords. Generally, what is meant is some kind of web-based setup, where course materials are delivered via the Internet or/and learners are collaborating using computer-mediated communication (CMC). An important trend in ICT-based learning is that of standardization for reusability. Standard formats for all aspects of so-called 'instructional management systems' are rapidly gaining acceptance in the e-learning industry. Thus, learning applications will need to support them in order to be commercially viable. This in turn means that the proposed standards should be general enough to support all conceivable kinds of educational content and learning systems. In this paper, we will discuss how ICALL applications can be related to the various standards proposals, basing our discussion on concrete experiences from a number of (I)CALL projects, where these standards are used or where their use has been contemplated.

1. Introduction

For some years, I have been actively involved in trying to combine computer-assisted language learning (CALL) with language technology (LT) (a.k.a. computational linguistics (CL), language engineering (LE), or natural language processing (NLP)) into what is often referred to as "Intelligent CALL" (ICALL), both as a teacher of CALL to LT students at the university, and as a researcher involved in a number of research efforts dealing with CALL/ICALL (see below), and also with neighboring areas, such as computer support for lesser used and lesser taught languages (Borin, 2000a; Allwood and Borin, 2001; Nilsson and Borin, 2002), and contrastive linguistic studies using computational methods (Borin, 1999; Borin, 2000b; Borin and Prütz, 2001; Borin and Prütz, 2002).

The present paper flows from a desire to make ICALL benefit from, as well as inform, ongoing standardization efforts in the computational linguistics and e-learning communities.

The rest of the paper is organized in the following way. First, I will try to sort out the relationships between CALL, LT, artificial intelligence (AI), and ICALL. Then I will describe briefly ongoing standardization work in the e-learning and CL communities, and some of the standards proposals that this work has produced. Following that, I will turn to a description of some (I)CALL projects in which I have been or am currently involved, where these standards are used or where their use has been contemplated, namely the SweLL Didax project, the LingoNet project, 'Corpus based language technology for computer-assisted learning of Nordic languages', the SVANTE learner corpus project, and 'IT-based collaborative learning in Grammar'. Finally, I will discuss the situation of ICALL with regard to this standardization work, in order to form an understanding of where we stand at the moment, but more importantly, of where we would like to go from here.

2. CALL, LT and ICALL

Intelligent computer-assisted language learning—Intelligent CALL, or ICALL—has been defined in a number of ways, but one understanding of the term relevant here is that of CALL incorporating LT techniques for e.g. analyzing language learners' language production or modeling their knowledge of a second/foreign language in order to provide them with more flexible—indeed, more 'intelligent'—feedback and guidance in their language learning process.

CALL, ICALL and LT have been three largely unrelated research areas, at least until recently:

1. The CALL 'killer apps' have been e-mail, chat and multimedia programs, developed and used by language teaching professionals with very little input from LT research (Pennington, 1996; Chapelle, 1997; Chapelle, 1999; Chapelle, 2001; Levy, 1997; Salaberry, 1999). The only kind of LT which has had any kind of impact on the CALL field is corpus linguistics, and even in this case it has been the Humanities Computing 'low-tech' kind of corpus linguistics,

rather than the kind pursued in LT (the latter is sometimes referred to as "empirical natural language processing").

2. ICALL has often been placed by its practitioners in the field of artificial intelligence (AI), rather than in LT (e.g. Swartz and Yazdani (1992); Holland et al. (1995)), more specifically in the subfield of AI known as *intelligent tutoring systems* (ITS) (e.g. Frasson et al. (1996); Goettl et al. (1998)). Partly for this reason, work on ICALL has proceeded, by and large, without feedback into the LT community.

3. But on the other hand, in LT in general, (human) language learning has not been seen as an application area worth pursuing. In the recent broad *State of the art of human language technology* overview edited by Cole et al. (1996), 'language learning' does not appear even once in the index, and there is no section on CALL. Certainly there are some exceptions to this general trend; there have been occasional COLING (*International Conference on Computational Linguistics*) papers on ICALL, although few and far between (e.g. Borissova (1988); Zock (1996); Schneider and McCoy (1998)), and there is a research group in Groningen which has been working very actively on LT-based CALL applications for quite some time (Nerbonne and Smit, 1996; Dokter, 1997; Dokter, 1998; Dokter and Nerbonne, 1997; Dokter et al., 1997; Jager et al., 1998). The situation has been changing somewhat only in the last few years, however, with dedicated workshops on language learning applications of CL being arranged in connection with LT conferences and the like (e.g. Olsen (1999); Schulze et al. (1999); Efthimiou (2000)).

3. Standardization in e-Learning and Language Technology

3.1. E-learning standardization efforts

In the world of education, 'e-learning' and 'ICT-based learning'[1] are the new buzzwords (see, e.g., European Commission (2000)). Generally, what is meant is some kind of web-based setup, where course materials are delivered via the Internet or/and learners are collaborating using computer-mediated communication (CMC) methods.

An important trend in ICT-based learning is that of standardization for reusability. Standard formats are defined for all aspects of so-called 'instructional management systems'. Thus, not only educational content formats are agreed upon, but also course structure formats, test formats, as well as how their interaction with recordkeeping systems used in education should take place. There is a number of organizations working on standards in the e-learning area, the most important ones being IMS (Instructional Management System Inc. `http://www.imsproject.org/`), IEEE's LTSC (Learning Technology Standards Committee; `http://ltsc.ieee.org/`), the American Department of Defence ADL (Advanced Distributed Learning; `http://www.adlnet.org/`) initiative, and the European ARIADNE project. Standards being developed by these and other bodies include educational metadata (Learning Objects Metadata – LOM; Anderson and Wason (2000)), test formats (IMS Question and Test Interoperability – QTI; Smythe and Shepherd (2000)), content packaging formats (IMS Content Packaging; Anderson (2000)), modular courseware (ADL SCORM; Dodds (2001)), and others (see, e.g. the IMS and LTSC websites referred to above). At least some of these standards are rapidly gaining acceptance in the e-learning industry. Thus, learning applications will need to support them in order to be commercially viable. This in turn means that the proposed standards should be general enough to support all conceivable kinds of educational content and learning systems.

The general idea is to create standards which are

> "pedagogically neutral, content-neutral, culturally neutral and platform-neutral"
> (Farance and Tonkel, 1999, 9),

and which support. . .

> "common, interoperable tools used for developing learning systems [. . .]
>
> a rich, searchable library of interoperable, "plug-compatible" learning content [. . .]
>
> common methods for locating, accessing and retrieving learning content"
> (Farance and Tonkel, 1999, 14)

One may certainly entertain doubts as to the general attainability of these goals, but one cannot afford to ignore the huge amount of time and labor invested in pursuit of their fulfillment by the organizations mentioned above and others. This being so, it is of course not unimportant if learning and teaching within a particular field—such as language learning—is adequately covered by the proposed standards or not.

3.2. Standardization in Language Technology/Computational Linguistics

In the LT world, too, standardization efforts are legion, and a recurring theme at the LREC (Language Resources and Evaluation Conference) series of conferences.

There is LT standardization work going on at least in the areas of

- resource storage and exchange: TIPSTER (Grishman et al., 1997), ATLAS (Bird et al., 2000), XCES (Ide et al., 2000);
- resource annotation: XCES (Ide et al., 2000), EAGLES (e.g., tagsets: see Monachini and Calzolari (1996));
- resource metadata: OLAC, ISLE (Wittenburg et al., 2000);
- resource presentation and manipulation, and software integration: THISTLE, GATE (Cunningham, 2001), KABA (Olsson, 2002).

[1] ICT is to be read out "Information and Communication Technologies".

To the best of my knowledge, however, the work within LT on resource markup and annotation has not been informed by language learning applications or by the work done on compiling and investigating so-called learner corpora by applied linguistics researchers (see, e.g., Granger (1998)).

4. (I)CALL Case Studies

In this section, we will look at some CALL research projects, where the issue of combining (I)CALL applications with e-learning standards has arisen in various ways.

4.1. Didax

Didax – the Digital Interactive Diagnostic Administering and Correction System, is a project in the framework of the *Swedish Learning Lab* (SweLL), a research effort funded by the Knut & Alice Wallenberg Foundation as part of the larger *Wallenberg Global Learning Network* endeavor, where a number of centers—or "nodes"—worldwide receive funding for exploring the use of ICT and other new technologies in higher education.

At present, there are three nodes in the WGLN: (1) SweLL, with three participating institutions of higher education, (1a) the Royal Institute of Technology and (1b) Karolinska Institutet in Stockholm, and (1c) Uppsala University, (2) the Stanford Learning Lab (SLL), at Stanford University, California, USA, and (3) Learning Lab Lower Saxony (L3S), at the University of Hannover, Germany. SweLL research is currently organized into a multi-tiered structure, with two top-level 'projects' subdivided into a number of 'experiments´. Each experiment is further subdivided into 'tracks', where each track in turn typically is made up of several research teams cooperating on related research issues. Our work on Didax is thus carried out in the *Digital Resources in the Humanities* (DRHum) track of the *Archives – Portfolios – Environments* (APE) experiment of the SweLL project *New meeting places for learning – New learning environments*.

The Didax research team currently consists of three computational linguists and one SLA researcher, but we also cooperate closely with the other DRHum research teams, drawing on the other kinds of competence found there, especially the teams working with digital archives for humanities teaching, as well as with the Uppsala Learning Lab e-folio project group.

The end result of the Didax project is supposed to be a web-based language testing environment, which will provide both students and teachers with a more flexible format for taking, marking, constructing and setting diagnostic language tests in higher education. In Figure 1, the overall architecture of Didax is shown. The three Didax clients (*teacher – setting test*, *teacher – marking test*, and *student*) run in ordinary web browsers. There is nothing out of the ordinary to be seen in any of the client interfaces. This is quite deliberate. Most of the innovation is hidden under the surface, and the interface is a familiar one from many web applications. Didax is described in more detail by Borin et al. (2001).

4.2. LingoNet

LingoNet is a one-year R&D project funded by the Swedish Agency for Distance Education. The project is a cooperation between the Divison of IT Services and the Department of Humanities, Mid Sweden University, and the Department of Linguistics, Uppsala University (see `http://www.mitt.mh.se/lingonet/`).

The aim of the LingoNet project is to build a 'language lab on the Internet', i.e. a web site with a collection of language training resources to be used in higher education, both locally and in distance education. Even though the point of departure for the LingoNet project is the traditional language lab, we actually envision a more general language training resource than this, i.e. a 'computer language lab', rather than a 'computerized version of the tape recorder-based language lab', as the idea is not only to transfer older techniques into this new technology, but also to exploit the additional possibilities offered by the new technology itself, including the incorporation of LT-based language learning resources in the LingoNet lab.

Specifically, in the LingoNet project, we make systematic use of quality control and metadata. It is a well-known fact that the information to be found on the web on any topic is, not only abundant in almost all cases, but also—to put it mildly—of extremely varying quality. At the same time, web search engines are still fairly primitive, so that finding educational resources, appropriate as to their content and level—regardless of their quality—in itself takes some work (Howard Chen, 1999, 24f.). It is only after they have been found that the real work begins, however, when the chaff—resources which are of low quality or of the wrong kind—is to be separated from the wheat—the resources which we can use for our educational purpose, i.e. educational web resources which are quality controlled and classified as to their content and level. In the LingoNet project, the quality control and metadata markup are done by academic language teachers. For more details about the LingoNet project, see Borin and Gustavsson (2000).

4.3. Corpus based language technology for computer-assisted learning of Nordic languages

'Corpus based language technology for computer-assisted learning of Nordic languages', or in short, the Squirrel project, is funded by the Nordic Council of Ministers, and represents a collaboration between the University of Helsinki in Finland, the research foundation SINTEF in Norway, and Stockholm University in Sweden (see `http://www.informatics.sintef.no/projects/CbLTCallNordicLang/squirrel.html`).

One of the aims of the Squirrel project has been to build a prototype web browser for students and teachers of Nordic languages as a second language, which will help them to find practice texts on the web according to the three parameters *language*, *topic*, and *text difficulty* (Nilsson and Borin, 2002). For more details about the Squirrel project, see Borin et al. (2002)

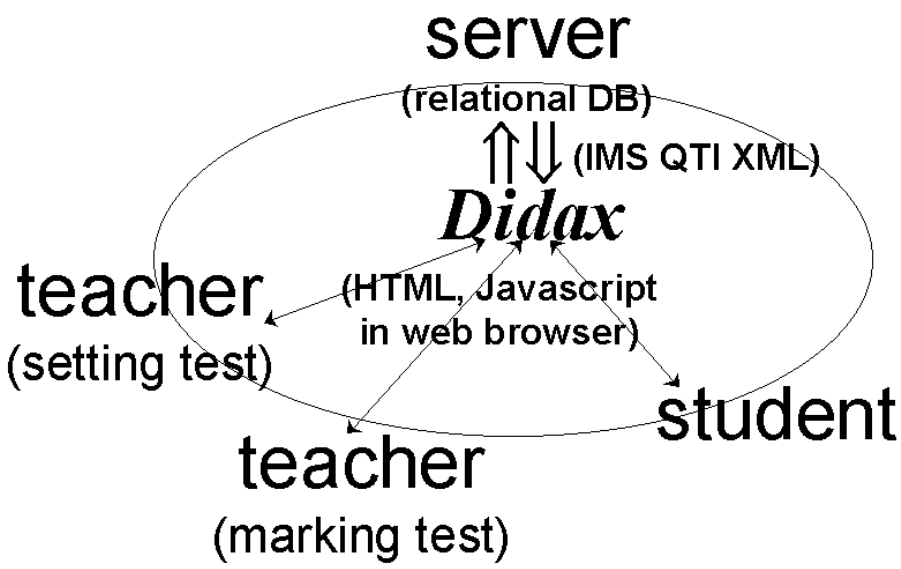

Figure 1: The anatomy of Didax

4.4. SVANTE

SVANTE (SVenska ANdraspråksTexter – Swedish Second Language Texts) is a loose collaboration between linguists, computational linguists, and teachers of Swedish as a second language, with the aim of creating a versatile learner corpus of written Swedish, to complement the learner corpora of spoken Swedish that already exist (see `http://www.ling.uu.se/lars/SVANTE/`). The SVANTE project is partly funded by VINNOVA within the CrossCheck second language Swedish grammar checking project (see `http://www.nada.kth.se/theory/projects/xcheck/`).

4.5. IT-based collaborative learning in Grammar

'IT-based collaborative learning in Grammar' is a collaborative project, funded by the Swedish Agency for Distance Education, with partners in the Linguistics Departments at the universities in Uppsala and Stockholm, and the IT Department and two language departments at Uppsala University. This project revolves around two fundamental assumptions:

1. The use of web-based communication and collaboration technologies will help us make make basic grammar courses better and more effective for students and teachers alike;

2. Language resources originally developed in a research setting, such as tagged and parsed corpora (of Swedish in our case) and grammar writing workbenches, can be (re)used in the context of teaching grammar (Borin and Dahllöf, 1999).

Perhaps I should clarify at this point that this is not primarily an application intended for *language* students, but rather for students of Linguistics and Computational Linguistics, although we believe that it will be useful also as a component in language courses (Saxena and Borin, 2002).

4.6. Relation to e-learning standards and to ICALL

These projects are variously related to ICALL on the one hand and to e-learning standards on the other:

- Didax is not an ICALL project *per se*, but creates an infrastructure which can be used for ICALL applications, and thus must be able to accomodate them. It uses the IMS QTI, and the IEEE, IMS, ARIADNE LOM emerging standards.

- LingoNet is not an ICALL project either, but it goes without saying that among the more exciting possibilities for a web-based language lab are language training applications built on LT methods and resources; hence, we must take this into consideration in designing the underlying language lab format. Like Didax, LingoNet can be considered as an infrastructure project which should be able to accomodate ICALL applications. The standards involved are IMS Content Packaging, and IEEE, IMS, ARIADNE LOM.

- Squirrel is an ICALL project, which does not (yet) utilize any of the proposed e-learning standards, but we see how e.g. the LOM could be used to mark up the located text resources, e.g. for inclusion in something like the LingoNet database.

- SVANTE forms an integral part of an ICALL project, namely the CrossCheck second language grammar checking project, but SVANTE itself is more in the way of a linguistic resource project, where LT standards for basic markup and linguistic annotation of the texts are important.

- 'IT-based collaborative learning in Grammar' is very much an ICALL project. At this initial stage of the project (it started in January 2002), there are still a number of implementational details left to be decided.

However, we would certainly like to make our learning resources as widely useful as possible, meaning, i.a.,

1. that they should be—wholly or in part—easy to integrate into other e-learning environments, but also
2. that it should be easy to use corpus resources for other languages than Swedish in our application.

The first requirement implies the existence and use of general standards for e-learning applications, while the fulfillment of the second requirement certainly would be facilitated by standardization of language resources.

5. So, where will the Standards for ICALL Come from?

Summing up the foregoing, we may say that there are three communities which would benefit from closer interaction, because of a considerable overlap in their goals, but which thus far have pursued these goals separately:

1. The 'ordinary' CALL community—including those researchers working with learner corpora—has extremely tenuous links to LT (see e.g. Chapelle (2001, 32ff.)), and, as far as I have been able to acertain, none at all to the ongoing e-learning standardization work mentioned in section 3.1. above.

2. Nor is the e-learning community working on any standardization for *language learning* (as opposed to *learning* in general). For example, the IMS Question and Test Interoperability (QTI) proposal specifies five test question response types, which can be rendered in up to three different formats (Smythe and Shepherd, 2000, 17). However, for the 'IT-based collaborative learning in Grammar' application, as well as for many other of the corpus-based CALL applications found in the literature, a response type "select (portion/s of) a text" would certainly be good to have.[2]

3. The LT community is not involved in any standardization effort for *language learning* information (as opposed to *language* information in general). The kinds of standards that come to mind first are those involving linguistic annotation schemes, with regard to both their content and their form:

   So-called *learner interlanguage* is characterized by a number of linguistic features absent from the native-speaker version of the target language (and sometimes absent from the learner's native language as well (Richards and Sampson, 1974, 6)). Interlanguage goes through a number of stages, terminating in a final (hopefully close) approximation of the target language. This has some implications for linguistic annotations of learner language production, whether in learner corpora (longer texts) or in analyzers of free learner language production in ICALL language exercises. Thus, part-of-speech (POS) tagging or parsing of learners' interlanguage may have to deal with categories absent from the canonical target language grammar as reflected in an LT standard, etc., but which can be related either to categories in the learner's native language, to universally unmarked categories, to a conflation of target categories, to the pedagogy used, to some combination of these, etc. (Cook, 1993, 18f.). The status of a given linguistic element can change from one language learning stage to another, e.g. the unmarked form in a morphological paradigm becoming functionally more and more specified, as the learner acquires the marked forms and their functions.[3]

   Hence, multiple linguistic annotations of the kind proposed for XCES (Ide et al., 2000) and ATLAS (Bird et al., 2000; Cotton and Bird, 2002) are a necessity for language learning applications of e.g. language corpora.[4] In addition to providing multiple annotations of the same linguistic object (a word, phrase, etc.), the annotations should also be relatable to each other, making it possible to relate an analysis of a form in learner production to the (inferred) intended interpretation of this form, for providing appropriate feedback to the learner. The linguistic categories provided by annotation standards would need to be different from the ones used by native speaker experts (which is arguably most often the kind of annotation aimed for now) if they are to be used for formulating feedback to language learners. They would also have to be different for different kinds of learners, depending on their level, background, native language, etc.

   Standardization of (formats for) *error typologies* would also be desirable. Again, this desideratum is not exclusive to language learning applications; work on grammar and style checkers for native speakers would also benefit from standardized formats for error typologies.

   In the same way as the learner's language progresses through successively more advanced stages, the authentic language that the learner is exposed to as part of her learning process should be successively more complex, in a linguistic sense. This is the main motivation for the Squirrel web search application described above (Nilsson and Borin, 2002). Here, there is consequently a need for a classification and concomitant annotation scheme which relates linguistic complexity to language learning stages, for applications where corpora are used for e.g. generating lan-

[2] In the QTI specification, there is actually a sixth response type response-extension, intended for proprietary response types, but the predefined types will always determine the 'path of least resistance', at least for many users.

[3] Here I have in mind cases such as when e.g. learners of English initially use the infinitive (or sometimes gerund) as their only—and hence extremely polyfunctional—verb form, and then gradually start using other forms (tensed forms in finite clauses, etc.), which then usurp, as it were, some of the functions of the initial forms.

[4] Multiple annotations actually seem necessary for other reasons as well, see e.g. Sampson (2000).

guage learning exercises.

In language learning applications, the need to cater for *bilingual* and *multilingual* text materials is evident, which raises the issues of how to handle multiple writing systems in a standardized way, e.g. left-to-right and right-to-left writing in the same text corpus (the latter issue is raised by Cotton and Bird (2002) as still not having been determined for ATLAS).

Hopefully, the state of affairs depicted here is really due more to lack of interaction than anything else, and if the present paper can be instrumental in bringing about this interaction, it will have served its purpose.

6. Acknowledgements

The work reported herein was carried out partly within the project 'Corpus based language technology for computer-assisted learning of Nordic languages', in the framework of the Nordic Language Technology Research Program 2000–2004 (Holmboe, 2002), funded by the Nordic Council of Ministers through Nordisk Forskeruddannelsesakademi (NorFA), partly within the project 'Digital resources in the humanities', funded by the Knut & Alice Wallenberg Foundation, as part of the Wallenberg Global Learning Network, and partly within the CrossCheck/SVANTE project, funded by VINNOVA within the Language Technology Program.

Personal Names in Unrestricted Chinese Texts: Nature and Identification

Benjamin K. TSOU, Lawrence Y. L. Cheung

Language Information Sciences Research Centre
City University of Hong Kong
Tat Chee Avenue, Kowloon Tong,
Hong Kong

{rlbtsou, rlylc}@cityu.edu.hk

Abstract

The detection of personal names as well as proper names, and the identification of unknown words in unrestricted texts are critical tasks in NLP for East Asian languages, especially for word segmentation, information retrieval and machine translation. This is even more critical for Chinese which uses almost exclusively only the Chinese script and has little overt morphological markings and no equivalent use of capital letters for proper nouns as in English. This paper: (1) discusses the extent of the problems in some relevant IT applications, (2) analyzes the structure of Chinese personal names, and (3) presents some relevant processing strategies and the supporting language resources in general. Differences among Chinese personal names in Beijing and in Hong Kong are highlighted. It is argued that the awareness of variation in names across different Chinese communities constitutes a critical factor in enhancing the effectiveness of Chinese personal name identification algorithms.

Keywords: Chinese, personal name identification, word segmentation, Chinese IT applications, Chinese linguistic differences

1. Introduction

Personal names constitute an important linguistic symbol in conveying meaning. They are anchors of ideas, events, cultural artifacts, etc., e.g. Nobel Prize, Newtonian physics, Clinton-like behaviour and Thatcherism. Personal names provide a rich source for terminology in many domains. Efficiency in personal name identification is important for improving the detection and extraction of terms in the field of computational terminology. The last few years have seen the growth of research in this area (Miller et al., 1999; Cucchiarelli and Velardi, 2001). Named entity recognition was highlighted as an evaluation task in the Sixth and Seventh Message Understanding Conferences (MUC-6 and MUC-7) and First and Second Multilingual Entity Task (MET-1 and MET-2).

Because of the diverse and important linguistic differences between Chinese and English, personal name identification in Chinese involves many more complex issues than in English, e.g., word segmentation, absence of capital/small letter distinction, morphological paucity, syntactic ambiguity, and significant social and cultural differences among Chinese communities (Tsou and Kwong, 2001). Recent statistics from Chinese corpora provides an indicative range of personal names appearing in different domains (Tsou, 2000; Tsou, 2001). Table 1 shows that personal names account for as much as 16.8% of all word types in the 3-year LIVAC[1] newspaper corpus. They represent up to 2.4% of the word tokens in the 29 million character corpus.

	Newspaper Headlines[2]		Newspaper Texts[2]	Court Proceedings
%	Hong Kong (1 yr)	Taiwan (1 yr)	6 Chinese Communities (3 yrs)	Hong Kong (1 case)
Type	4.5	4.2	12.8 to 16.8	4.6
Token	4.4	3.7	1.6 to 2.4	0.6

Table 1 Amount of personal names in different domains

Because of the inherent linguistic problems above, the processing of Chinese personal names (as well as other named entities) in NLP requires much more than itemized listing, and poses a serious challenge.

The rest of the paper will be divided into three main sections: (1) assesses some relevant basic problems encountered in IT applications, (2) introduces the structure of Chinese personal names and the relevant processing strategies, and (3) highlights the importance of building language resources for personal name extraction.

[1] LIVAC synchronous corpus collects newspaper texts every four days since 1995 from Chinese newspapers in 6 Chinese communities including Beijing, Hong Kong, Macau, Shanghai, Singapore and Taiwan.
(LIVAC website: http://www.rcl.cityu.edu.hk/livac)

[2] The estimation is based on the 3 year data (1995—98) from the LIVAC corpus. It contains 29 million characters.

2. Significance of Personal Names in IT Applications

Efficient identification of personal names is crucial in many IT applications. Poor management of personal names in these systems can compound the errors in other NLP modules, resulting in serious deterioration of system performance. Cheung et al. (2002) conducted tests showing that poor personal name processing results in serious webpage retrieval errors.

(1) 陳中將與俄羅斯選手爭奪跆拳道金牌 (Sina) [3]
Chen Zhongjiang will compete with a Russian athlete for the gold medal for Taekwondo.

(2) 司令陳中將視導南測中心受訓部隊 (Google Chi.)[3]
Admiral Chen Zhongjiang inspected the trainee army force in Nance centre.

For example, the examined search engines mistook 中將 *zhongjiang* in (1) and (2) as the common noun for the military rank of "lieutenant general", whereas, in fact, they represent given names in the above contexts. The problem is similar to identifying *Dean Martin*, the well known American entertainer, as the head of a faculty in a university.

Tsou and Kwong (2001) also reported that the Chinese-to-English machine translation systems [4] have serious but unrecognized problems handling personal names. Table 2 shows that all four machine translation systems perform rather poorly in personal name identification. The probable cause for the errors is the use of static name list to identify personal names. The above demonstrates that IT applications need far more sophisticated algorithms than simple character matching and name database to adequately detect personal names in Chinese texts.

Data Source	Translation Accuracy			
	EWGate	*TongYi*	*Transtar*	*WorldLingo*
Hong Kong	24%	5%	9%	15%
Beijing	30%	6%	20%	56%
Taiwan	19%	0%	5%	16%

Table 2 Translation accuracy of personal names

3. Processing Chinese Personal Names: Challenges and Strategy

3.1. Challenges in Processing Chinese Personal Names

The basic structure of modern Chinese personal names is largely similar across different Chinese communities. Although the frequent length is 2 to 3 characters, the maximum can be as long as 6 characters. Table 3 shows the possible structures of Chinese personal name. Chinese personal names begin with a one- or two-character surname, followed by a one- or two-character given name. The name of a married female may be preceded by her husband's surname, as in (e) and (f). The unique structure

	Full Name	Husband's Surname			Surname			Given Name		Length
		H1	(H2)	+	S1	(S2)	+	G1	(G2)	
a.	李鵬 *Li Peng*				李 *Li*			鵬 *Peng*		2
b.	鄧小平 *Deng Xiaoping*				鄧 *Deng*			小 *Xiao*	平 *Ping*	3
c.	諸葛亮 *Zhuge Liang*				諸 *Zhu*	葛 *Ge*		亮 *Liang*		3
d.	東方聞櫻 *Dongfang Wenying*				東 *Dong*	方 *Fang*		聞 *Wen*	櫻 *Ying*	4
e.	陳方安生 *Chen Fang Ansheng*	陳 *Chen*			方 *Fang*			安 *An*	生 *Sheng*	4
f.	諸葛東方聞櫻 *Zhuge Dungfang Wenying*	諸 *Zhu*	葛 *Ge*		東 *Dong*	方 *Fang*		聞 *Wen*	櫻 *Ying*	6

Table 3 Structure of Chinese personal names

[3] *Google* [Big5 Chinese] URL: http://www.google.com/intl/zh-TW and *Sina* URL: http://www.sina.com.cn

[4] (1) Transtar V3.0, (2) TongYi '98, (3) *WorldLingo* (http://www.worldlingo.com), (4) EWGate: (http://www.EWGate.com/ewtranslite.html)

is found in speech or writing of formal register in some Chinese communities such as Hong Kong.

Apart from variable length, several characteristics make Chinese personal name processing difficult:

(a) There is no explicit morphological marking or capitalization for names in Chinese.

(b) Chinese texts do not have explicit word boundary.

(c) The character set for surnames and given names is a subset of Chinese characters for common Chinese words, and hence readily gives rise to structural ambiguity.

(d) Some personal names may be simple mono-syllabic words.

(e) Some polysyllabic words can be embedded in Chinese personal names, e.g. 王朝聞 *Wang Chaowen* (王朝 *wangchao* = dynasty), 馬勝利 *Ma Shengli* (勝利 *shengli* = victory) and 嚴肅 *Yan Su* (嚴肅 *yansu* = serious(ly)).

3.2. Basic Strategies

The complexity of Chinese personal name identification task calls for a combination of different processing strategies. They can be broadly divided into statistical approach and linguistic approach.

3.2.1. Linguistic Approach

Linguistic context provides important cues to locate Chinese personal names. Syntactic structures and lexical collocation provide good indication on whether or not the character string immediately before or after it is a potential personal name, e.g. 張志偉先生 (*Mr.* Zhang Zhiwei) and 朱鎔基總理 (*Premier* Zhu Rongji). Sun et al. (1995) integrates features to detect frequently used patterns, lexical items and syntactic structures that are useful for identifying names. For example, personal names often precede verbs like 說 *shuo* (say), 指出 *zhichu* (point out), etc. Lü et al. (2001) detect personal names by evaluating the interaction between potential personal names and neighbouring words. The POS co-occurrence restriction is checked and the best segmentation for potential name string is computed so as to generate the most probable context. Luo and Song (2001) studied the structure of personal name and place name formation. The linguistic knowledge is represented as a set of generative rules in finite state automata. Additional exceptional handling is added to deal with easily confused ambiguous contexts.

3.2.2. Statistical Approach

Statistical approach has been the most popular approach for name identification task. Previous studies typically exploited the character distribution frequency in different parts of a name and designed algorithms to extract string patterns that match the distributional criteria. For example, Sun et al. (1995) and Song and Tsou (2001) reported that about 400 characters[5] could cover over 99% of all Chinese surnames in texts. Furthermore, some character combinations in given names are more frequent than others. Cheung et al. (2002) also pointed out that there are significant variations among Chinese communities. The character preference in given names varies depending on a range of factors like gender, geography, character position in a given name, social changes, etc. The character probability is approximated by frequency distribution from large text corpora or name databases.

Sun et al. (1995) and Zheng et al. (1999) evaluated every candidate string by computing mutually exclusive probability for the 3 characters in a name candidate string, as in (6).

(6) $p_{pn}(c_1\, c_2\, c_3) = p_{sur}(c_1) * p_{m1}(c_2) * p_{m2}(c_3)$

where
$p_{pn}(s)$ = probability of candidate string s being a personal name
$p_{sur}(x)$ = probability of character x being a surname
$p_{m1}(x)$ = probability of character x being the first character of a given name
$p_{m2}(x)$ = probability of character x being the second character of a given name

Lü et al. (2001) proposed to measure probability of a potential name string by considering the probability of the 3 characters in a name candidate string as mutually inclusive events, as in (7) adapted from Lü et al. (2001).

(7) $p_{pn}(c_1\, c_2\, c_3) = p_{1F}(c_1) + p_{1M}(c_2) + p_{nE}(c_3)$

where
$p_{pn}(s)$ = probability of candidate string s being a personal name
$p_{1F}(x)$ = probability of character x being a surname
$p_{1M}(x)$ = probability of character x being the first character of a given name
$p_{nE}(x)$ = probability of character x being the second character of a given name

Most Chinese personal name identification algorithms incorporate linguistic and statistical techniques. These hybrid systems have been reported to achieve 80—90% precision and recall rates (Sun et al., 1995; Lü et al., 2001; Luo and Song, 2001).

[5] There are 21,886 characters in the GBK Chinese character set.

4. Personal Name Language Resources for Terminology Extraction

Statistical frequency data, as discussed in Section 3, has to be based on empirical data from large text corpora. Thus relevant personal name databases become a critical resource to support name identification systems and to customize algorithms. At least four major dimensions should be adequately addressed in the construction of personal name language resources, including: (1) structural distribution, (2) character frequency of personal names, (3) character co-occurrence for given names, and (4) communal differences. The significance and relevance of appropriate personal name database cannot be overemphasized because of the rarely understood magnitude of variation of personal names among Chinese communities which is much greater than that existing in English speaking communities. We will illustrate the differences in personal name patterns by using name databases taken from Beijing and Hong Kong.[6]

4.1. Structural Distribution

Single-character surnames predominate both databases, accounting for over 99%, as in Table 4. This suggests that double-character surnames may be handled separately using item listing in view of its very limited number of types and tokens. The data shows a divergence in the preference for single- and double-character given names in Beijing and in Hong Kong. Single-character names account for 29% of the Beijing database.[7] In contrast, single-character given names only cover 2% of the data for Hong Kong. The findings are crucial to the prioritization of rules related to the length of personal names in identification algorithms.

	Surname		Given Name	
%	Beijing	HK	Beijing	HK
Single-Character	99.9	99.6	29.1	2.1
Double-Character	0.1	0.4	70.9	97.9

Table 4 Distribution of name structures

[6] The Beijing name database has 125,033 names, and is drawn from a county in Beijing. They are representative of names in Mainland China because the county population is composed of migrants coming from different provinces of China. The Hong Kong database contains 11,358 names. They are student and staff names taken from the Registrar's Office, City University of Hong Kong.

[7] Sun et al. (1995) reported that single-character given names account for about 37% of the name database for all students' names (10 years) at Tsinghua University in Beijing.

4.2. Character Frequency of Personal Names

Not all characters are equally probable in being different parts of a Chinese personal name. All studies mentioned in Section 3 have exploited such characteristics to different extent. Table 5, 6 and 7 show that the ten most frequently used surnames, first character and second character of given names.

	Beijing				Hong Kong		
Rank	Surname	%	Cum. %	Rank	Surname	%	Cum. %
1	王 *Wang*	9.1	9.1	1	陳 *Chen*	10.2	10.2
2	張 *Zhang*	8.3	17.4	2	黃 *Wang*	6.7	16.9
3	李 *Li*	7.9	25.3	3	李 *Li*	5.9	22.8
4	劉 *Liu*	6.5	31.8	4	梁 *Liang*	4.6	27.4
5	陳 *Chen*	3.2	35.0	5	林 *Lin*	4.2	31.6
6	趙 *Zhao*	3.2	38.2	6	張 *Zhang*	3.6	35.2
7	楊 *Yang*	3.0	41.2	7	劉 *Liu*	3.0	38.2
8	孫 *Sun*	2.0	43.2	8	吳 *Wu*	3.0	41.2
9	馬 *Ma*	1.7	44.9	9	何 *He*	2.8	44.0
10	吳 *Wu*	1.6	46.5	10	鄭 *Zheng*	2.1	46.1

Table 5 10 most frequent single-character surnames in Beijing and Hong Kong

(Shaded items appear in both columns.)

	Beijing				Hong Kong		
Rank	G1	%	Cum. %	Rank	G1	%	Cum. %
1	淑 *shu*	3.2	3.2	1	嘉 *jia*	3.8	3.8

8	生 *sheng*	1.5	17.6	8	欣 *xin*	1.6	17.0
9	芳 *fang*	1.3	18.9	9	輝 *hui*	1.6	18.6
10	琴 *qin*	1.3	20.1	10	雯 *wen*	1.6	20.1

Table 7 10 most frequent second characters (G2) of double-character given names

(Shaded items appear in both columns.)

The character type for Chinese surnames is fairly limited in actual data. In Table 5, the ten most frequent surnames cover over 46% of the name tokens though the ranking of surnames is quite different in both databases. For example, the most frequent surname 王 *Wang* in Beijing is ranked as 14th in the Hong Kong. In contrast, the character types for given names are far more diverse. In the Hong Kong database, there are over 820 character types for given names as opposed to 257 character types for surnames. As shown in Table 6 and 7, the ten most frequently used G1 and G2 character cover no more than 26% of all name tokens in both databases respectively.

4.3. Character Co-occurrence for Given Names

Apart from localized character preference in given names, our data also reveals that the character combinations of double-character given names are far from being random. Previous research tended to consider the probabilities of each character position in isolation, and ignored interesting patterns of character co-occurrence in given names. The information is useful for resolving ambiguity given rise by the diverse character types in given names. Here are two examples for the two most common G1 characters from Hong Kong database: 嘉 *jia* and 偉 *wei*. Given G1 = 嘉 *jia* / 偉 *wei*, there is about 30% of chance that the given name is one of the combinations in a—e and f—j respectively. (Table 8)

	Combina-tion	%	Cum. %		Combina-tion	%	Cum. %
a	嘉 + 敏 *jia + min*	11.2	11.2	f	偉 + 強 *wei + qiang*	6.4	6.4
b	嘉 + 儀 *jia + yi*	6.5	17.7	g	偉 + 文 *wei + wen*	5.7	12.1
c	嘉 + 雯 *jia + min*	4.6	22.3	h	偉 + 雄 *wei + xiong*	5.7	17.7
d	嘉 + 琦 *jia + qi*	4.3	26.6	i	偉 + 傑 *wei + jie*	*5.4*	23.2
e	嘉 + 慧 *jia + wei*	3.6	30.1	j	偉 + 明 *wei + ming*	5.2	28.3

Table 8 *5* most frequent combinations provided G1 = 嘉 *jia* / 偉 *wei*

4.4. Communal Differences

Previous studies do not seem to pay much attention to the sociolinguistic aspects of name variation among Chinese communities. It has been mentioned in Section 4.1 that there are far more single-character given names in the Beijing database. If we further compare the columns for Beijing and Hong Kong in Table 6 and 7, only two characters overlap. The divergence in character preference is obvious in the two databases. The implication is that name identification algorithms using statistical approach should maintain character probability derived from various Chinese communities in order to maximize the performance. Other sociolinguistic differences such as married female's names, nicknames, etc, have yet to be studied. The assumption that personal name identification can be simplistically tackled on the basis of personal name language resources from a single community will certainly be problematical for NLP applications that have to process unrestricted texts from different geographical locations.

5. Further Works

Based on Section 4.2 and 4.3, further investigation into the statistical distribution of personal names can be done. First, it seems that previous studies tended to have overlooked character co-occurrence phenomenon. Co-occurrence probability can be used to improve existing algorithms for Chinese personal name tagger. For example, instead of merely utilizing the probability of a candidate character being part of a name, the tagger may give a higher rating to those candidate strings whose G1 and G2 combination is commonly found in Chinese names. Statistical studies like those in Section 4.3 will be conducted for all character combination in the two databases to identify high frequency patterns.

Second, as we mentioned earlier and noted by a reviewer, gender is a significant factor in character choice for given names. Such data may find applications in transcription system and speech recognition application such as caller name identification. The recognition engine may first determine the caller's gender based on the speaker's voice pitch and then select the appropriate probability database for name identification task accordingly.

Third, the communal differences revealed by our preliminary analysis suggest that name databases from other Chinese communities are important language resources. For example, more name databases will be collected (e.g. Shanghai, Taiwan and Singapore) for comparison.

6. Conclusion

Personal names provide an important source for new terms in text processing. Personal name identification is crucial to terminology extraction. This paper discusses the challenge and basic strategies in personal name identification in unrestricted Chinese texts. The review of IT applications shows that reliability in the processing of Chinese personal names is still far from acceptable. This situation contributes to serious errors in other NLP tasks such as incorrect data retrieval and parsing. Current Chinese personal name identification systems capitalize on linguistic and statistical techniques to deal with the processing. To adequately support such systems, personal name language resources are critical. Four dimensions have been highlighted in the construction of such resources, including (1) structural distribution, (2) character frequency of personal names, (3) character co-occurrence for given names, and (4) communal differences. Despite the potential contribution to the identification task, the latter two dimensions seem to have gone largely unnoticed in the literature. More empirical study of personal names will be beneficial to the performance improvement of personal name identification systems.

7. Acknowledgement

This research study is supported by the Language Information Sciences Research Centre, City University of Hong Kong and by a Competitive Earmarked Research Grant (CityU 1238/00H) from the Research Grant Council of Hong Kong and supported by NTT Service Integration Laboratory. We would also like to thank Rou SONG for his kindness in providing us with the Beijing personal name database, and Registrar's Office, City University of Hong Kong, for their contribution to our Hong Kong personal name database.

Changes in the Etymological Type of New Terminology in Japanese
-The Decrease of Sino-Japanese and Increase of Alphabetical Terms-

SHIODA, Takehiro

NHK Broadcasting Culture Research Institute
Mori Tower 16F, 2-5-1
Tokyo 105-6216, Japan
sioda@culture.nhk.or.jp

Abstract

In this paper, the author surveys how the proportions of etymological type have changed in current computer-related terms of Japanese. As a result of inquiry regarding recent computer terminology, the fact that the decreasing of Sino-Japanese words and the increasing of Alphabetical words has confirmed.

Introduction

Japanese words are conventionally divided into three etymological types, known as *goshu* in Japanese, according to whether they are of pure Japanese, Sino-Japanese or Western-loans. In this paper, the author surveys how the proportions of each type have changed in current computer-related terms, and considers what the future may hold for Japanese technical terms.

First, some technical terms required for the analysis are explained, and previous studies introduced. The materials and analytical method are then described, and the results reported. The results of opinion polls on people's thoughts regarding the use of foreign words are also introduced, and a proposal on word coining is presented.

1 "GOSHU " in Japanese Linguistics

The term *goshu* refers to a basic convention used in classifying the parts of the Japanese vocabulary. It is the taxonomical concept for defining words according to their etymological source. The three basic types that are taken to constitute the Japanese vocabulary are the words of pure Japanese, Sino-Japanese and Western-loan.

The pure Japanese words, *wago*, are the words of traditional Japanese origin. These are frequently found in terms that express fundamental concepts in Japanese. They are written in *hiragana* syllabary or *kanji* (Chinese characters) in general.

The Sino-Japanese words, *kango*, can primarily be described as words that are borrowed from Chinese. However, the *kango* are read in a Japanese, not a Chinese way, despite the use of the Chinese characters. (This is similar to the many different pronunciations of the word *euro*, which varies so much from language to language.)
There is also the concept of *wasei-kango*, namely Sino-Japanese words created in Japan, as a subdivision of *kango*. These are unique Japanese coinages that use Chinese morphemes.
The traditional scientific terms include many Sino-Japanese words. It is usual to use Chinese characters when writing these Sino-Japanese terms. It has been observed that weight of the Sino-Japanese words in Japanese language is similar to that of words of Latin origin in English (Miyajima, 1995).

The Western-loans, called *gairaigo*, are mostly loan words from Western languages (mainly English), and sometimes the words of not-western origin are also included exceptionally. The newest terms include many words of western origin. It is usual to use *katakana* syllabary when writing these Western-loans, but the alphabet is also used in some cases.

These three types compose the fundamental taxonomy of Japanese etymological word types.

In addition, some new words are formed by combining the different types. These hybrid words are called *konshugo*.

2 Previous research

It has been shown in quantitative terms that the use of *kango*, Sino-Japanese words, was chiefly utilized in new coinages around 1900, and that ratio gradually decreased thereafter (Miyajima, 1967). This tendency has continued in recent years and the word-formation capability of *kango* fell sharply in the very short period from 1960 to 1980 (Nomura, 1984). As for writing means, it has been predicted that the use of Chinese characters will decrease and that of the alphabet will increase from now on (Kabashima, 1981).

3 Purpose of inquiry

In order to predict future transitions in Japanese terminology, the present situation was gauged with reference to the following points:

1. It has been observed that the word-formation capability of *kango* has been decreasing. What is the rate of this decrease?

2. It is known that the proportion of Western-loans is increasing in Japanese. The author believes that the increase may be greatest for alphabetical words. Can this be demonstrated quantitatively?

In this paper, the author reports the results obtained regarding computer terminology.

4 Procedure of inquiry

Subject of inquiry:
"Gendai Yoogono Kiso Chisiki (Basic knowledge of contemporary words)" 1985, 1990, 1995, 2000: Tokyo, Jiyuu Kokuminsha.

This book is a single volume encyclopedia published annually. It provides rich data for considering the status and progress of new words from year to year. For this study, the entries related to the computer field (computer terms, office automation terms, etc.) were extracted.
Each entry was classified according to the *goshu* category.

1. We observe the transitions of Sino-Japanese and Western-loans in the first, *goshu* classification phase. Since there are very few pure Japanese words, these are disregarded here. "*Katakana* words" and "alphabetical words" are provided as sub-classifications of Western-loans, and the transitions for each are noted. Here, we only observe the number of entries belonging to single *goshu* categories. *Konshugo* are taken up in the second phase below.

2. Next, consideration is also given to the hybrid words, *konshugo*. (This can be described as classification by *goshu* element). Since there are also very few elements of pure Japanese words here, these are again disregarded.

A hybrid word consisting, for example, of one Sino-Japanese and one Western-loan is counted once in each of the Sino-Japanese element and Western-loan element categories. For convenience, however, a term consisting of multiple Sino-Japanese elements is counted only once in the Sino-Japanese element category.

Examples:
「情報検索」(information retrieval):
Scores 1 for the Sino-Japanese element
「エレクトロニック・バンキング」
(electronic banking):
Scores 1 for the *Katakana* word element
「磁気ディスク装置」 (magnetic disk unit):
Scores 1 for the Sino-Japanese element
Scores 1 for the *Katakana* word element
「ＯＣＲ」(Optical Character Recognition):
Scores 1 for the alphabetical word element
「双方向ＣＡＴＶ」(two-way CATV):
Scores 1 for the Sino-Japanese element
Scores 1 for the alphabetical word element

5 Results and discussion

5.1 1st phase (classification by *goshu*)

	1985	*1990*	*1995*	*2000*
Total	398	344	357	402
Sino-Japanese	54(13.6%)	46(13.4)	51(14.3)	37(9.2)
Katakana	136(34.1)	108(31.4)	114(31.9)	118(29.4)
Alphabetical	19(4.8)	30(8.7)	27(7.6)	66(16.4)

(*see* Figure 1)
→ The rates for Sino-Japanese words and alphabetical words were substantially reversed from 1995 to 2000.

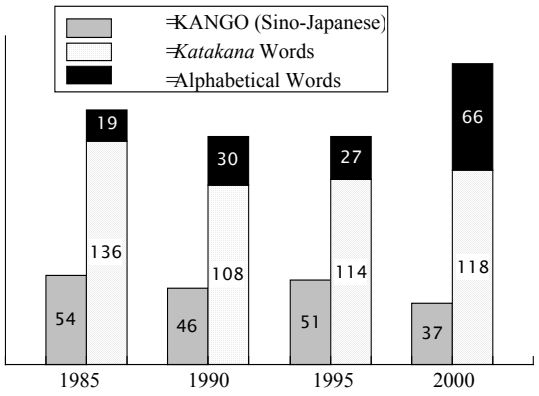

Figure 1: The transition by GOSHU in computer te

5.2 2nd phase (classification by *goshu* element)

	1985	*1990*	*1995*	*2000*
Total	398	344	357	402
Sino-Japanese	218(54.8)	186(54.1)	193(54.1)	155 (38.6)
Katakana	305(76.6)	239(69.5)	251(70.3)	270(67.2)
Alphabetical	66(16.6)	86(25.0)	79(22.1)	158 (39.3)

(*see* Figure 2)

→ The rates for Sino-Japanese and alphabetical elements drew much closer to each other in the data for 1995 to 2000.

Prospect: The likelihood of a further increase in the rate of use of alphabetical words appears to be quite strong.

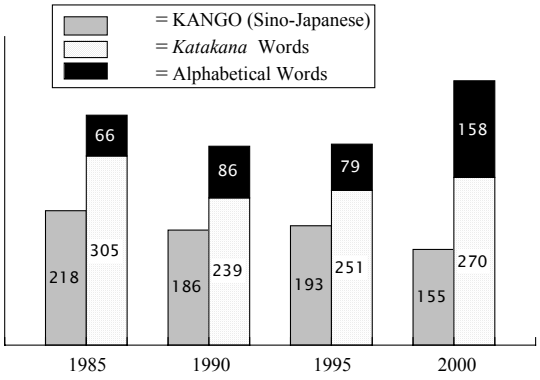

Figure 2: The transition by GOSHU element

6 Views on Western-loans

The excessive use of words of foreign origin can hinder communication. We next introduce some results on this subject from public opinion polls.

"Do you feel that many loan words and other foreign words are used in everyday Japanese?"
Frequent: 51.6%
Occasional: 32.2%
(Agency for Cultural Affairs, 2000)

"Have you been troubled because you cannot understand the meaning of a *katakana* word in newspaper or TV?"
Frequently : 17.1%
Occasionally : 37.5%
(Agency for Cultural Affairs, 1997)

The entry of new foreign terms cannot be prevented. But, as these surveys indicate, we should be aware of the dangers of excess.

7 Concluding remarks

It has been observed that one of the merits of the increase in foreign words is the acceptance of terms that are understood internationally (Ishiwata, 2001). Alphabetical words, in particular, can be read and understood by those who cannot read Japanese script, so the level of international communicability is very high. The risk is that more fluent international communication may be matched by weaker internal communication. The use of such words as technical terms has clear merits, but thought is also required to the selection of words that are best able to acquire general acceptability within the specific language-speaking group concerned. We should remember that *not* all the people understand English.

Some technical terms do gradually come to be used as general terms in each language. Those who coin new terms or standardize the terminology would, therefore, be well advised to consider their suitability for both international and internal communication purposes, with the awareness that these decisions may have some future influence on general terms kept clearly in mind.

A Corpus-based Approach to Term Bank Construction

Bai Xiaojing, Hu Junfeng, Zan Hongying, Chen Yuzhong, Yu Shiwen

Institute of Computational Linguistics, Peking University, China

E-mail: {baixj, hujf, zanhy}@pku.edu.cn

Abstract

In this paper, a corpus-base approach is presented in the construction of the information science and technology term bank in which domain classification, reference and part of the definition are extracted from corpus. Farther experiments show that the structure analysis of the terms can be helpful in the corpus-based domain classification of the terms.

1. Introduction

Currently, a joint project is under way between China National Institute of Standardization(CNIS) and the Institute of Computational Linguistics(ICL), Peking University to construct a term bank in the field of information science and technology. The project aims at :

1. an ontology system
2. a corpus for term bank construction
3. a corpus-based terminology extraction program
4. a constructed term bank and the related specifications and standards, and others for terminologies in the field of information science and technology

The implementation of the whole project features various approaches, among which the corpus-based one constitutes our present focus.

The corpus in this project consists of two parts, an essential corpus of 15 million Chinese characters and an extension corpus of 60 million and more, responsible for different tasks respectively. The corpus-based approach enables us to address the goals of our project by the following schemes:

1. Categorization of the terminologies in our term bank
2. Assistance for defining the terminologies in our term bank
3. Training and testing of the automatic extraction program

Now, initial plans have been made for the implementation of these schemes, with experiments conducted in support of our further efforts.

2. The Classification Scheme of Information science and Technology

An ontology system is very important for the standardization of the term bank establishment. Up to now, there still do not have a ready-made classification scheme of information science and technology, not to say to put each specific terminology into one specific domain category. So the first thing for constructing the term bank in the field of information science and technology is to build an appropriate knowledge category system or concept system.

The information science and technology field contains not only the computer and communication subjects. In general, this field includes all subjects relative to information. Now there is no acknowledged opinion that bounds this field. We intend to set up an appropriate and practical classification while make it integrated with the some existed international or national standards. We have referred to the ACM Computing Classification System, ICS(the International Classification for Standards), CLC(the Chinese Library Classification), computer encyclopedias, and some technical dictionaries. After we have consulted many materials, we classify the

knowledge of information science and technology field into five subjects:

1. pandects of information science and technology
2. computer
3. automatization
4. telecommunication
5. electronics

under each subject we provide four subclass: theory, technology, application and product & material. We also have set up a mapping between ICS and our classification. For example, ICS:35:220 are integrate into our classification in data storage device(its classification number is 020403).

Generally, our classification is on the second level of subjects, and some detail on the third or fourth level. Frankly, Our knowledge classification system has fewer hierarchical levels. The reason is that we plan to get a more general and shallow classification and to avoid the frequent modification of the structure of the term bank due to the slight change of term category. The change of terms' intension and extension will be reflected through some attributes in our term bank. The attributes in the term bank are very easily modified or expanded.

3. Corpus Compilation

For the essential corpus, we turn to experts in the field of information science and technology. All the texts are chosen and provided by experts of specified branches.

In the meaning time, with the help of a program, field experts will tag all the terms and the related information in the corpus, i.e., categorize them into the very branches of the field they belong to. The essential corpus is built for data training in the automatic extraction program.

For the extension corpus, the size is more than 60 million Chinese characters. In this corpus, we can get concordance and collocation information about the terms, as automatic processing will be possible for this part, and further, considerable amount of useful information, which can facilitate the definition of the terms, can be extracted from the corpus. Moreover, this corpus will serve as a test set for the terminology extraction program.

4. Corpus-based Categorization of Terminologies

Up till now, a basic framework has been drafted out for the purpose of categorization, while the terminologies available now are more than 70,000. Given the possibility that the initial framework can be developed to a sound system for categorization, locating the Terms into this system will still be a hard job.

It is in this consideration that we come up with the corpus-based approach. The essential corpus provided by various field experts carries the field information and the terminology tagging. Terminologies tagged by field experts are to be compared with the Terms. This is designed to be a process of matching, after which the Terms can be put into their respective categories. In other words, we try to classify the terms according to their distribution in the corpus. For the first step, as a test, we obtained 100 texts (258,045 characters in total) about Computer Network, with 2,486 different terms tagged out (i.e., 2,486 terminologies are regarded as valid). Considerable terms, which are unlikely network ones, proved otherwise in the corpus.

For example:缓冲/cache, which does not seem to be an OS term in Chinese, is a true network concept in the following sentence: "与我们熟悉的磁盘缓冲技术类似，Internet 缓冲是在一台本地服务器上开辟一块缓冲区，保存访问 Internet 时获得的数据，这样在以后的浏览过程中如果还是访问那些网页，就不需要再次访问Internet ，而直接从缓冲中获得数据就可以了".

That means corpus based categorization can give a more accurate description of the field information about the terms. This will benefit not only the term categorization, but also the definition of the terms. In some cases, it can

even give us clues to find out terms with different shades of meaning.

5. Corpus-based Reference for Terminology Definition

Accuracy and standardization in defining terminologies also attract our attention and efforts. In the database of our term bank, there is a field named Reference, storing contexts of the Terms from the whole corpus, which are deemed as competent reference. Reference for terminology definition can be at various levels, namely, it can be sentence(s), paragraph(s) or even full text(s). Here the role of the corpus is significant, as it contains all the information that will be filled into the Reference field, and what is more, we are expecting templates for terminology reference or even for terminology definition, to be learned from the essential corpus and then applied to the extension part, thus achieving the corpus-based automatic referencing. In addition to category and terminology tagging, our field experts also have to tag the text contents that they regard as the competent references for terminologies. A program is designed to extract a language unit bearing a reference tag (starting with <Reference> and ending with </Reference>) containing or following a terminology tag (starting with <Term> and ending with </Term>), which is recognized as the reference information for the tagged terminology and will then be stored in the Reference field accordingly. The following are three examples.

Example 1: (a single sentence)

<Reference><Term>Vo I P **</Term>**可以定义为以IP 包交换的方式传输话音。**</Reference>**

Example 2: (a paragraph)

<Reference><Term>Vo I P 网关**</Term>**主要提供PSTN 电话通信网络与IP 网络的接口和转换。目前，一般采用H.323 作为IP 网络信令和SS7 作为PSTN 的信令。在这个市场的设备提供商中既有传统的数据网络公司如3Com 、Cisco 等，也有老牌的电信设备提供商如Alcatel 、Ericsson 、Nortel 、Lucent 等，以及Sonus 、Clarent 、convergent network 、Nuera 等公司。**</Reference>**

Example 3: (a full text)

<Reference>何谓**<Term>**DHC**P</Term>**？动态主机配置协议（Dynamic Host Configuration Protocol，DHCP）从原有的BootP 协议发展而来，原来的目的是为无盘工作站分配IP 地址的协议，当前更多地用于对多个客户计算机集中分配IP 地址以及IP 地址相关的信息的协议，这样就能将IP 地址和TCP/IP 的设置统一管理起来，而避免不必要的地址冲突的问题，因此常常用在网络中对众多DOS/Windows 计算机的管理方面，节省了网络管理员手工设置和分配地址的麻烦。中继代理服务器必须知道DHCP 服务器的地址，还要知道如何把接收到的报文转发给该服务器**</Reference>**

Sufficient data will avail us of the opportunity to learn reference templates, like “XX 可以定义为/can be defined as XX” in Example1; “XX 主要提供/is mainly for XX” in Example 2 etc. These are sample templates that can be used to extract the definition of the terms from corpus. Surely there can only have small number of the terms that can find definition directly from corpus, but the corpus-based contextual information, such as concordance and collocation are also helpful for experts to analysis the meaning and give the proper definition of the terms.

6. Automatic Extraction of Terminologies from Corpus

The third scheme is based on the understanding that the internal structure of terminologies is also a source of valuable knowledge for term bank construction. In this project, the internal structure of a terminology consists of three elements: 1) term constituents, including prefixes, suffixes, words and phrases that are frequently used in related technical documents, e.g., “性” and “接口”; 2) POS; and 3) semantic categories, each describing the common feature of a group of term constituents, like

the semantic category “equipped with/without a system of wires” derived from “无线” and “有线 ”. Patterning the internal structure of terminologies is a prerequisite to the automatic extraction of terminologies from the corpus. On the one hand, we analyze the Terms, together with those from the essential corpus and tagged by our field experts, and pattern their structures, using term constituents and POS information, e.g., “noun + 接口”. On the other hand, we generate new terms, replacing term constituents of the same categories in exiting terms with the other.

With “有线通讯”, “有线电视”, “有线电报”, for instance, we generate “无线通讯”,“无线电视”, “无线电报”. The automatic extraction program will then use the structure patterns and the new terms generated to extract terminologies from the extension corpus, either by character matching or by POS matching, or both. Large in amount as they are, the terminologies we have obtained r reach up till now. In this sense, the extension corpus is both a test set for the automatic extraction program and a source for additional terminologies by using the program. It therefore are still far from being enough. Considering the limited sources, we have to rely on the extension corpus for the automatic extraction of terminologies that remain out of oucalls our attention to the competence and performance of our corpus, and especially, the extension part.

7. Conclusion

We have devised the initial schemes for the application of the corpus-based approach to

1. the categorization of existing terminologies in our term bank
2. the learning of reference templates and the extraction of reference information from the corpus
3. the modeling of automatic terminology extraction

Experiments show that corpus can be very useful to illuminate the meaning of terms, which will help a lot to standardize the terms in the future.

Abstract

This paper presents an abstract data model for linguistic annotations and its implementation using XML, RDF and related standards; and to outline the work of a newly formed committee of the International Standards Organization (ISO), ISO/TC 37/SC 4 Language Resource Management, which will use this work as its starting point. The primary motive for presenting the latter is to solicit the participation of members of the research community to contribute to the work of the committee.

1. Introduction

The goal of this paper is two-fold: to present an abstract data model for linguistic annotations and its implementation using XML, RDF and related standards; and to outline the work of a newly formed committee of the International Standards Organization (ISO), ISO/TC 37/SC 4 Language Resource Management, which will use this work as its starting point. The primary motive for presenting the latter is to solicit the participation of members of the research community to contribute to the work of the committee.

The objective of ISO/TC 37/SC 4 is to prepare international standards and guidelines for effective language resource management in applications in the multilingual information society. To this end, the committee will develop principles and methods for creating, coding, processing and managing language resources, such as written corpora, lexical corpora, speech corpora, dictionary compiling and classification schemes. The focus of the work is on data modeling, markup, data exchange and the evaluation of language resources other than terminologies (which have already been treated in ISO/TC 37). The worldwide use of ISO/TC 37/SC 4 standards should improve information management within industrial, technical and scientific environments, and increase efficiency in computer-supported language communication.

2. Motivation

The standardization of principles and methods for the collection, processing and presentation of language resources requires a distinct type of activity. Basic standards must be produced with wide-ranging applications in view. In the area of language resources, these standards should provide various technical committees of ISO, IEC and other standardizing bodies with the groundwork for building more precise standards for language resource management.

The need for harmonization of representation formats for different kinds of linguistic information is critical, as resources and information are more and more frequently merged, compared, or otherwise utilized in common systems. This is perhaps most obvious for processing multi-modal information, which must support the fusion of multimodal inputs and represent the combined and integrated contributions of different types of input (e.g., a spoken utterance combined with gesture and facial expression), and enable multimodal output (see, for example, Bunt and Romary, 2002). However, language processing applications of any kind require the integration of varieties of linguistic information, which, in today's environment, come from potentially diverse sources. We can therefore expect use and integration of, for example, syntactic, morphological, discourse, etc. information for multiple languages, as well as information structures like domain models and ontologies.

We are aware that standardization is a difficult business, and that many members of the targeted communities are skeptical about imposing any sort of standards at all. There are two major arguments against the idea of standardization for language resources. First, the diversity of theoretical approaches to, in particular, the annotation of various linguistic phenomena suggests that standardization is at least impractical, if not impossible. Second, it is feared that vast amounts of existing data and processing software, which may have taken years of effort and considerable funding to develop, will be rendered obsolete by the acceptance of new standards by the community. To answer both of these concerns, we stress that the efforts of the committee are geared toward defining *abstract models* and *general frameworks* for creation and representation of language resources, rather than specific formats. These models should, in principle, be abstract enough to accommodate diverse theoretical approaches. The model so far developed in ISO TC/37 for terminology, which has informed and been informed by work on representation schemes for dictionaries and other lexical data (Ide, *et al.*, 2000) and syntactic annotation (Ide & Romary, 2001) demonstrates that this is not an unrealizable goal. Also, by situating all of the standards development squarely in the framework of XML and related standards such as RDF, DAML+OIL, etc., we hope to ensure not only that the standards developed by the committee provide for compatibility with established and widely accepted web-based technologies, but also that

transduction from legacy formats into XML formats conformant to the new standards is feasible.

ISO/TC 37/SC 4 will liaison with ISLE (International Standards for Language Engineering), which has implemented various recent efforts to integrate EC and US efforts for language resources. Where possible, these and other standards set up in EAGLES will be incorporated into the ISO standards. ISO/TC 37/SC 4 will also broaden the work of EAGLES/ISLE by including languages (e.g. Asian languages) that are not currently covered by EAGLES/ISLE standards.

At present, language professionals and standardization experts are not sufficiently aware of the standardization efforts being undertaken by ISO/TC 37/SC 4. Promoting awareness of future activities and rising problems, therefore, will be a crucial factor in the success of the committee, and will be required to ensure widespread adoption of the standards it develops. An even more critical factor for the success of the committee's work is to involve, from the outset, as many and as broad a range of potential users of the standards as possible. This presentation serves as a call for participation to the linguistics and computational linguistics research communities.

3. Objectives

ISO TC37/SC 4's goal is to develop a platform for the design and implementation of linguistic resource formats and processes in order to facilitate the exchange of information between language processing modules. This will be accomplished by defining a *common interface format* capable of representing multiple kinds of linguistic information. The interface format must support the communication among all modules in the system, and be adequate for representing not only the end result of interpretation, but also intermediate results.

A well-defined representational framework for linguistic information will also provide for the specification and comparison of existing application-specific representations and the definition of new ones, while ensuring a level of interoperability between them.

3.1. Requirements

Very generally, a linguistic representation framework must meet the following requirements:

- *Expressive adequacy:* the framework should be expressive enough to represent all varieties of linguistic information;
- *Semantic adequacy:* the representation structures should have a formal semantics, i.e., their definition should provide a rigorous basis for further processing (e.g., deductive reasoning, statistical analysis, generation, etc.).

Providing interface formats within a system architecture demands that "incremental" construction of intermediate and partial representations be supported. In addition, if the construction of a final representation does not succeed, the representation must capture the information required to enable appropriate system action. This dictates additional requirements:

- *Incrementality:* support for the various stages of input interpretation and output generation, allowing both early and late fusion and fission.
- *Uniformity:* the representation of various types of input and output should utilize the same "building blocks" and the same methods for combining complex structures composed of these building blocks.
- *Underspecification and partiality*: support for the representation of partial and intermediate results, including the capture of unresolved ambiguities.

Finally, the representational framework must be accommodate the developing field of language processing system design by satisfying these further requirements:

- *Openness:* the framework should not depend on a single linguistic theory, but should enable representations based on different theories and approaches;
- *Extensibilty*. The framework should be compatible with alternative methods for designing representation schemas (e.g., XML) rather than being tied to a specific schema.

3.2. Methodology

A working group of SC 4 (WG1/WI-1) has been charged with the task of defining a linguistic annotation framework, which will be used by other SC 4 working groups to develop more precise specifications for particular annotation types. The full list of SC 4 working groups is as follows:

- WG1/WI-0: Terminology for Language Resources
- WG1/WI-1: Linguistic annotation framework
- WG1/WI-2: Meta-data for multimodal and multilingual information
- WG2/WI-3: Structural content representation (syntax and morphology)
- WG2/WI-4: Multimodal content representation
- WG2/WI-5: Discourse level representation
- WG3/WI-6a: Multilingual text representation
- WG4/WI-7: Lexicons
- WG5/WI-8: Validation of language resources
- WG5/WI-9: Net-based distributed cooperative work for the creation of LRs

We focus here on the work of WG1/WI-1, which will serve as the starting point for that of most of the others. This group will propose a *data architecture* consisting of basic mechanisms and data structures for linguistic annotation and representation, comprised of the following:

- *Basic components*: the basic constructs for building representations of linguistic information; specifically, identification of types of building blocks and ways to connect them.
- *General mechanisms*: representation techniques that make the annotations more compact and flexible and enable linking them to external sources of information; for example, sub-structure labeling, argument under-specification, restrictions on label values and/or disjunctions or lists to represent ambiguity or partiality, structure sharing; linking to

domain models, linking to other levels of annotation, etc.

- *Contextual data categories*: administrative (meta-) data relevant for processing, such as environment data (e.g., time stamps, spatial information); processing information (e.g., module that produced the representation; confidence level); interaction information (speaker, audience, etc.).

The following section outlines a linguistic framework which will serve as the starting point for development within SC 4. The current model is based on work on development of annotation formats for lexicons (Ide, et al., 2001), morphosyntactic and syntactic annotation (Ide & Romary, 2001a; Ide & Romary, 2001b; Ide & Romary, forthcoming), and which has been further developed within TC37/SC4 for the definition of TMF (Terminological Markup Framework; ISO 16642, under DIS ballot).

4. A Framework for Linguistic Annotation

Our fundamental assumption is that representation formats for linguistic data and its annotations can be modeled by combining a structural *meta-model,* that is, an abstract structure shared by all documents of a given type (e.g. syntactic annotation), with a set of *data categories* that are associated with the various components of the meta-model. Our work in SC4 is concerned, first, with identification of a reduced set of meta-models that can be used for any type of linguistic data and its annotations. Data categories, on the other hand, are defined by the implementer; interoperability among formats is ensured by providing a *Data Category Registry* in which the categories and relations required for a particular type of annotation are precisely defined.

The model for linguistic annotation must satisfy two general criteria:

1. It must be possible to instantiate it using a standard representational format;
2. It must be designed so as to serve as a pivot format into and out of which proprietary formats can be transduced, in order to enable comparison and merging, as well as operation on the data by common tools.

4.1. Abstract model for annotation

At its highest level of abstraction, an annotation is a set of data or information (in our case, linguistic information) that is associated with some other data. The latter is what could be called "primary" data (e.g., a part of a text or speech signal, etc.), but this need not be the case; consider, for example, the alignment of parallel translations, where the "annotation" is a link between two primary data objects (the aligned texts). Typically, primary data objects are represented by "locations" in an electronic file, for example, the span of characters comprising a sentence or word, or a point at which a given temporal event begins or ends (as in speech annotation). As such, at the base primary data objects are relatively simple in their structure; more complex data objects may consist of a list or set of contiguous or non-contiguous locations. Annotation objects, on the other hand, often have a more complex internal structure: syntactic annotation, for example, may be expressed as a tree structure, and may include more elemental annotations such as dependency relations (which is itself an annotation relating two objects, where the relation is directional (dependent-to-head)).

Thus, we can conceive of an annotation as a one- or two-way link between an annotation object and a point (or a list/set of points) or span (or a list/set of spans) within a base data set. Links may or may not have a semantics--i.e., a type--associated with them. Points and spans in the base data may themselves be objects, or sets or lists of objects. This abstract formulation can serve as the basis for defining a general model for linguistic annotation that can be realized in a standard representational format. In fact, this model is consistent with well-established data modeling concepts used in diverse areas, including knowledge representation (KR), object-oriented design, and database systems, and which inform fundamental data structures in computer science (trees, graphs, etc.) and database design (notably, the Entity-Relationship (ER) model). As such, the model provides us with established means to describe our data objects (in terms of composition, attributes, class membership, applicable procedures, etc.) and relations among them, independent of their instantiation in any particular form. It also ensures that standardized representation formats exist that can instantiate the model.

One way to represent linguistic annotation in terms of the abstract model is as a graph of elementary *structural nodes* to which one or more *information units* are attached. The distinction between the structure of annotations and the informational units of which it is comprised is, we feel, critical to the design of a truly general model for annotations. Annotations may be structured in several ways; perhaps the most common structure is hierarchical. For example, phrase structure analyses of syntax are structured as trees; in addition, hierarchy is often used to break annotation information into sub-components, as in the case of lexical and terminological information.

There are several special relations *among* annotations that must be represented in the model, including the following:

- *Parallelism:* two or more annotations refer to the same data object;
- *Alternatives:* two or more annotations comprise a set of mutually exclusive alternatives (e.g., two possible part-of-speech assignments, before disambiguation);
- *Aggregation:* two or more annotations comprise a list or set that should be taken as a unit.

Information units or *data categories* provide the semantics of the annotation. Data categories are the most theory and application-specific part of an annotation scheme. We do not attempt to define the relevant data categories for given types of annotation. Rather, we propose the development of a Data Category Registry to provide a framework in which the research community can formally define data categories for reference and use in annotation. To make them maximally interoperable and consistent with existing standards, data categories can be defined using RDF schemas to formalize the properties and relations associated with each. Note that RDF descriptions function much like class definitions in an

object-oriented programming language: they provide, effectively, templates that describe how objects may be instantiated, but do not constitute the objects themselves. Thus, in a document containing an actual annotation, several objects with the same type may be instantiated, each with a different value. The RDF schema ensures that each instantiation is recognized as a sub-class of more general classes and inherits the appropriate properties.

A formally defined set of categories will have several functions: (1) it will provide a precise semantics for annotation categories that can be either used "off the shelf" by annotators or modified to serve specific needs; (2) it will provide a set of reference categories onto which scheme-specific names can be mapped; and (3) it will provide a point of departure for definition of variant or more precise categories. Thus the overall goal of the Data Category Registry is not to impose a specific set of categories, but rather to ensure that the semantics of data categories included in annotations (whether they exist in the Registry or not) are well-defined and understood.

5. An Example

We illustrate a simple application of the framework presented above for the domain of morpho-syntactic annotation. For the purposes of illustration, it is necessary to make technical choices concerning the representation format. XML and related standards developed by the World Wide Web consortium appear at present to provide the best means to represent information structures intended to be transmitted across a network. For the purposes of linguistic resource representation, XML provides several important features:

- it is both Unicode and ISO 10646 compatible;
- XML namespaces provide the options of combining element definitions from multiple sources in an XML document, thereby fostering modularity and reuse;
- XML schemas provide a powerful means to define, constrain, and extend definitions of the structure and contents of classes of XML documents and document sub-parts;
- W3C has defined accompanying standards for inter- and intra-document linkage (XPath, XPointer, and Xlink) as well as document traversal and transformation (XSLT);
- XML is fully integrated with emerging standards such as the Resource Definition Framework (RDF) and DAML+OIL, which can be "layered" on top of XML documents to provide a formal semantics defining XML-instantiated objects and relations.

We have defined an XML format for representing linguistic annotations called the *Generic Mapping Tool (GMT*). The GMT defines XML elements for encoding annotation structure (primarily, a nestable `<struct>` element) and data categories (a nestable `<feat>` tag). A `<seg>` element provides a pointer to the annotated data using XPointers. Relations among objects can be specified explicitly using a `<rel>` element or may be implicit in the hierarchical nesting of `<struct>` elements. The GMT is described in detail in Ide & Romary, 2001b. We stress, however, that the details of the XML format—in particular, element names—is arbitrary; the only requirement is that the underlying data model can be expressed using the format.

5.1. Morpho-syntactic annotation

Morpho-syntactic annotation provides a good example of how the data model instantiated in the GMT is applied, and demonstrates some of the mechanisms required for representing annotations in general. Morpho-syntactic annotation involves the identification of word classes over a continuous stream of word tokens. The annotations may refer to the segmentation of the input stream into word tokens, but may also involve grouping together sequences of tokens or identifying sub-token units (or morphemes), depending on the language under consideration and, in particular, the definitions of "word" and "morpheme" as applied to this language. The description of word classes may include one or several features such as syntactic category, lemma, gender, number etc., which is again dependent on the language being analyzed.

Morpho-syntactic annotation can be represented by a single type of structural node (named W-level) representing a word-level structure unit. One or several information units are associated with each structural node.

For the purposes of illustration, we identify the following data categories (in practice these would be defined in reference to categories in the Data Category Registry):

- /lemma/: contains or points to a reference word form for the token or sequence of tokens being described;
- /part of speech/: a reference to a morpho-syntactic category;
- /confidence/: a confidence level assigned by the manual or automatic annotator in ambiguous cases.
- /gender/: the grammatical gender information associated with a word token or a sequence of word tokens;
- /number/: the grammatical gender information associated with a word token or a sequence of word tokens;
- /tense/: the grammatical tense information associated with a word token or a sequence of word tokens;
- /person/: the grammatical person information associated with a word token or a sequence of word tokens.

The following provides an example of the morpho-syntactic annotation of the sentence "Paul aime les croissants" in the GMT format:[1]

```
<struct type="MSAnnot">
 <struct type="W-level">
   <feat type="lemma">Paul</feat>
   <feat type="pos">PNOUN</feat>
      <seg target="#w1"/>
 </struct>
 <struct type="W-level">
   <feat type="lemma">aimer</feat>
   <feat type="pos">VERB</feat>
   <feat type="tense">present</feat>
   <feat type="person">3</feat>
   <seg target="#w2"/>
 </struct>
```

[1] For brevity, we use an abbreviated pointer syntax to refer to the primary data in this example.

```
<struct type="W-level">
  <feat type="lemma">le</feat>
  <feat type="pos">DET</feat>
  <feat type="number">plural</feat>
  <seg target="#w3"/>
</struct>
<struct type="W-level">
  <feat type="lemma">croissant</feat>
  <feat type="pos">NOUN</feat>
  <feat type="number">plural</feat>
  <seg target="#w4"/>
</struct>
</struct>
```

Note that there is no limit to the number of information units that may be associated with a given structural node (as opposed to the text based representations that are usually provided by available POS taggers). It is also possible to structure the annotations by embedding <feat> elements to reflect a more complex feature-based annotation, or by pointing to a lexical entry providing the information.

In some cases, the morpho-syntactic annotation of a word or sequence of words requires a hierarchy of word level structures (e.g., when a word token results from the combination of several morphemes that must be annotated independently). For example, some occurrences of the token "du" in French can be analyzed as the fusion of the preposition "de" with the determiner "le" (as in "la queue *du* chat"). This is handled by embedding word-level structures as follows:

```
<struct type="W-level">
  <seg target="#w1"/>
  <struct type="W-level">
     <feat type="lemma">de</feat>
     <feat type="pos">PREP</feat>
  </struct>
  <struct type="W-level">
     <feat type="lemma">le</feat>
     <feat type="pos">DET</feat>
  </struct>
</struct>
```

Conversely, annotation of compound words may involve associating a single lemma to a sequence of word tokens at the surface level. In this case, the lemma is attached to the higher level of embedding and reference to the source is given at the leaves of the hierarchy, as in the following representation of the compound "pomme de terre" in French :

```
<struct type="W-level">
  <feat type="lemma">
        pomme_de_terre</feat>
  <feat type="pos">NOUN</feat>
  <struct type="W-level">
     <seg target="#w1"/>
     <feat type="lemma">pomme</feat>
     <feat type="pos">NOUN</feat>
  </struct>
  <struct type="W-level">
     <seg target="#w2"/>
     <feat type="lemma">de</feat>
     <feat type="pos">PREP</feat>
  </struct>
  <struct type="W-level">
     <seg target="#w3"/>
     <feat type="lemma">terre</feat>
     <feat type="pos">NOUN</feat>
  </struct>
</struct>
```

The ability to specify a hierarchical structure where needed enables specification of the level of granularity required. This is especially critical for a representation scheme, since the granularity of the segmentation in (or associated with) the primary data may not directly correspond to the level of granularity required for the annotation.

5.1.1. Alternatives

Morpho-syntactic annotation can be used to illustrate the representation of both structural and informational alternatives, which arises when a given word token is associated with two or more word classes. For example, the French word "bouche" which can be derived both from the verb "boucher" and the noun "bouche", which can be represented as follows:

```
<struct type="W-level">
  <seg target="#w1"/>
  <alt>
    <feat type="lemma">boucher</feat>
    <feat type="pos">VERB</feat>
    <feat type="tense">present</feat>
    <feat type="confidence">0.4</feat>
  </alt>
  <alt>
    <feat type="lemma">bouche</feat>
    <feat type="pos">NOUN</feat>
    <feat type="confidence">0.6</feat>
  </alt>
</struct>
```

5.1.2. Relating annotation levels

We assume the use of stand-off annotation; that is, an annotated corpus is represented as a lattice of stand-off annotation documents pointing to a primary source or intermediate annotation levels. However, depending on the point of view, the relations between various annotation levels can be more or less explicit. It is possible to identify three major ways to relate different levels of annotation: temporal anchoring, event-based anchoring, and object-based anchoring.

Temporal anchoring associates positional information to each structural level. This positional information is typically represented as a pair of numbers expressing the starting point and ending point of the segment being described. To do so in our framework, we introduce two attributes for the <seg> element:

- /startPosition/: the temporal or offset position of the beginning of the current structural node;
- /endPosition/: the temporal or offset position of the end of the current structural node.

For example, the following associates a phonetic transcription with a given portion of a primary text:

```
<struct type="phonetic">
  <seg startsAt="2300"
       endsAt="3200"/>
  <feat type="phone">iy</feat>
</struct>
```

We also define an event-based anchoring, which effectively introduces a structural node to represent a location in the text, to which all annotations for the object

at that location can refer. This strategy is useful in two cases:

- Situations where it is not possible or desirable to modify the primary data by inserting markup to identify specific objects or points in the data (e.g., speech annotation, associated with a speech signal, or in general any "read-only" data).
- Primary data marked with "milestones", such as time stamps in speech data, where spans across the various milestones must be identified. In this case, the `<struct>` elements represent the markup for segmentation (e.g., segmentation into words, sentences, etc.).[2]

To represent this, we introduce a specific type of structural node, named *landmark*, which is referred to by annotations for the defined span, as follows:

```
<struct type="landmark">
    <seg startsAt="2300"
         endsAt="3200"/>
</struct>
```

The third mechanism, object-based anchoring, enables pointing from a given level to one or several structural nodes at another level. This mechanism is particularly useful to make dependencies between two or more annotation levels explicit. For example, syntactic annotation can refer directly to the relevant nodes in a morpho-syntactically annotated corpus, in order, for example, to identify the correct NP "le chat" in "la queue du chat", as shown below:

```
<!-- Morphosyntactic level -->
<struct type="W-level">
   <seg target="#w3">
   <struct type="W-level">
     <seg target="#w3.1">
     <feat type="lemma">de</feat>
    <feat type="pos">PREP</feat>
    </struct>
     <struct type="W-level">
       <seg target="#w3.2">
        <feat type="lemma">le</feat>
       <feat type="pos">DET</feat>
       <feat type="gender">masc</feat>
    </struct>
  </struct>
   <struct type="W-level">
       <seg target="#w4">
       <feat type="lemma>chat</feat>
       <feat type="pos">NOUN</feat>
  </struct>
</struct>
<!-- Syntactic level (simplified) -->
<struct>
   <feat type="synCat">NP</feat>
   <seg targets="w3.2 w4"/>
</struct>
```

[2] The annotation graph (AG) formalism (Bird and Liberman, 2001) was explicitly designed to deal with time-stamped data. However, we feel the AG is not sufficiently general because (1) AG reifies the "arc" and distinguishes it from identification of spans via, e.g., XML tags; and (2) AG requires *ad hoc* mechanisms to deal with hierarchically organized annotations. In both cases, AG requires different mechanisms to treat analogous constructs.

5.2. Summary

The framework presented here for linguistic annotation is intended to allow for variation in annotation schemes while at the same time enabling comparison and evaluation, merging of different annotations, and development of common tools for creating and using annotated data. We have developed an abstract model for annotations that is capable of representing the necessary information while providing a common encoding format that can be used as a pivot for combining and comparing annotations, as well as an underlying format that can be manipulated and accessed with common tools. The details presented here provide a look "under the hood" in order to show the flexibility and representational power of the abstract scheme. However, the intention is that annotators and users of annotation schemes can continue to use their own or other formats with which they are comfortable; as long as the underlying data model is the same, translation into and out of this or any other instantiation of the abstract format will be automatic.

Our framework for linguistic annotation is built around some relatively straightforward ideas: separation of information conveyed by means of structure and information conveyed directly by specification of content categories; development of an abstract format that puts a layer of abstraction between site-specific annotation schemes and standard specifications; and creation of a Data Category Registry to provide a reference set of annotation categories. The emergence of XML and related standards, such as RDF, provides the enabling technology. We are, therefore, at a point where the creation and use of annotated data and concerns about the way it is represented can be treated separately—that is, researchers can focus on the question of *what* to encode, independent of the question of *how* to encode it. The end result should be greater coherence, consistency, and ease of use and access for linguistically annotated data.

6. Conclusion

ISO TC37/SC4 is just beginning its work, and will use the general framework discussed in the preceding sections as its starting point. However, the work of the committee will not be successful unless it is accepted by the language processing community. To ensure widespread acceptance, it is critical to involve as many representatives of the community in the development of the standards as possible, in order to ensure that all needs are addressed. This paper serves as a call for participation to the language processing community; those interested should contact the TC 37/SC 4 chairman (Laurent Romary: romary@loria.fr).

nkahusk@psych.ut.ee

Abstract

This paper describes a Web-based tool for tagging word senses according to Estonian WordNet. The tool makes use of EuroWordNet import-export format that is converted into XML. The user interface is divided into three main parts that provide information about the word to be tagged: (1) context (2) morphological analysis and (3) entries in lexicon (WordNet). The tool is aimed to facilitate lexicographers' work with languages, where morphological information is important at word sense disambiguation. The advantages of the tool and problems met are discussed in detail.

1. Introduction

The task of tagging word senses is demanding for the lexicographers. They have to find the words to tag from the text, find is the word presented in the lexicon, is there an appropriate meaning for the word in the lexicon, and finally, assign the meaning to the word in question.

Estonian is an agglutinative language, rich of word forms. A lot of word forms are ambiguous, and before getting lemma some morphological analysis is needed.

In the very beginning, the linguists who did the job, had to edit a plain text file and write the appropriate sense of word after its morphological reading.

To carry out word sense disambiguation, lexicographer has to know what are the different senses of the word. Thatswhy (s)he needs to see at least, definition (gloss), and example(s) of usage, and one hyperonym. Up to now, the people who did the job, edited files with a simple text editor and used Polaris tool, that seriously limited the number of workplaces where the job could be done. This drawback, and the fact that editing a file, where one can see only one word on a line, followed by morphological analysis, is a potential source of errors, rose the need for a tool that would be more task-oriented and usable on client-server basis.

As a result of integration output of morphological analyser and an automatic WSD system for finding words not in the thesaurus and pre-selecting senses, a tool was created that makes word sense tagging more accurate and less time-consuming.

The lexicographer's tool is working in two stages, off-line (preparatory) and on-line.

By implementing the tool we have found several problems that were not noticed at manual file-editing process. The dividing into parts of speech is a bit different in wordnets and Estonian morphological tradition; morphology, syntax and semantics are more tightly connected to each other than one can suppose. An additional feature of tagging multi-word units is needed.

2. Preparatory stage

For off-line stage, the following data files are needed: (1) current thesaurus (in import-export format); (2) file to disambiguate by word senses — it should be analysed by Estmorf, and piped through fs2kym. To ensure that the analysed text file has correct format (each word must have exactly one analysis), a small vaidating script is applied to it.

During off-line or preparatory stage, current version of Estonian WordNet (EstWN) is converted into XML. Then semyhe is applied to the data in two runs: on first run, nouns are disambiguated, on second one, verbs are disambiguated.

2.1. Morphological analysis

Morphological analysis is carried out with Estmorf provided by Kaalep (1997). In its original form, Estmorf outputs for every word its structure (stem, affixes and suffixes), part of speech and inflectional categories.

```
pea
    pea+0 //_D_ //
    pea+0 //_S_ sg g, sg n, //
    pida+0 //_V_ o, //
    pida+0 //_V_ o, //
```

Figure 1: Output of Estmorf from word form 'pea'.

Declinable words are differentiated into following parts of speech: common nouns or substantives (_S_), proper nouns (_H_), adjectives with positive degree, comparative degree and superlative degree (_A_, _C_, and _U_ respectively), numerals (_N_ cardinal, _O_ ordinal), pronouns and acronyms (_Y_). Possible sets of inflectional categories are given on the same line, if they occur inside one paradigm (structure and part of speech). Figure 1 illustrates analysis of 'pea':

1. adverb ('soon'; uninflected),
2. noun ('head'; singular, genitive or nominative),
3. and 4. verb (two homonyms[1]: 'keep' and 'must', both imperative, the last one modal, but this analysis does not show such features).

[1]There are more meanings: in EstWN there are 13 senses of verb 'pidama', but they can divided into 2 groups — the modal (3 senses) and main (10 senses) ones.

```
pea
    pea+0 //_D_ //
    pea+0 //_S_ com sg gen //
    pea+0 //_S_ com sg nom //
    pida+0 //_V_ main imper pres ps2 sg ps af //
    pida+0 //_V_ main imper pres ps2 sg ps neg //
    pida+0 //_V_ main indic pres ps neg //
    pida+0 //_V_ mod imper pres ps2 sg ps af //
    pida+0 //_V_ mod imper pres ps2 sg ps neg //
    pida+0 //_V_ mod indic pres ps neg //
```

Figure 2: Output of Estmorf from word form 'pea' piped through fs2kym.

It turned out that the output of Estmorf is not very good for disambiguation purposes. At first, the Estmorf analysis line itself contains ambiguous readings (different inflectional categories, although being inside one paradigm). Second, in some cases, the differentiation into parts of speech is too detailed. The authors of Estmorf have developed a conversion program fs2kym that modifies the output. Unfortunately the last version of fs2kym is not fully documented yet, the output is pretty much the same as used by Puolakainen (2001) and Roosmaa et al. (2001) for morphological disambiguation based on constraint grammar and syntactic analysis.

In fs2kym output, substantives and proper nouns are tagged as '_S_ com' and '_S_ prop' respectively. So are numerals and ordinals, '_N_ card' stands for numeral and '_N_ ord' for ordinal. In the same way all adjectives are tagged as _A_, their degree is added with next token: '_A_ pos' for positive adjective, '_A_ comp' for comparative and '_A_ super' for superlative one. For verbs, fs2kym adds inflectional readings with all possible solutions. Figure 2 illustrates previous example analysed with Estmorf and piped through fs2kym:

1. adverb ('soon'; uninflected),
2. noun ('head'; singular, genitive),
3. noun ('head'; singular, nominative),
4. verb ('to keep; to consider'; main, imperative, present, 2. person, singular, personal, affirmative)
5. verb ('to keep; to consider'; main, imperative, present, 2. person, singular, personal, negative)
6. verb ('to keep; to consider'; main, indicative, present, personal, negative)
7. verb ('must; should'; modal, imperative, present, 2. person, singular, personal, affirmative)
8. verb ('must; should'; modal, imperative, present, 2. person, singular, personal, negative)
9. verb ('must; should'; modal, indicative, present, personal, negative)

2.2. Preliminary word sense tagging

Preliminary word sense tagging is done with Semyhe system, as described by Vider and Kaljurand (2001). The main idea of Semyhe is based on a similar system by Agirre and Rigau (1996), using distances between the nodes corresponding to the word senses in the WordNet tree and the density of the tree. Contrast to the Agirre and Rigau system, Semyhe disambiguates both, nouns and verbs. Nouns and verbs are disambiguated in two separate runs, as they do not share the same hyperonym-hyponym hierarchies.

Fs2kym-piped output of Estmorf serves as input for Semyhe. As our aim at present stage is generating a word-sense disambiguated corpus, the Estmorf output is disambiguated by hand, so every word has only one reading. Semyhe adds its output to Estmorf analysis, an example is given in Figure 3 (upper part). Semyhe analysis is added to substantives and main or modal verbs. After last piece of morphological info '@' is added, then lemma in dictionary form (singular nominative for substantives, supine affirmative illative for verbs). The last two fields are separated with colon, last number denotes number of senses found from EstWN, the last but one is sense number found by Semyhe. If Semyhe finds more than one possible analysis, then the alternatives are separated by number sign (#).

2.3. XML format

The import-export (i/e) format of a language wordnet in EuroWordNet is derived from GEDCOM standard (Louw, 1998). The GEDCOM format[2] itself is hierarchical, so the initial conversion into XML is rather simple.

The main idea in converting EWN i/e format into XML was simplicity of conversion and not well-formedness or size of resulting file. So the current version of XML format is a simple translation of GEDCOM-format into XML: node labels are translated into elements (with some exceptions explained below), and node contents are translated into values of attribute 'VALUE'. If element name consists of multiple words, element will be built from first letters of label name (PART_OF_SPEECH will be POS). Still there are some labels in EWN format that would be ambigous at such conversion. They differ only by plural ending. Such labels are converted so, that the ending 'S' is added to every subword: e.g. USAGE_LABELS will be <USLS> and USAGE_LABEL will be <UL> (Figure 4).

</s>
```

Figure 3: Upper: Output of Semyhe. Lower: The same sentence in XML format. Explanations in text. The analysed sentence can be translated like '[she] considered a bit and added a little slice of meat.'

The format will do for simple tasks like converting the thesaurus to form needed for literal browsing, but is not very suitable for more general tasks and is definitely not a good human-readable one.

There are several versions of EWN in XML that are more readable: (Kunze and Lemnizer, 2002; Smrz, 2002; Dowdall et al., 2002), and there is a special tool for viewing and editing WordNet in XML format: VisDic (Pavelek and Pala, 2002).

2.4. Text File in XML

The text file is also converted into XML. The format is similar to the one that was used at Senseval-2 task and training files, with some modifications. The `<sat>` elements are omitted (see sec. 4.3.), and `<other>` element is introduced for words being not heads, and for other tokens (punctuation marks). Morphological information is given as attributes for `<head>`[3]: `lemma, pos, class` and `rest`, the last one for other morphological reading. The identification number (position of token in text) is given as `id` attribute. Semyhe adds more attributes: `noofsenses` for number of senses in EstWN, `semyhe` for Semyhe applied sense number (Figure 3, lower part). Finally, the sense number assigned by lexicographer, will be inserted as value of `sense` attribute (not shown in the figure).

[3] `id, pos, class` and `rest`, if applicable, are added to `other` elements as well.

3. User Interface

After entering his/her name and selecting file to work with, user can move to main interface of the program.

The program window is divided into four frames: the main frame for text being analysed, morf frame and thesaurus frame. The lowest frame is for entering comments. In the uppermost frame user can browse text, words to disambiguate are in boldface, and depending on browser settings, underlined. Each word to disambiguate is preceeded by an identification number for references in comments.

User has to select appropriate sense for each word that needs disambiguation (these words are emphasized in bold and linkable). By clicking on appropriate word, user can see morphological information about the word (part of speech and word class), and thesaurus entries. The thesaurus entries are presented in a table: each row represents one synset. The 2nd column of the table shows members of synsets with sense numbers. In the 3rd column, there are explanations (glosses), and in last column there are ex-

amples of usage. The first column indicates hyperonym of each synset, displaying its first literal and sense number.

The sense numbers to select are immediately after the emphasised words in the text, as selection boxes. The sense that semyhe offered to the word is pre-selected. User has to select appropriate sense, and after finishing (or leaving the program) save his/her work with appropriate button in the lowest frame.

4. Problems of compatibility

4.1. Part of speech, WSD and syntax

There parts of speech used in EuroWordNet are: noun, proper noun, verb, adjective, adverb. Semyhe looks at Estmorf output only for nouns and verbs. With noun it gets, by default, `_S_ com` and `_S_ prop` — that is substantives and proper nouns. In EWN, numerals (`_N_ card` and `_N_ ord` in Estmorf output) are classified also as nouns. Seems to be a minor bug, but there is a famous example of homonymy in Estonian: 'viis' means number 'five', and 'a way to do something', and 'melody'. For an English analog, consider the homophony of '4' and 'for', for example. By using morphologically disambiguated text, we have already pre-selected one sense (or reduced the possible number of senses) and left the other(s). The same stands for some features, that belong to syntax: verb may be main, auxiliary or modal, by determining the type, we can tell the sense.

4.2. A word about encoding

As Latin alphabet is used to write Estonian, it seems that there should not be a problem with encoding. There are some umlaut letters in Estonian (ä, ö, ü and Ä, Ö, Ü) that rise no problems, since they can be found in many West-European languages and in Latin-1 encoding as well. Some ten years ago there have been some problems with another quite frequent letter 'õ, Õ', known as o tilde. It is in Latin-1 now and is OK, but historically there have been problems, as it was not included in so-called 'extended ASCII character set' provided by first PC-s running DOS.

There are some really 'nasty' letters in Estonian alphabet, s caron and z caron (š, ž, Š, Ž). They are not very frequent, but they figure in important foreign words like 'žanr' (genre), 'dušš' (shower), or 'garaaž' (garage), that do not have any synonyms without these 'horned' letters. There have been proposals to stop using them and replace them with 'sh' and 'zh', like in English word 'bush', but it can happen in Estonian that syllable boundary—or even word boundary in compounds—is between 's' and 'h' like in 'klaashelmes' (klaas+helmes, glass bead), so it is not reasonable to use 'sh' as ligature. These letters are not contained in Latin-1 character set.

The new standard sets Latin-15 as character set of Estonian, but many applications do not recognise it yet.

The caron letters are in Latin-2 (Windows 1250, Central Europe) encoding, but the places of 'õ' and 'Õ' are taken by 'ő' and 'Ő' (o with double acute, used in Hungarian). The bad news is, that our Polaris uses Windows 1250 encoding, and so are the export files. In order to get relevant results about words containing 'š' and 'ž', we had to convert the EWN export files into Latin-15 before applying semyhe. Still, some XML tools do not recognize Latin-15 encoding, so we must rebuild everything for at least UTF-8 encoding, to get rid of constant converting to and forth.

4.3. Multi-word expressions

There is still a problem with multi-word expressions. Semyhe does not recognise multi-word expressions at present stage, and so they get no sense number, nor display in thesaurus frame (unless they are synonyms of some one-word literal). So lexicographers have to mention the multi-word units separately in the comment field. The problem is more accute with multi-word verbs, as they may consist of words the senses of which by themselves have little, if anything, to do with the meaning of the whole phrase. Fortunately enough, we are going to have a representative list of of Estonian phrasal verbs and idiomatic expressions by Kaalep and Muischnek (2002). Even with the ready-made list the algoritm of founding multi-word semantic units from the text would not be trivial. The same problems that Kaalep and Muischnek met at compiling the database, will haunt us at finding multi-word units from text by semyhe: relevant words may be intervened by other words in the sentence, and we need to meet the ends of lexicon form of word (lemma) and the form that is used in the text. The question of multi-word phrases, verbs in particular, is not a minor one, as there are 1070 two-word phrases in EstWN, 824 of them verb phrases. That makes about 28% of all verb literals[4].

5. Conclusions and future improvements

The tool has turned out to be useable, but there are problems as well, some of them being technical, some theoretical.

We are using morphologically disambiguated text. For semantic analysis, only these nouns and main (or modal) verbs are presented, that are currently in the thesaurus. If there has been made a mistake during morphological disambiguation, a lexicographer using the program can not make any corrections directly, but only make notes about the mistake in the comments field.

Multi-word phrases missing from analysis is a serious drawback, especially in case of verbs. If user does not see the possibility of multi-word phrase in the thesaurus, then it takes him or her much more time to think about this possibility among others. This slows down the process of analysis and is a potential source of errors.

The possibility to see all senses of a word together, in one table, is an advantage that even Polaris does not afford. This gives us direct comparison of senses, that is useful not only for WSD task, but for improvement of the thesaurus as well.

Approaches to Checking Subsumption in GermaNet

Piklu Gupta

Fraunhofer Integrated Publication and Information Systems Institute
Dolivostr. 15
D-64283 Darmstadt, Germany
gupta@ipsi.fraunhofer.de

Abstract

The paper describes different approaches for checking the subsumption relation in GermaNet using database queries and subsequent manual analysis. The work was carried out in an object-oriented tool environment hosting the GermaNet data. Finally there is a brief note comparing GermaNet coverage with that of Duden dictionaries.

1. Introduction

The context of the work presented here was a study for Bibliographisches Institut & F.A. Brockhaus (BIFAB), publishers of Duden dictionaries; the main purpose of the study was to subject GermaNet (Hamp and Feldweg, 1997; Kunze, 2000) to close scrutiny by examining semantic relations in terms of consistency and subsequently to compare coverage of GermaNet with Duden dictionaries. The relations we focused on were the generic hierarchical relation expressed by hyponymy/hyperonymy and its synonymous variant for verbs (troponymy/troponymyOf), since this is the fundamental relation in GermaNet (Kunze, 1999). The tool hosting GermaNet for this work was the TerminologyFramework system, briefly described below in subsection 2.1. Various approaches to investigating the subsumption relation were adopted:

- formal consistency checks using database queries and manual analysis of results
- manual inspection of the non-overlapping parts of a semantic field and the corresponding concept hierarchy in GermaNet
- manual inspection of subsumption links reachable from a 10% sample of the denotation strings of GermaNet which also belong to the single volume Duden dictionary (DUDEN, 2000b) as lexical entries.
- top concepts were identified and analysed.

The starting point for the manual tests was rigid or strict subsumption: concept A is subsumed by concept B iff all instances of A are also instances of B.

Duden made their dictionary material available to us in machine-readable format thus enabling us to also compare the coverage of GermaNet with both the 10 volume (DUDEN, 2000a) and the single volume Duden dictionaries.

2. Formal Consistency Checks with Queries in Terminology Framework

2.1. Terminology Framework

TerminologyFramework (henceforth TFw) is a general purpose tool for representation and maintenance of thesaurus-like structures, ranging from conventional thesauri to the published CyC upper ontology or lexical databases such as WordNet (Fischer, 1998). GermaNet was imported into a TFw application, using an identical schema previously developed for investigating WordNet (Fischer, 1997). This import generated an object-oriented representation of GermaNet including persistent storage. Its contents could be inspected with tools including a frame to slot to value list view and graphic view (described in Möhr and Rostek (1993)) and investigated by means of database queries. The import turns every synset into an object (known in TFw as a **concept**) and the synset elements are represented as **terms**, which are denotation objects with disambiguated denotation strings. One of the advantages of TFw is that it allows for computable relations such as the transitive closure of the subsumption relation.

2.2. Formal Consistency Checks

A broad range of formal checks for redundancy and consistency in WordNet had already been devised and described by Fischer (1997). We restricted ourselves to consistency checks with respect to the subsumption relation in GermaNet. Fischer's investigation employed three distinct queries relevant to this relation:

1. Are there opposed concepts where one subsumes the other?
2. Are there opposed concepts which have a common subconcept?
3. Are there examples where the commutativity of subsumption and opposedness does not hold?

We understand subsumption not only as a relation that holds directly but also indirectly between concepts (as a result of the transitivity of this relation), which means that these questions presuppose the availability of the transitive closure of hyponymy/hyperonymy in GermaNet. The 'opposed' relation is defined thus: two concepts are opposed (or synonymously 'antosemous') if at least two of their terms are antonyms. Therefore a further computable semantic (concept-concept) relation is induced from a lexical (term-term) relation and both computable relations are prerequisites for the check. If we consider the third query, we need to explain what is meant by commutativity of subsumption and opposedness. Fischer (1997) defines this as follows:

For each concept *c:* If *antosem(c)* is not empty, then the equation *hypernym(antosem(c)) = antosem(hypernym(c))* or set inclusion in one direction or the other should hold.

All three rules may be justified by a concept model with feature inheritance, assuming that opposed concepts necessarily have some kind of contradictory feature which must not be inherited simultaneously by a more specific concept, otherwise this would lead to an oxymoron (e.g. bittersweet). We use this example, however, to illustrate that it is by no means impossible for language to creatively violate this logical inheritance rule. These three questions are therefore best seen as a heuristic to detect on the one hand cases which entail errors and on the other hand cases which invalidate the generality of the rule.

We did not consider the last of the three questions concerning commutativity, but concentrated instead on the first two. The retrieval results are discussed below in subsections 2.3. and 2.4.

2.3. Does GermaNet contain opposed concepts where one subsumes the other?

This query posed to the classes of verb and adjective concepts returned no hits, but when posed to the class of noun concepts it returned three noun concept pairs, illustrated by the three figures below:

- *Ziegenbock* (male goat) and *Ziege(2)*[1] (goat, in the generic rather than female sense),
- *Subjekt(2)* (subject in the sense of a living being) and *Objekt(2)* (object in the sense of living being)
- *Titelverteidiger* (title holder) and *Herausforderer* (challenger)

Figure 1 illustrates the case of *Ziegenbock*. Here we see that the antonymy relation has been falsely assigned between the generic and the male form; there should be a link showing antonymy stretching from left to right in the figure, that is from the term *Ziegenbock* to the term *Ziege* of the concept *Ziege* in its female sense. This case appears to be the result of an incorrectly assigned pointer due to homographs; we can only speculate as to whether inappropriate tools or limited views used in linking concepts by the lexicographer are the source of the error here.

Figure 2 illustrates the case of *Subjekt (2)* and *Objekt(2)*. The opposed relation between *Subjekt(2)* and *Objekt (2)* induced by antonymy is clearly false. We suggest that another pair of concepts, 'namesakes' to the given pair – *Subjekt (1)* and *Objekt (1)*, both in the grammatical sense, should be linked as opposed concepts. The 'namesakes' relation is a computable TFw relation which links concepts with homographic denotation strings.

The case of *Titelverteidiger* (title holder) and *Herausforderer* (challenger), illustrated in Figure 3 below, leads to a different diagnosis. We maintain that the hyponym link

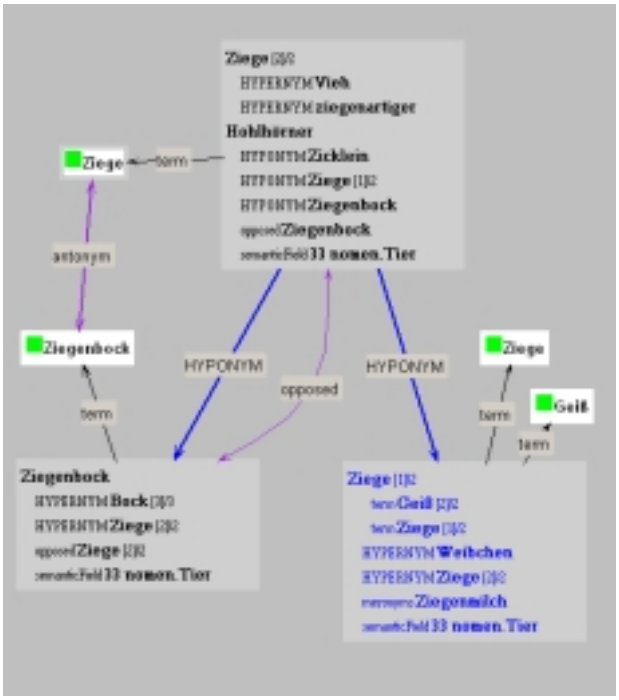

Figure 1: Faulty antonymy target

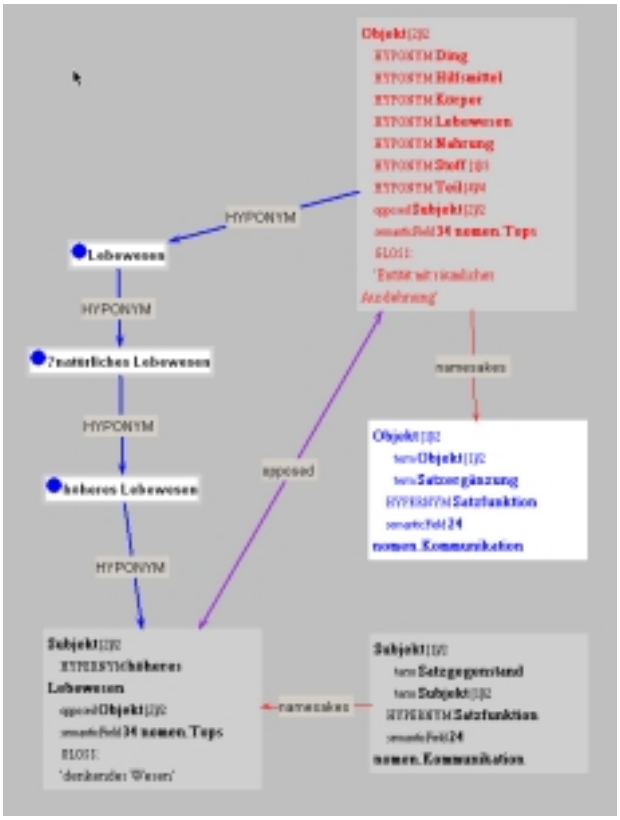

Figure 2: Faulty antonymy pair

between *Herausforderer* and *Champion* (champion) is incorrect, since not every champion is a challenger. [2]

[1] The number after the word denotes a homograph counter generated by TFw; the figures also show the number of homographs for each respective homographic string, separated by a '/'.

[2] Note that an antonym link is missing between the gender-inclusive forms *HerausforderIn* and *TitelverteidigerIn*.

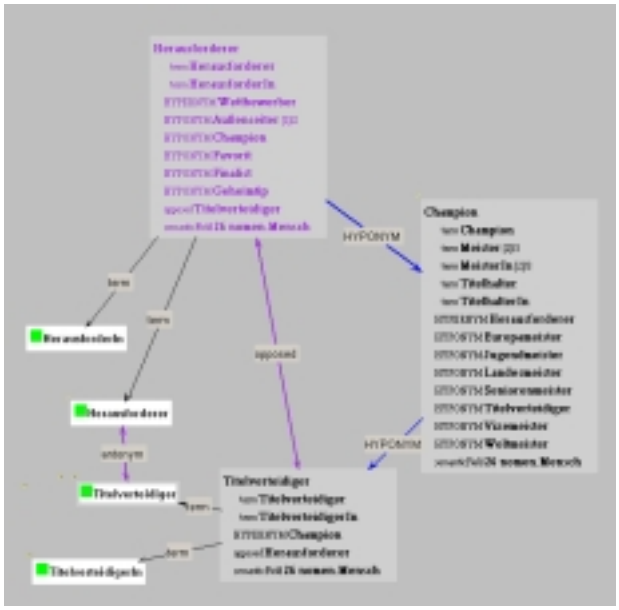

Figure 3: Faulty hyponym link between *Herausforderer* and *Champion*

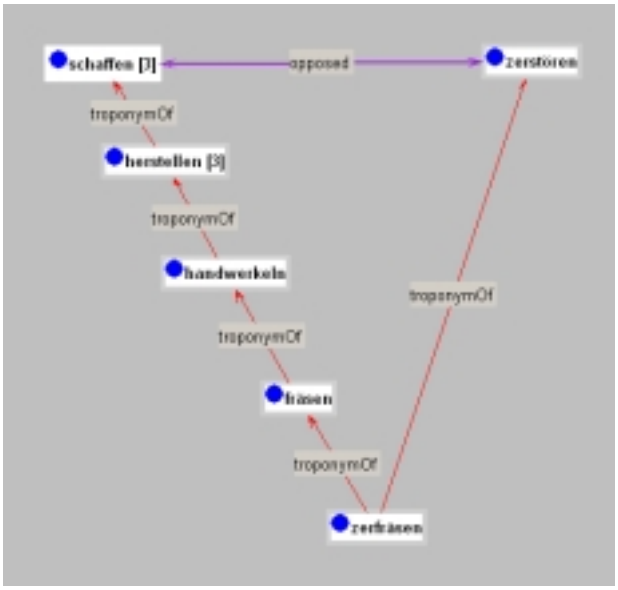

Figure 4: Strict versus defeasible hyperonymy

2.4. Does GermaNet contain opposed concepts with a common hyponym?

The query posed to the class of verb concepts returned two verb concept pairs, illustrated by the two figures below:

- *schaffen (3)* (in the sense of to create) and *zerstören* (to destroy); their common troponyms are *zersägen* (to saw up), *zerkochen* (to overcook or cook to a pulp), and *zerfräsen* (to mill to pieces)

- *nehmen (1)* (in the sense of to take something) and *geben (2)* (in the sense of to give something); there are 8 common troponyms including e.g. *tauschen* (to exchange something for another thing) and *dealen* (in the sense of dealing e.g. drugs).

This query returned results which are not indicative of incorrect pointer assignment but rather raise non-trivial questions about the nature of the subsumption relation or the antonymy relation in GermaNet.

The figure shows that *zerfräsen* is simultaneously a hyponym of verb concepts denoting creation and destruction. At first sight this seems counterintuitive. How can we account for this phenomenon? The hyponymy relation of *zerfräsen* and *zerstören* is obviously correct and is a rigid subsumption link. Looking at the left hand side of the figure, we check the link from *zerfräsen* to *fräsen*. This we deem to be acceptable as a rigid subsumption link, if we *fräsen* means to use a milling tool or mould in its neutral sense irrespective of its creative or destructive effect. If, however, we proceed from that concept node upwards to *schaffen (3)* we leave the neutral sense of *fräsen* and adopt a sense in which a creative or non-destructive use of the tool is implicit. It therefore follows that we have given the concept node *fräsen* two different meanings, and therefore according to the general WordNet philosophy we should split the node into 3: *fräsen(neutral)* , *fräsen (constructive)* and finally *fräsen (destructive)*, which already exists as *zerfräsen*.

Another possible remedy is to differentiate between strict and defeasible (non-strict) subsumption; the link between *zerfräsen* and *fräsen* would be strict whereas the link between *fräsen* and its direct superordinate *handwerken* or its indirect superordinate *schaffen (3)* is non-strict, i.e. in most cases the use of a milling tool or mould is constructive. Introducing a new subsumption relation type to the WordNet software, however, is likely to be difficult in contrast to TFw. This would entail checking all subsumption links for their type. Note that we cannot assume transitivity for the concatenation of strict and non-strict subsumption links.

A radically different diagnosis and remedy spring to mind when considering the case of Figure 5. At first sight the constellation appears to be acceptable, thus disproving the general validity of the rule. Our intuition may tell us that *tauschen* implies simultaneous acts of giving and taking and thus even the conjunction of the superordinates *nehmen* and *geben* seems plausible. On closer inspection, however, we see that a *tauschen* act implies the taking of **one item** in exchange for **another**, which means that the act of exchange consists of two simultaneous (or more probably) consecutive acts of giving X and taking Y where X and Y are not identical. The opposition of the concepts 'giving' and 'taking', however, obviously implies that the object of both is the same otherwise there would be no opposition. For example, teaching linguistics is not the 'opposite' of learning mathematics. What does the antonym or opposed link actually mean? (cf. Woods (1991, pp. 54ff)) If it means every act of giving is opposed to every act of taking, in the same way as every sweet object is opposed to every savoury object then the opposed link is faulty. If it means that for every giving act there exists a taking act which is opposed, then the rule implicit in the query does not have

general validity! This demonstrates the inconsistent use of the antonym/opposed link. Instead of the troponymOf links between *tauschen* and *nehmen* and *tauschen* and *geben* we propose a pair of 'entails' links, which would show that exchanging entails both giving and taking.

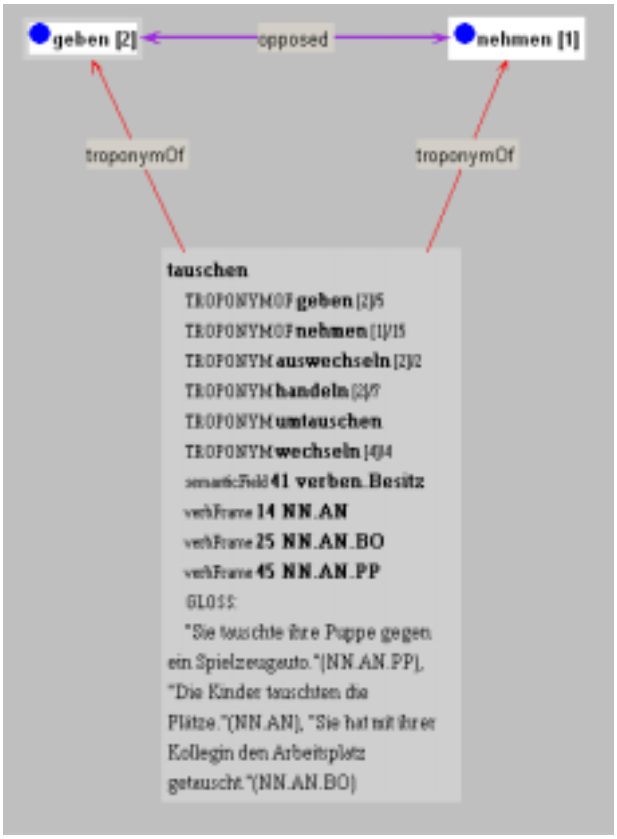

Figure 5: *Geben (2)* and *nehmen (2)* only opposed with a common object

Posing the query to the class of adjective concepts returned one concept pair, *farbig (2)* (in the non-racial sense of coloured) and *farblos* (colourless) with the common hyponym *falb* (dun, as applied to horses). This constellation contains a highly questionable hyponym link between *fahl* (pale) and *farblos* (colourless).

Posing the same query to the class of noun concepts also returned a single concept pair, *Vermögen* (property) and the non-lexicalised concept *?negativer Besitz* (negative ownership). In this case two highly questionable hyponym links exist, on the one hand between *Zins* (interest) and *Vermögen* or *Finanzen* (finances) and on the other between *Verzugszins* (interest payable on arrears) and *?negativer Besitz*.

In concluding this section, we note that retrieval results for both kinds of questions did not invalidate the implicit heuristic rules.

3. Semantic fields and hyponymy

According to GermaNet documentation (http://www.sfs.nphil.uni-tuebingen.de/lsd) , the division of GermaNet into semantic fields served an organisational purpose in that a field corresponds to a data file for editing by lexicographers. It was nonetheless interesting to investigate to what extent the semantic fields did in fact contain the expected content and to this end we looked at the hyponymy relation in cases where an available top concept corresponded to a semantic field label. Wherever this proved to be the case, we would expect all hyponyms to be members of that semantic field. Those elements **not** in the intersection of both sets demanded closer inspection, for instance with regard to which hierarchy they should actually belong to. This is another fruitful method for delimitation of the set of hyponym links to be checked manually.

Among others, the semantic field *nomen.Tier* (noun animal) was examined in tandem with the concept *Tier* (animal) and queries led us to obtain the following results:

- the concept *Tier* has 2049 hyponyms.
- the semantic field contains 2086 elements.
- only one concept *Pute* (turkey in its food sense) is an indirect hyponym of *Tier* but not a member of the semantic field *nomen.Tier* and instead belongs to the semantic field *nomen.Nahrung* (noun food). Here we have a clear-cut case of 'animal grinding' (Briscoe et al., 1995), in which a count noun (animal) becomes a mass noun (food). It might therefore be useful to assign a different kind of link which is applicable to the grinding operation.
- 38 concepts are in the semantic field but are not hyponyms of *Tier*; almost half of these consist of mythical beasts. The remainder include borderline cases such as single-celled beings, bacteria and microorganisms. If we maintain that mythical beasts such as *Einhorn* (unicorn) are animals irrespective of their real existence, then they should by rights also be hyponyms of *Tier*. There are also concepts such as *Männchen* (male animal) and *Weibchen* (female animal) which should properly be classed as animals.

4. Missing links

Formally speaking, top concepts are those which have no superordinates. GermaNet contains 500 such formal top noun concepts, but it should be noted, however, that of these 500 concepts only 125 are what we would term genuine top concepts in that they also have hyponyms, the remaining 375 are therefore isolated having neither superordinates nor hyponyms. For verbs there are 125 genuine tops and 94 isolated concepts and for adjectives there are 34 genuine tops and 246 isolated concepts. This points towards the transitional status of these concepts – GermaNet is, after all, a work in progress. The large number of remaining top concepts for nouns and verbs in particular is therefore arguably due to missing structure at this highest level. For example, a number of the genuine tops should either be hyponyms of other tops or hyponyms of new, more general concepts – *Wurstware* (sausages) is a top and is not a hyponym of *Nahrung* (food) as would be expected and tops such as *Arbeitszeit* (working hours), *arbeitsfreie Zeit* (leisure time) are not linked to the possible concept of time interval. Another approach to finding missing antonym links is to run

the third query mentioned above in subsection 2.2. and discussed for WordNet in Fischer et al. (1996, p. 253) and Fischer (1997, p. 28).

5. Manual evaluation of generic links in a sample of GermaNet

This section summarises results of an investigation of a sample of GermaNet with regard to the correctness of the hyponymy relation. The basis of the sample was a list of GermaNet synset elements which also appear in the single volume Duden dictionary as lexicon entries. Starting with the ninth list entry and subsequently every tenth entry was extracted from a list of adjectives, nouns and verbs thus providing us with a 10% sample of GermaNet. A total of 3511 hyperonym links were examined and classical tests for strict hyponymy were applied. We distinguished between correctly assigned, doubtful [3] and incorrectly assigned hyperonymy. Results were as follows:

- out of 519 verb denotation strings we derived 914 hyperonym links , 89% were deemed to have correctly assigned hyperonymy, 4% were doubtful and 7% were incorrect,
- out of 396 adjective denotation strings we derived 489 hyperonym links, 92% were correct, 2.5% were doubtful and 5% were incorrect,
- out of 1664 noun denotation strings we derived 2108 hyperonym links, 96.6% were correct, 1.2% were doubtful and 2.2% were incorrect,
- of a total of 2579 denotation strings for all 3 GermaNet word classes we derived 3511 hyperonym links, 94.1% were correct, 2.1% were doubtful and 2.1% were incorrect.

Some of the commonest errors were mistaken assignment of hyponym/troponym where a merge of concepts would be more appropriate because their terms are stylistic variants and therefore synonyms. For instance, the stylistic variants *pennen*, *knacken* and *ratzen* (to kip; colloquial for to sleep) are deemed to be troponyms of *schlafen* (to sleep) rather than as what Cruse (1986) regards as 'cognitive synonyms'. The assignment of hyponymy seemed on occasions to be based on morphological factors rather than semantic ones (e.g. *Fahrgast* (passenger) as a hyponym of *Gast* (guest).

6. Coverage of GermaNet compared with Duden dictionaries

It is a truism that both the single volume and 10 volume Duden dictionaries have wider coverage than GermaNet, with around 100,000 entries and 200,000 entries respectively so it is arguably more interesting to look at what is to be found in GermaNet but not in single or multi-volume reference works rather than to simply enumerate what is in the dictionary but not in GermaNet. GermaNet contained [4] a total of 41359 entry strings, of which 25798 appear in both GermaNet and the single volume Duden. A total of 15561 entry strings were to be found in GermaNet but not in the single volume Duden. 28862 entry strings appeared in both GermaNet and the 10 volume Duden and 12497 entry strings were present in GermaNet and not in the 10 volume Duden.

A number of groups in GermaNet and in neither of the Duden dictionaries can be identified as follows:

- gender-neutral terms denoting roles (e.g. *AntifaschistIn* (anti-fascist))
- very specific specialised language (e.g. terms from a biological taxonomy)
- selected compounds; compounding is highly productive in German and therefore criteria for their selection and inclusion are dependent on e.g. frequency, corpus evidence
- orthographic variants
- misspellings

GermaNet contains 1869 gender-neutral terms denoting roles which are not present in the form with an upper case 'I' in either the single or 10 volume Duden, but feminine forms are to be found if the upper case I is eliminated by a normalisation to lower case letters. GermaNet appears to contain an exhaustive biological taxonomy (despite claims for inclusion on the basis of corpus frequency), so on inspection of the 2049 hyponyms of *Tier* (animal) and the 189 hyponyms of *Pflanze* (plant), 1043 animal hyponyms and 1119 plant hyponyms are present that are not to be found in the 10 volume Duden. The difference between what is present in GermaNet and in dictionaries raises important questions for lexicographers – for instance, which criteria should be employed for inclusion of compounds, which can in any case never be completely covered due to the productivity of compounding. Also, how subjective frequency decisions made by lexicographers are and to what extent the use of balanced corpora can contribute to lexicography.

[3] Some of the links that we deemed in this analysis to be merely doubtful (such as the link between *tauschen* (to exchange) and the *geben* (to give) and *nehmen* (to take) pair) were deemed incorrect after the formal checks described in subsection 2.4..

[4] We used version 3.0, current as of 22.01.01

7. Acknowledgements

I am grateful to Dietrich Fischer for his insights and encouragement in the writing of this paper. Constructive discussion with him proved invaluable. I would also like to thank Lothar Rostek for initiating the study in the first place and for playing a major role in setting up the working environment and the scenario.

Evaluation of GermanNet: Problems Using GermaNet for Automatic Word Sense Disambiguation

Jahn-Takeshi Saito, Joachim Wagner, Graham Katz, Philip Reuter, Michael Burke, Sabine Reinhard

Institute for Cognitive Science
University of Osnabrück
49074 Osnabrück

Abstract

WordNets such as GermaNet have been frequently used as an inventory of word-senses for word-sense disambiguation tasks. In the work described here we evaluate the adequacy of GermaNet for this task. That is we attempt to determine the degree to which GermaNet provides an adequate inventory of senses for word-sense annotation of running text. Our findings were on the whole very encouraging. GermaNet provides an appropriate sense for 83 % of the content words in our texts. More interestingly, an error analysis showed that simple morphological processing could significantly improve coverage.

1. Introduction

The use of WordNet for sense tagging of English is by now an established research program (Miller, et.al 1994; Resnik 1998; Landes, Leacock & Tengi 1998). With the advent of WordNet-style lexical resources for languages other than English (Bloksma, Díez-Orzas & Vossen 1996) the application of these resources, to sense-tagging for these languages is a natural evolution. A number of questions arise in this context, however. While the original WordNet has been used with success for English, there is no guarantee that this experience generalizes to other WordNets for other languages. Both the language itself and the particular WordNet developed for it may present problems that were not present in the WordNet/English case. Our goal here was to evaluate how useful GermaNet is as a resource for word sense tagging for German.

Our task, then, was to annotate a corpus of German text using GermaNet and to determine how close to the ideal of providing an appropriate sense tag for all content words in the corpus GermaNet is. This is of interest both as an evaluation of GermaNet itself, and also because German and English differ in ways that, *a priori*, might indicate that German would be a difficult language to sense-tag (Hamp & Feldweg 1997). German has, for example, highly productive word-formation processes and a rich derivational morphology.

In form, however, our work was very similar to that done for English by Landes, Leacock & Tengi (1998) in that we simply set out to manually disambiguated words in a corpus, tagging each appearance of a content word in the corpus. In contrast to their work, we developed our own (German language) corpus and used GermaNet as our repository of word senses. Additionally, work was separate from the development of GermaNet and we did not have contact with GermaNet lexicographers.

2. GermaNet

GermaNet is a lexical-semantic net based on the WordNet example (Kunze & Wagner 1999a). It is intended to cover the basic vocabulary of German. Although GermaNet relies on the design principles and shares the same database structure as the Princeton WordNet (Miller 1990), it is build from scratch and features some modifications. In contrast to WordNet, GermaNet includes non-lexicalized *artificial* concepts to fill lexical gaps (e.g. to provide the missing antonym for *thirsty*) and to avoid unjustified co-hyponomy. Additionally, cross-classification of concepts, which is seldom used in WordNet, is an essential feature of GermaNet, and regular polysemy is integrated via a special relation between synsets. There are also some particular differences with respect to the way parts of speech are handled. Adjectives in GermaNet, for example, are hierarchically structured (in contrast to a clustering approach in WordNet). It wasn't clear that any of these differences affected the usefulness of GermaNet for sense-tagging, however.

More important was GermaNets coverage. Although GermaNet is comparable in size to WordNet, it is significantly smaller, as indicated in Table 1.

	GermaNet	WordNet 1.7
Noun	27824	74488
Verb	8810	12754
Adjective	5141	18523
Adverb	2	3612
Total:	41777	109377

Table 1. GermaNet vs. WordNet

Although GermaNet has been integrated into EuroWordNet (Kunze & Wagner 1999b), the version we used for our research was the stand-alone GermaNet.

3. The annotation task

As a preliminary to the development of an automatic sense tagger for German we hand-tagged eleven small German texts. We used these hand tagged texts to evaluate the applicability of GermaNet to large-scale

sense tagging applications. The procedure we used for annotation was fairly straightforward. We automatically lemmatized the words and tagged them for part of speech using the Stuttgart TreeTagger. To actually carry out sense tagging, we developed a software tool for presenting words in texts along with their GermaNet synsets, which was used by five annotators to annotate the texts. The texts were annotated on a word-by-word basis, with each token that had been tagged either as a verb, a noun or an adjective presented for word-sense tagging. For words that could not be annotated with GermaNet synsets, the problem that the word appeared to pose was noted by the annotator, if one was apparent. These error-annotations were used to classify the types of words that presented difficulties for sense-tagging using GermaNet synsets.

3.1. Corpus preparation

As there is not yet a standard representative German corpus, we choose to develop our own corpus. The corpus consisted of eight short excerpts from novels for children and young people and three articles taken from German newspapers. The total number of words in our corpus was 5625 and the individual subcorpora varied in size from 257 to 1021 words.

The entire corpus was both lemmatized and tagged for part of speech by the IMS TreeTagger (Schmid 1994). These lemmata were then used to automatically compile a list of GermaNet synsets for each token in the corpus that appeared in GermaNet. For each lemma, the complete set of GermaNet synsets associated with the lemma by GermaNet was stored alongside the lemma. The POS information was **not** used in this step for filtering, so as to exclude this as a source of error. As indicated in Table 2, GermaNet assigned a synset to more than 90% of the content words (noun, verb or adjective tagged words) in the texts. Strikingly, the percentage of content words not assigned an appropriate synset by GermaNet is lower for the newspaper corpora (about 80%) then for the childrens fiction corpora (about 85%).

3.2. Corpus Annotation

For purposes of annotation, the eight short-novel corpora were split up randomly into 24 pieces which were recombined into equal-sized subcorpora and distributed among our five annotators. The pieces were systematically permutated in order to minimize the influence of inter annotator differences. After annotation was complete the pieces were reordered, so that statistics could be obtained on a per corpus basis. At a later stage the newspaper subcorpora News 1, News 2, and News 3 were annotated. Although the annotation procedure was the same, these subcorpora were annotated by a single annotator.

The actual annotation was carried out as follows. The five annotators – all native speakers of German – were provided with a software tool and a set of files to be tagged. The software tool (see fig. 1) presented the annotator with each occurrence of a lemma for which GermaNet provided synsets.

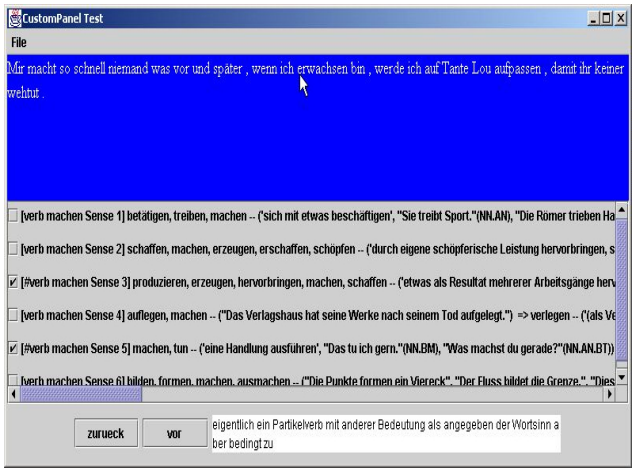

Figure 1. The TAZAN annotation tool

The annotator task was to mark the appropriate synset, if there was one. In addition to the textual context the word appeared in, i.e. the sentence, annotators were shown the set of synsets for the lemma and the basic characterization provided by GermaNet for these synsets. These contained brief descriptions of the synset, examples of typical uses of that sense of the word and an indication of where the synset was located in the GermaNet hierarchy. For verbs the syntactic frame associated with the sense was also indicated. The synsets were presented to the annotator grouped by POS. In choosing a synset, annotators also implicitly indicated what they took to be the correct POS for the word in contexts.

For the lemma *essen*, for example, the following information was presented, with three noun senses and one verbal sense.

[nomen essen Sense 1] Essen, Mahl, Mahlzeit --
('Einnahme von Speisen')
[nomen essen Sense 2] Gericht, Speise, Essen --
('Speise, die für eine Mahlzeit zubereitet ist') =>

Corpus	Word Tokens	Content words	Synset Assigned	Marked	Marked (of Assigned)
Fiction	4330	1770	1658 (93.7%)	1497 (84.6%)	90.3%
Newspaper 1	257	143	129 (90.2%)	124 (86.7%)	86.7%
Newspaper 2	474	206	179 (86.9%)	161 (78.2%)	89.9%
Newspaper 3	564	270	233 (86.3%)	205 (75.9%)	76.3%

Table 2: Quantitative Characterization of the Corpora and Annotation Results

Nahrung, Nahrungsmittel, Lebensmittel, Esswaren, Eßwaren*o, Essen, Speisen
[nomen essen Sense 3] Nahrung, Nahrungsmittel, Lebensmittel, Esswaren, Eßwaren*o, Essen, Speisen => Objekt -- ('Entität mit räumlicher Ausdehnung')
[verb essen Sense 1] essen, futtern*s, nehmen -- ('etwas zu sich nehmen', "Er isst kein Fleisch."(NN.AN), "Er futtert wie ein Scheunendrescher."(NN.BR), "Sie nimmt viel Flüssigkeit zu sich."(NN.AN.PP), "Die Kinder futtern fleißig Schokolade."(NN.AN.BM) "Heute abend werde ich warm essen."(NN.BM)) => verzehren -- ('Ein Lebensmittel essen oder trinken, Perspektive auf Lebensmittel', "Auf der Weihnachstfeier haben die Mitarbeiter zehn Kilo Fleisch verzehrt.", "Sie verzehrte ihr Gemüse ohne Appetit.")

The annotators were also encouraged to use the GermaNet browser to locate additional information about a synset if a decision was difficult.

To annotate, the annotator simply selected (via check box) the appropriate sense(s) for the word as used in the context presented. They were able to move freely forwards and backwards through the corpus and to change their choice of synset at any time. The task was not an easy one. To fully annotate even one of our 24 small subcorpora took our annotators approximately an hour of annotation time. Typically, however, our annotators divided up the task into a number of sessions.

Note that annotators were instructed to mark all synsets considered appropriate. That means that the annotator could mark more than one of the senses GermaNet assigned to the word or reject all of them. This means that words which were not assigned at least one GermaNet synset were not presented for tagging at all. As indicated in the sixth column of Table 2, this was typically around 10% of the content words.

3.3. Results of annotation task

The results of our annotation exercise are indicated in the final columns of Table 2. This column indicates the percentage of the total number of content words (NVA tagged words) for which an annotator marked at least one of the supplied senses as correct and the percentage of the total number of words assigned a synset by GermNet for which at least one of the synsets assigned was marked by an annotator as being appropriate. This is a raw measure of how well GermaNet could be used to sense tag our corpora. That is, in about 90% of the cases, if a word appears in GermaNet, then the annotators found that GermaNet provided an appropriate sense for the word as used in the corpus. While not disappointing, the numbers may seem low. In fact they are misleadingly low, as a significant proportion of these errors are not due to GermaNet at all. In section 4 we will discuss these error factors extensively.

3.4. Inter annotator agreement

An important question, however, was the degree to which the judgement of our annotators varied. We made provision for evaluating inter annotator agreement by having all the annotators tag one small subset of the short novel corpus. This subcorpus contains 431 tokens and was annotated by all five annotators. Only 170 of these tokens were assigned a list of synsets by the GermaNet. So there were 170 points the annotators could disagree on. To evaluate inter annotator agreement, we looked at whether for each of these 170 tokens any synset was marked or not by the annotators. The number of tokens that were not marked as having any acceptable GermaNet assigned synset is shown in Table 3. All five numbers are in the 95% intervall [35, 57] of the binomial distribution with n = 170 and p = 46.0 / 170 = 0.271.

Annotator	1	2	3	4	5
Token with no synset marked	40	44	56	50	40
Mean	46.0				
Variance	38.4				
Standard deviation	6.2				

Table 3: Basic statistics of annatation

It is not, of course, correct to infer from this that the annotators agree on which tokens to mark. To evaluate the more narrow question of whether our annotators agree on this we compared our annotators pairwise. Table 4 shows how many tokens can be counted in the union and intersection of two annotators' annotation records filtered for tokens that have no marked synset and in which each token was prefixed with a unique token ID. The size of the intersection gives the number of tokens that they agree on and the difference to the size of the union gives the number of tokens they disagree on. If, for example, annotator 1 and 2 completely agreed, the number of tokens would be max(40,44) = 44 in the union and min(40,44) = 40 in the intersection. If they disagreed as often as possible, the numbers would be 40+44 = 84 and 0. Table 4 gives these numbers, with the possible ranges in square brackets. The numbers seem to show quite good agreement.

A way of measuring inter annotator agreement is provided by Cohen's (1960) kappa statistic. This measure indicates the degree to which the observed agreement rate differs from chance, and is given by:

$$\kappa = \frac{P_a - P_e}{1 - P_e}$$

where P_a is the observed agreement rate and P_e is the expected chance agreement. Numbers above 0.80 are generally considered to give evidence for a good agreement, whereas numbers below 0.67 indicate poor agreement (Carletta 1996). Our κ values – indicated in the final column of Table 4 – are between or even above these standard values, indicating acceptable agreement.

We did not analyze agreement of polysemy judgements, that is, agreement on what sense should be assigned to which word (c.f. Veronis 1998), because they are irrelevant to our study. Furthermore, token counts per type are too small to get significant results. It is important to keep in mind that we were primarily interested in whether GermaNet is a rich enough lexical resource, not with whether the annotators agreed exactly on how to use it.

Annotator pair	Token in Union	Intersection	κ
(1, 2)	48 [44, 84]	36 [0, 40]	0.81
(1, 3)	58 [56, 96]	38 [0, 40]	0.71
(1, 4)	51 [50, 90]	39 [0, 40]	0.82
(1, 5)	45 [40, 80]	35 [0, 40]	0.84
(2, 3)	61 [56, 100]	39 [0, 44]	0.69
(2, 4)	54 [50, 94]	40 [0, 44]	0.79
(2, 5)	50 [44, 84]	34 [0, 40]	0.75
(3, 4)	62 [56, 106]	44 [0, 50]	0.75
(3, 5)	58 [56, 96]	38 [0, 40]	0.71
(4, 5)	55 [50, 90]	35 [0, 40]	0.70
all five	64 [56, 107]	30 [0, 40]	0.75

Table 4: Inter annotator agreement

4. Error analysis

In order to analyze the quality and extent of GermaNet's coverage, then, we chose to further examine those tokens for which GermaNet should provide a synset, but for which no sysnset was marked by our annotators. These are the cases in which GermaNet fails to do its job. Our goal was to quantify this failure and to assess its most likely causes.

We take it to be the case that in the ideal case GermaNet would associate an appropriate sense for all occurrences of nouns, verbs, and adjectives. Given a perfect POS tagger a perfect lemmatizer, a perfect GermaNet and a perfect human annotator, every NVA-tagged word in our corpus should be marked by the annotators with at least one synset. (Perhaps *exactly* one would be more ideal; in our study we ignored this however. We were concerned that GermaNet be rich enough, not that it be too rich.)

In practice, of course, the results are not perfect. In the following we will discuss the degree to which our results deviated from the ideal. As we saw in Table 2, the number of content words which could be assigned a synset at all by GermaNet ranges from just over 83% to just under 94%. In only about 90% of the cases was one of the synsets assigned to a word by GermaNet marked as being the correct one by our annotators.

In fact, however, a large proportion of this error was introduced not by GermaNet, but by TreeTagger, which we used to lemmatize and tag our texts for part of speech. While errors in POS tagging could lead to suboptimal performance, POS tagging errors were fairly rare in our texts (as Schmid (1994) shows the tagger employed can reach an accuracy of about 97.5%). Furthermore, the kinds of errors that would be problematic in our task (mistagging of prepositions, adverbs or articles as nouns, verbs or adjectives) are the least common type. So POS tagging did not contribute significantly to the errors. Lemmatization errors, however, contribute significantly to the error rate, since every incorrectly lemmatized word resulted directly in an error: When a word is not properly lemmatized it is impossible for the human annotator to choose the correct synset, since this synset is not an available choice, as we have looked up the wrong word in GermaNet.

In order to evaluate GermaNet, then, we needed to classify our errors, so as to determine which errors were the result of GermaNet design or coverage problems and which, like lemmatization errors, were epiphenomenal.

4.1. The error classes

For purposes of our evaluation we took any NVA tagged token in our corpus to which no GermaNet synset was assigned to be an error, and we assigned each error occurrence to one of the following error classes: **lemma, particle**, **collocation, compound**, **derivation**, **auxiliary**, and **other**. The classification of errors was carried out by a single annotator (JS) using a Java-implemented GUI-tool. Each error was assigned to exactly one of the error classes. These classes were chosen because either they were a type of error that was particularly common, or because they were a type of error that the GermaNet developers had suggested might cause problems.

The error classes are described as follows:

Lemma. As mentioned, when a word is not properly lemmatized it is impossible for the human annotator to choose the correct synset, since it is not available for choice. An example of this kind of error is when the particle *mal* in "Mal wieder hat er es getan" is lemmatized as *malen*, the verb 'to draw'.

Particle. German seperable verbs, such as *vorschlagen*, contain prefixes which significantly alter the meaning of a verb (*schlagen* – "hit"; *vorschlagen* – "propose"). These verbs should be lemmatized as a single lexeme. Unfortunately in many contexts the prefix is not concatenated with the verb, as in:

Er *schlug* einen Kompromiss *vor*.
"He proposed a compromise."

This presents difficulties for lemmatizers. Very often the lemmatizer does not link the particle verb's root and prefix leading to a wrong lemmatized form, omitting the prefix (e.g. *schlagen* instead of *vorschlagen*).

Auxiliary. The verbs *sein* and *haben* (as well as certain modals and others) are also problematic. These verbs can be used simply as syntactic operators – auxiliaries – on the one hand, or as main verb on the other. As auxiliaries, there is a sense in which they should not be sense tagged (since they are not "open class"). In this group we mark those cases in which such a verb is not tagged but is recognized as being used as an auxiliary.

Strictly, speaking both **particle** and **auxiliary** errors can be thought of as lemmatization errors of a very specific type, and cannot really be attributed to GermaNet. In contrast to these we distinguished three types of errors that can be attributed to word-formation processes:

Collocation. Many words are used in a very specific sense in combination with other words (*ins Wasser fallen* to mean "cancelled", for example). In those cases in which the word to be tagged was recognized as forming part of a collocation, it was assigned to this class. While it is arguably not the task of a lexicon to account for collocations and idioms, we were interested in assessing the degree to which these are problematic.

Compound. Compounding – the formation of a new word from two or more existing words (for example

Errors class	Corpus			
	Fiction	News 1	News 2	News 3
Lemma	12.3	5.3	13.3	10.8
Particle	5.9	0	4.4	4.6
Auxiliary	25.3	21.1	22.2	21.5
Compound	11.5	31.1	11.1	32.3
Derivation	5.2	10.5	4.4	6.1
Collocation	2.2	5.3	2.2	1.5
Other	36.8	26.3	42.2	23.1
Total errors	269	19	46	62

Table 5: Distribution of errors by class and corpus (in percent)

Montagsauto) is a productive word formation process in German (as in English). As the sense to be associated with the compound is a fairly arbitrary function of the meaning of the constituent words (cf. Fanselow 1981), it is in principle difficult to provide appropriate synsets for words formed this way.

Derivation. The generation of nouns from verbs (for example *Vorbereitung* from *vorbereiten*) and the generation of diminutive forms (for example *Hündchen* from *Hund*) are productive process in German. These are somewhat more regular and might be accounted for by a GermaNet with sophisticated morphological processing (like that suggested by Kunze (1999) for particle verbs).

Finally there are the errors that fit into none of these classes:

Other. All other forms of derivation are covered by the "other coverage" default error class. The major component of this class is simply the set of words which are simply missing form GermaNet, i.e, those that should be and could be listed, but are not.

4.2. Results of error analysis

In Table 5 we present the distribution of the different type of errors by error class in each of our small corpora. It is clear there was significant variation across the corpora as to which error classes were predominant. The variation was particularly evident in the case of **lemma** and **compound** errors. The most significant class of errors was the **auxiliary** class. These were fairly uniform, accounting for between a quarter and a fifth of all errors in each of the corpora. The surprising fact that we noted in section 3, that the newspaper corpora appear to be better handled by GermaNet than the fiction corpus, gets a simple explanation: lemmatization-related errors were more pronounced in the newspaper corpus. In fact, looking only at non lemmatization-related errors, we see that the childrens fiction is, as we might expect, less error prone than the newspaper articles.

The newspaper corpora evidenced significantly more errors that were due to the use of productive morphology. The **compound** errors were the most prominent, particularly in the newspaper corpora, although was significant variation here as well. Other **derivation** errors, however, had a relatively small share. **Collocations** though they appear in most corpora, also play a minor role.

In Table 6 the distribution of errors by POS is displayed. It is obvious why **particle** and **auxiliary** errors would be limited to verbs, as they are verb-specific error types. More interesting is the fact that errors that could be attributed to productive morphology were essentially limited to nouns and adjectives. Essentially only nouns were involved in **derivation** errors, while for adjectives (other than **lemma** errors) essentially only **compound** errors were present

Error class	Part of Speech		
	Verb	Noun	Adjective
Lemma	3.5	23.7	13.9
Particle	13.2	0	1.3
Auxiliary	58.8	0	1.3
Compound	0	31.6	8.9
Derivation	1.8	17.1	1.3
Collocation	3.5	2.6	0
Other	19.3	25	73.4
Total errors	114	76	79

Table 6: Distributions of errors in Fiction corpus by class and part of speech (in percent)

5. Conclusion

Our results were very encouraging. On average 92% of the words which were tagged as verbs, nouns or adjectives were provided with at least one sense by GermaNet, and more than 83% were provided with at least one sense that was judged as the correct sense by our annotators. One of the major sources of error was, in fact, external to GermaNet: On average 15% of the content words were incorrectly lemmatized, leading to incorrect lookup. Additionally we found that many of the potential sources of coverage failure suggested by Hamp & Feldweg (1997) were indeed evident: productive morphological processes such as derivation and compounding as well as collocative uses of words accounted for a nearly 25% of the errors we noted. Particle verbs also presented problems for our annotators, as in some cases the verb was not lemmatized with its separable prefix. Clearly a more sophisticated lemmatizer could have eliminated some of these errors. In other cases productive combinations with main verbs gave rise to forms which were not covered by GermaNet. For nouns a predominant source of errors was the existence of a large number of nouns that were clearly derived via productive rules of derivation from verbs. These could, presumably, be looked up on the verbal hierarchy. Words formed via compounds were also a significant source of noun and adjective errors. Words that could not be properly tagged because they were used as part of a collocation accounted for only minority of the errors overall, however.

We also found that the effectiveness of GermaNet as used for the word-sense disambiguation task as well as the kinds of errors that were found was highly dependent on the variety of text to be disambiguated. This suggests that it is crucial that in WordNet evaluation both domain and text type be standardized, and that a variety of types be used.

Finally, many of the types of errors that we found were clearly German-language specific. This finding suggests that language-specific issues are quite important when evaluating the effectiveness of a particular WordNet and that simple cross-WordNet evaluation will likely lead to a incorrect evaluation of the value or coverage of a particular WordNet. With respect to GermaNet, our results suggest that sense-tagging using GermaNet, while quite good as it is, could be significantly improved by integrating additional morphological processing into the tagger. In particular, methods for dealing with compound words and derived words could lead to significant improvements.

Abstract

In this contribution we present an analysis of selected WN 1.5 glosses and dictionary definitions from other resources -- we examined what is the internal (semantic) organization of the glosses and dictionary definitions, i.e. how reliably and systematically they follow the standard principles of building dictionary definitions. The results following from the presented analysis should be applied in building glosses within Czech WordNet and hopefully they can serve as an exercise for other partners within Balkanet Project

1. Introduction

In this contribution we present an analysis of selected WN 1.5 glosses and dictionary definitions from other resources -- we examined what is the internal (semantic) organization of the glosses and dictionary definitions, i.e. how reliably and systematically they follow the standard principles of building dictionary definitions. The results following from the presented analysis should be applied in building glosses within Czech WordNet and hopefully they can serve as an exercise for other partners within Balkanet Project (2001).

When working on EuroWordNet (Vossen,1999) and now on Balkanet (2001) one has to have a look at the glosses in WN 1.5 and examine them quite closely since so far they have been regularly used as the references to the individual synsets or, in other words, as the descriptions of their senses. It is no secret that there are many reservations with regard to the glosses, especially to their properties from the lexicographical point of view. The main objections that can be heard are that the glosses are not consistent enough, that quite often they are nothing more than just examples and sometimes they are completely missing .

In writing dictionary definitions the following techniques are regarded as the standard ones:

1. definitions using *genus proximum* and the *distinguishers* (typically for nouns),
2. definitions using semantic components or features (verbs, e. g. **hurt***:*6 = cause pain),
3. definitions based on the relation of *troponymy* (*laugh – guffaw*),
4. definitions using synonymical explanations (typical for adjectives, e. g. *clever – smart*),
5. definitions based on collocational determination of the sense (e. g. *a bad student*, *bad debt*).
6. definitions based on the descriptions of events or situations (see e.g. definition of **bend**:1 (in Cobuild95, p.144) – *when you* **bend** *you move top part of your body downwards and forwards*,
7. definitions exploiting various kinds of *ad hoc* descriptions or explanations or just mere examples as e.g .**bring**:2 in WordNet 1.5 – *bring or fetch; "Could you bring over the wine?"*

2. Noun Glosses in WN 1.5

A large group of nouns denote the particular physical objects such as *table:1*, *chair:2*, etc. Thus we selected few "furniture" expressions and examined their glosses. It can be said that they "behave" in a relatively standard way, typically, these glosses follow the classical dictionary definition pattern, i.e. first part of the gloss consists of *genus proximum* (GP) and the second one represents the *distinguishers* (d1, d2, …, dn). Some slight inconsistencies can be observed: while **table***:*2 has as its genus proximum *a piece of furniture* (and other hyponyms of it as well), **chair***:*2 has as its GP *a seat for one person* (**seat**:2) and only then **seat**:2 displays as its GP *a piece of furniture.* Thus a question may be asked why the principle of GP is not followed strictly here. The good news perhaps is that the GP expressions in the whole WordNet can be checked and in our view corrected semi-automatically using the corresponding H/H trees. The same can hardly be applied to the distinguishers but we suggest to formalize this part of the gloss giving it a rigid structure in the form GP + *d1, d2, ..., dn.* More examples from WN 1.5 can be given, e.g.: **knife**:1 *cutting instrument + d1, d2,...* but in the corresponding H/H tree we find as the next upper node **edge tool**:1 – *any tool with sharp cutting edge*. The conclusion is obvious: we should try to avoid these inconsistencies in building Czech glosses and it can be seen that they can be checked semi-automatically as well. We examined also some other nouns like **digital computer**:1 or **house**:1 and it can be concluded that the situation with respect to their glosses is more or less the same.

The next point we are interested in is the semantic organization of the noun glosses or dictionary definitions in general, and how it is related to their syntactic structures. We can observe here quite a good parallelism between GP and the first noun group in the dictionary definition.

If we have look at the distinguishers it can be seen that they are expressed in several ways: as noun groups, relative sentences, adjectival phrases with complements or as prepositional groups. The closer examination, however, shows that the picture is more complicated and the

no of entries ("sentences" processed)	5935	100 %	
not applied	1207	20.3 %	
applied	4728	79.7 %	
from this:			
def1:	548	11.6 %	entry = one_word_synonym
def2:	2987	63.2 %	entry = (Ng | Pg)+
def3:	877	18.5 %	entry = (Ng | Pg)+ Ap (Ng | Pg)+
def4:	92	2.0 %	entry = Ng Sr
def5:	5	0.1 %	combination of def3 and def4
def6:	201	4.2 %	[kdo|co|někdo|něco] .*
def7:	17	0.4 %	[schopnost|neschopnost] .*

Table 1. Frequencies of the different definition types

corresponding surface syntactic structures are much richer (see below).

Thus it is our opinion that we should try to parse the dictionary definitions in order to discover the inventory of the syntactic structures that may correspond to the GP + d1, d2, ... dn scheme. For this purpose we again selected several typical "furniture"examples from SSJČ (1960) together with their English equivalents from NODE (1998). Angle brackets in Czech descriptions mark out the particular groups (and the grammatical cases in which they may occur).

stůl: <*kus*>$_{ng1}$ <*nábytku*>$_{ng2}$ <*tvořený*>$_{ap}$ <(*vodorovnou*) *deskou*>$_{ng7}$ <*na nohách*>$_{png6}$ <*nebo*>$_{conj}$ <*na podstavci*>$_{png6}$

table: ***a piece of furniture*** *with a flat top and one or more legs, providing a level surface on which objects may be placed, and which can be used for such purpose as eating, writing, working or playing games*

židle: <*přenosný kus*>$_{ng1}$ <*nábytku*>$_{ng2}$ <(*s opěradlem*)>$_{ng7}$ <*k sezení*>$_{png3}$ <*pro jednu osobu*>$_{png4}$

chair: ***a separate seat*** *for one person, typically with a back and four legs*

křeslo: <*pohodlné sedadlo*>$_{ng1}$ <*s opěradly*>$_{ng7}$

armchair: ***a large, comfortable chair*** *with side supports for a person's arm*

skříň: <*vyšší kus*>$_{ng1}$ <*nábytku*>$_{ng2}$ <*na ukládání různých předmětů*>$_{png4}$ <*nebo*>$_{conj}$ <*na věšení šatstva*>$_{png4}$

cupboard: ***a piece of furniture*** *with a door and usually shelves, used for storage*

blbec, **blb**: <*velký hlupák*>$_{ng1}$, <*pitomec*>$_{ng1}$, <*idiot*>$_{ng1}$

idiot: *a stupid* ***person***

student: <*posluchač*>$_{ng1}$ <*vysoké školy*>$_{ng2}$ <*nebo*>$_{conj}$ <*žák*>$_{ng1}$ <*střední školy*>$_{ng2}$

student: ***a person*** *who is studying at a university or other place of higher education*}

2.1. Syntactic structures of the dictionary definitions

The basic Table 1 has been obtained from the sample containing 10 000 noun dictionary definitions from SSJČ and show the main types of the syntactic patterns as they can be found within the noun dictionary definitions in SSJČ.

It can be said the definitions of the entries for whose no structure has been found usually can be intuitively classified as belonging to some of the groups 1-5. However, they may display very complicated structures (e.g. very complicated attributive noun groups), that prevent the parser (the particular rules in it) from recognizing them. There are only few entries that do not belong into any of the introduced groups/categories, for example *názor*, *že ...* (*the opinion that …*)

2.2. Czech WordNet

What also can be done is to check semi-automatically the heads of these noun groups against the corresponding nouns in Czech WordNet and to see how regularly they contain the hyperonymical expressions (such as **furniture** in our example group of selected furniture nouns) – this can be done by comparing them with the corresponding H/H trees in WordNet.

If we take the parsed syntactic structures of the processed dictionary definitions and extract their head noun groups representing (according to our parser) the GP pattern we obtain a list of expressions that are hyperonyms of the headwords in the dictionary definitions. The first part of this list is given below and it contains 30 most frequent (Czech) hyperonyms (sorted according to their frequency) from our sample of dictionary definitions. To confirm that they are hyperonyms we compared them with the corresponding expressions from Czech and English WordNet (the first number indicates the frequency in the Czech sample, then there is Czech literal with its sense number in Czech WordNet and its English equivalent with its respective sense number as well. The results of the comparison show that all the expressions extracted from the dictionary definitions are hyperonymical, thus in this way confirming our starting assumption that GP patterns can be processed and obtained from the dictionary definitions automatically. Then it is also possible to check for their consistency. The next goal is to try to recognize the distinguishers at least in a semi-automatic way though we are aware that this task is not going to be as easy as the former one.

173: kdo (who)

3. Verb Glosses in WN 1.5

At the first glance it can be observed that the verb glosses are less consistent and regular than noun ones. Also some glosses are missing more frequently (e.g. *write:*7). We have selected verb *to kill* and its hyponyms to see how reliable the glosses are and how they are built. If we take *kill:5 cause to die* we can immediately see that GP + d1,…, dn principle does not apply here. This is generally due to the fact that the semantic nature of verbs as the relational elements is different from the nouns and that is why they require other types of definitions.

With *kill:5* the analysis to the simpler semantic components is used (type 2 above), however the problem is that the respective semantic components are used rather spontaneously, they are not defined anywhere and they are in no way related to the Top Ontology which certainly represents a collection of the specific semantic components or features. It is very instructive to examine some of the hyponyms of *kill:5* and their glosses:

behead:1 cut the head of sb (synonymical explanation)

drown:3 kill by submerging in water (troponymy relation)

poison:5 no gloss at all

shoot:16 kill by firing a missile (troponymy relation)

stone:7 "adulterers should be stoned according to the Koran" (just the example)

strangle:1 squeeze the throat of sb (synonymical explanation)

sabre: in the sense of killing not found in BNC

overlay: in the sense of killing not found in BNC

The picture we can see is rather confusing: in the cases of *drown:3* and *shoot:16* the relation of troponymy is used as the defining principle in the gloss (different manners of killing), *behead:1* and *strangle1* are defined by synonymical explanations, however *strangle:1* is not defined correctly, to squeeze the throat of a person is not enough to kill him or her, thus the gloss is defective. Moreover, for *stone:1* the example is offered instead of the definition, though *to kill by stoning* certainly could have been used. To complete this certainly not consistent view we can only add that *poison:5* has no gloss assigned at all in WN 1.5 though again *kill by using poison* offers itself as an obvious solution. It may be interesting to note that *sabre*:4 given in WordNet 1.5 as a hyponym of *kill*:5 does not occur in British National Corpus at all.

3.1. The Possible Solutions for Verbs

One of the techniques that has to be considered with regard to the verbs is an appropriate semantic classification of verbs yielding the semantic classes of verbs. The information about the semantic class a verb belongs to can become a part of the gloss/definition and can make it more systematic. Though the criteria for establishing the semantic classes may be in a certain degree arbitrary on the other hand they may be compared with Genus Proximum principle that seem to work well for nouns.

Levin's (Levin, 1993) semantic classification of English verbs appears as an interesting solution – we have tried to develop a similar semantic classification of Czech verbs that can be applied here.

4. Adjective (and Adverb) Glosses in WN 1.5

The selected examples of the adjective synsets for *good* can well demonstrate the point.

good:8, dear:2 with or in a close relationship: "a good friend"

good:10 "good taste" (an example only)

good:12 resulting favorably: "it is a good thing that I wasn't there"

good:13, unspoiled:2 "the meat is still good" (an example only)

good:14 not forged: "a good dollar bill"

good:15 having desirable or positive qualities, esp. those suitable for a thing specified: "good news from the hospital", "a good joke", "a good secretary"

good:16 morally admirable

good:23, just:6 of moral excellence: "a genuinely good person"

good:18 appealing to the mind: "good music", "a serious book"

good:19 agreeable or pleasant: "good manners"

good:25, secure:12 financially sound: "a good investment"

good:26 in excellent condition: "good teeth"

good:27 well above average in performance: "a good student"

good:29, lucky:4 "it is good that nobody saw you" (an example only)

in good taste:1 no gloss, syntactically this case can be hardly classified as an adjective.

It can be seen that for adjective *good* the definitions of the type 4, 5, 6 are used. The most frequently used are the synonymical explanations (type 4 definitions) combined with the examples of typical collocations (type 6 definitions). Only *good:16* does not include a collocational example.

The presented examples also clearly demonstrate that many senses of *good* are very close to each other and it is not easy to discriminate them. It can be observed that *good:15* seems to cover/represent the main sense of *good* and that *good:18* or *:26* or *:*27 just stress some rather arbitrarily selected semantic features such as *in excellent condition* which can be certainly classified under *a positive quality*. The adduced examples convincingly show how the senses of *good* are split into the fine grained senses but at the same time the question has to be asked what can we gain by splitting senses in this way (quite typical for WN 1.5)? The hope is that the split senses can be integrated into the larger groups and in this way the number of senses can be reasonably reduced to obtain simpler and better applicable collection of the senses. In our view the appropriate sets of the semantic features have to be considered in combination with the collocational examples – in this way the operational classification procedures (relying on corpora) for reasonably large group of adjectives and adverbs can be obtained.

The obvious conclusion also is that it is necessary to pay the more detailed attention to the collocational examples (type 6 definitions, if they can be taken as such), to explore their behaviour in the corpora and on this ground to design the techniques of their semiautomatic handling.

5. The Conclusions for Standardization

The above analysis leads us to the following steps in the building glosses within Czech WordNet (with the hope that they can appear useful in the development of other WordNets as well):

- to use the different types of definitions for the different parts of speech in a systematic way, i.e.. GP + d1, d2,…, dn mostly for nouns, semantic components and troponymy relations for verbs and synonymical explanations combined with collocational examples for adjectives,
- to use the semantic classification of Czech verbs and integrate it appropriately into the glosses,
- to examine in a more detailed way the GP + d1, d2,…, dn definitions for nouns and to check whether the distinguishers can be inherited systematically within H/H trees,
- to examine whether the distinguishers can also capture the relation of meronymy/holonymy and in the positive case to find out how frequent it is,
- to explore systematically the collocational examples using corpus data and integrate them systematically into the adjective glosses,
- the ultimate goal of the mentioned steps is to obtain the glosses for the particular synsets that would be as systematic, formal and consistent as possible.

We have tried to show how the indicated solutions may work for the selected collections of Czech synsets and in this way they may help to standardize the glosses used in Czech WordNet..

Standardizing Wordnets in a Web-compliant Format: The Case of GermaNet

Claudia Kunze, Lothar Lemnitzer

Seminar für Sprachwissenschaft
Universität Tübingen
Wilhelmstr. 113, 72074 Tübingen, Germany
{kunze,lothar}@sfs.uni-tuebingen.de

Abstract

Following the success of the Princeton WordNet, a range of wordnet initiatives have been launched, either monolingual or multilingual. The variety of wordnets which have a common core architecture but also their language-specific peculiarities calls for a common standard to enhance interoperability, to merge of different lexical resources and to define a common application programme interfaces. At the same time, the drive for the "semantic web" and the resp. need for ontologies calls for XML- and RDF-binding of at least the common core architecture of wordnets. The GermaNet group therefore wishes to contribute to the standardization of wordnet architectures by presenting the data model of GermaNet, an XML binding of this data model and some proposals for a common terminology.

1. Introduction

Have you ever tried to use your razor or your hair dryer in another country than that where you bought this device? Even in Europe you might be caught in a situation where the plug of your device and the socket in your hotel room are incompatible. You might end up buying an expensive adapter at the reception desk of your hotel. Missing standards can be a burden or even an obstacle to further development.

Avoiding a waste of time and money is one incentive of undergoing the effort of negotiating a standard, which in itself can be a time-consuming task.

The situation of the European traveller might be comparable to that of a language engineer who wants to:

- Use wordnets of various languages in a multilingual application environment
- Adapt an application which uses a wordnet in one language to another language and wants to adapt an available wordnet for that language, too
- Couple a dictionary management or visualization tool for a wordnet in one language with the wordnet of his / her language (see Pavelek and Pala, this volume)

It is therefore in our opinion worth the effort to discuss the following issues. In what manner are the WordNet architecture, the EuroWordNet architecture and the architecture of any individual wordnet are related? Is there a common core architecture? Do we really mean the same if we use the same concepts and terms to describe our resources? Do we perhaps refer to the same concepts though we are using different terms?

The GermaNet development group wants to contribute to this discussion. First of all, we describe the features which GermaNets shares with other wordnets, in particular the Princeton WordNet (section 2). We will present the data model of GermaNet in an application neutral graphical form, using the Entity Relationship model (section 3), as well s an XML binding of the GermaNet data model (section 4). In section 5 we will show a way of integrating the Interlingual Index of the EuroWordNet architecture into the GermaNet architecture. We will explicate the terminology we use and relate it to other wordnet terminologies, the Princeton WordNet and the Czech word net in particular (section 6). Finally, we will raise compatibility issues and suggest solutions to at least some of them (section 7).

The task we are facing is not exciting nor is it easy. Anyway, our motivation to solve it should be clear to all developers of wordnets: Think of the plug and the socket!

2. GermaNet: its standard core and its peculiarities

2.1. General Remarks

The fundamental lack of electronic lexical-semantic resources for German (see Hamp & Feldweg (1997)) was the major motivation for constructing GermaNet a few years ago. Therefore, a first project (SLD) created an on-line thesaurus covering the German basic vocabulary. GermaNet adopted the design principles and the database technology from the Princeton WordNet. However, GermaNet includes principle-based modifications on the constructional and content-oriented level which we will describe later on.

GermaNet currently covers some 40,000 synsets with more than 60,000 word meanings, modelling nouns, verbs, adjectives and adverbs (see Kunze (2001)). Within the EuroWordNet project, GermaNet was integrated into the polylingual EuroWordNet database (see Vossen (1999), Wagner and Kunze (1999)). We followed the merge approach, i.e., a wordnet is built independently from WordNet and the synsets are linked to the Interlingual Index (ILI) by creating the appropriate relations. The merge approach preserves language-specific patterns with differing hierarchical structures in comparison to the WordNet structure.

2.2. Major differences to WordNet

In spite of its general similarity with and compatibility to WordNet, we can state the following differences for GermaNet:

- we are using **artificial**, i.e. non-lexicalised **concepts**, which have been introduced to fill

- lexical gaps, to balance the taxonomical structure more adequately and to avoid unjustified co-hyponymy;
- in GermaNet, **adjectives** are ordered hierarchically as opposed to Princeton's grouping by the satellite approach;
- we pursued a uniform treatment of **meronymy** within GermaNet, whereas WordNet has established three different pointers for *Part, Member* and *Substance*;
- within GermaNet, the **causation relation** can be encoded between all parts of speech, not only between verbs and adjectives;
- due to emphasizing the syntax-semantics-interface for disambiguation tasks we accounted for over one hundred verbal **subcategorisation frames**. These frames are more elaborate than the WordNet frames, and, furthermore, for each verb reading we provide a typical **example**.

These differences and their technical impact on compatibility for the XML conversion are outlined in more detail below.

3. The data model of GermaNet

We visualize the data structure by graphic means using the Entity-Relationship Model (Chen, 1976).

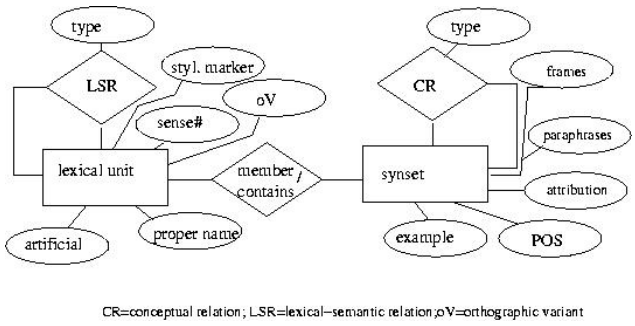

Fig. 1: Entity-Relationship graph of the GermaNet data model

The graph in figure 1depicts:

- the **objects**, synsets and lexical units, which are represented as *rectangles*,
- the **attributes** of these objects, represented as *circles*,
- the **relations**, represented as *diamonds*. In GermaNet, like in WordNet, we distinguish:
  - **conceptual** relations (CR) which hold between instances of the synset object (e.g. hyperonymy) from
  - **lexical-semantic** relations (LSR) which hold between instances of the lexical unit object (e.g. antonymy).

From an Entity-Relationship model, one can formally derive the conceptual structure of a relational database in a normalized form (Seesing, 1993). One can also, however not as unambiguously, derive a DTD or schema for an encoding of the data which is in line with the XML standard.

4. An XML Binding of the Data Model

We have converted the GermaNet data into a set of XML-encoded documents which conform to two *Document type definitions* (DTDs). One DTD represents the objects (synsets and lexical units) and their attributes, the other represents the relations between these objects.

In the following, we will describe both DTDs. The first DTD represents the data model of the objects and their attributes. It is recorded completely in fig. 2.

```

Fig 2: The GermaNet objects DTD

Description: Documents which conform to this DTD contain a set of *synsets*. Every *synset* consists of at least one *lexical unit*. *Paraphrases* may be given to characterize the meaning of the synset and an *attribution* as well as *examples* may be added to illustrate the use of its member lexical units. For verb synsets, subcategorization *frames* are given. The individual lexical units are characterized by a set of attributes, e.g. *sense* number and stylistic marker (*StilMarkierung*). A concept can be represented by a string which does not correspond to a lexical unit in the German vocabulary. Such a unit will be marked as *artificial*. The content model of most atomic elements is set to *#PCDATA*, therefore minimizing data type restrictions. It is up to the lexicographers to fill the elements with appropriate data.

Fig. 3: The GermaNet relations DTD

Description: Documents which conform to this DTD contain a set of relations which are either conceptual or lexical relations. These relations are characterized by their type (attribute: name) and they are marked as either symmetrical or directed (attribute: dir). They are realized as links according to the XLink specification: a link consists of two nodes (locators, specified through the IDs of the synsets or lexical units) and one or two arcs, depending on whether the relation is directed or symmetrical. The attributes of the 'arc' element specifies the processual behaviour whenever a link is traversed.

5. Extensions of the Data Model and DTD

5.1. Cross-lingual extension with EuroWordNet

Within a European project, the wordnets of several languages, including German, have been integrated into the polylingual architecture of the EuroWordNet database. This has been achieved by linking the language-specific concepts to the Interlingual Index (ILI) of EuroWordNet (Vossen, 1999). The ILI has the following features:

- It is an unordered list of synsets, so-called ILI-records;
- Each ILI-record has a unique identifier, consisting of a categorial marker and a sense ID;
- The ILI-records have basically been derived from the Princeton WordNet; some new ones have evolved from the project;
- The ILI does not account for structural relations between the records. The structural relations are provided by the language-specific wordnets being linked to the ILI.

An example of the ILI and its satellites is shown in fig. 4

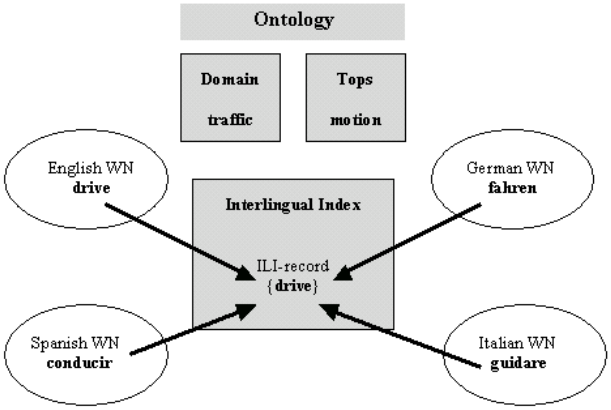

Fig 4: Partial architecture of the EuroWordNet database

From fig. 6, one can derive that there is no direct connection between the wordnets of the various languages. Mappings between language-specific wordnets are mediated by the Interlingual Index.

The following inventory of equivalence relations for connecting synsets of an individual wordnet to the ILI is provided by the EWN specification:

- EQ_SYNONYM
- EQ_NEAR_SYNONYM
- EQ_HAS_HYPERONYM
- EQ_HAS_HYPONYM
- EQ_INVOLVED
- EQ_ROLE
- EQ_IS_CAUSED_BY
- EQ_CAUSES
- EQ_HAS_HOLONYM
- EQ_HAS_MERONYM
- EQ_HAS_SUBEVENT
- EQ_IS_SUBEVENT OF
- EQ_BE_IN STATE
- EQ_IS_STATE_OF

Furthermore, the relations between a wordnet synset and an ILI element are directed. The wordnet synset is the source and the ILI element is the target of this link.

Given these characteristics, we extend the GermaNet relations DTD in the following way:

- Introduce an additional element for this new class of links ("equivalence link")
- Characterize the link as directed
- Define an attribute with the closed set of types which characterize ILI links in the EuroWordNet architecture
- Define two locators for the link, one of which must have an identifier designating a GermaNet synset, the other an identifier designating an ILI element
- Define an arc between these two locators and specify the application semantics of the link during traversal of this arc.

The result of this procedure is shown in fig. 5.

```
<!-- DTD for GermaNet relation files – extended,
interlingual version.-->
....
<!ELEMENT relations (lex_rel | con_rel | eq_rel)+>
…
<!ELEMENT eq_rel (locator+, arc+)>
<!ATTLIST eq_rel name (EQ_SYNONYM|
EQ_NEAR_SYNONYM| EQ_HAS_HYPERONYM|
EQ_HAS_HYPONYM| EQ_INVOLVED| EQ_ROLE|
EQ_IS_CAUSED_BY| EQ_CAUSES|
EQ_HAS_HOLONYM| EQ_HAS_MERONYM|
EQ_HAS_SUBEVENT| EQ_IS_SUBEVENT OF|
EQ_BE_IN STATE| EQ_IS_STATE_OF) #REQUIRED
                dir (one | both) #FIXED 'one'
                xmlns:xlink CDATA #FIXED
'http://www.w3.org/1999/xlink'
                 xlink:type (extended) #FIXED 'extended'>
…..
```

Fig. 5: Extended interlingual relations DTD

A core of GermaNet synsets has been linked to the Interlingual Index (ILI). In the process of linking these synsets have got a separate ID. We could have used the IDs as a key to those synsets. The fact however that only one third of the synsets is linked to the ILI led us to the decision to employ our own scheme of IDs, which are processed on conversion of the data. We will provide a mapping from ILI link IDs to the IDs generated by our programs.

6. Terminology

In this section we want to compare the terminology we use with those employed by other wordnet development groups. The documents we refer to are the description of the Princeton WordNet (Miller, Fellbaum) and the description of the Czech WordNet (Pavelek and Pala, this volume).

Uncontroversially the *synset* is the central object of every wordnet. A synset consists of one or many members. In the RDF binding of WordNet these members are called *word forms*. Some wordnet development groups call them *synonyms*. We decided to use neither because:

- *Word form* denotes a concrete linguistic entity, in many times inflected and found in texts, whereas the members of synsets are lexical abstractions which are represented by one form, the so called base form.
- *Synonym* is a genuinly relational term. A lexical sign can be a synonym only in relation to some other lexical sign.

In contrast, we use the tem *lexical unit* to establish a distinct kind of object which has its own attribute-value pairs. Furthermore, the term is also used with traditionally organized lexical resources and can therefore facilitate a merge of different kinds of lexical resources.

Lexical units are organized in synsets by the central relation of *synonymy*. It is however not clear to us wether all groups employ the same definition of *synonymy* and the same set of operational tests. On the other hand, the linking of synsets with a narrow definition of *synonymy* to synsets with a wider definition of it – in interlingual relations – might cause severe problems in multi-lingual application environments. We believe that the reliability of equivalence relations between synsets is worth testing.

Lexical units are represented by "literal strings" (we are using the term *orthographical form*) and sense numbers.

Part of speech plays a central role as a feature of synsets in that it divides the set of concepts into subsets. Most wordnets comprise nouns, verbs and adjectives. There is a strong tendency therefore to stick to these parts of speech even if they do not prove adequate for all languages (see Kahusk, this volume, for a more detailed discussion).

Most wordnets provide a textual description of synsets. In WordNet and in the Czech word net they are called *glosses*, whereas we are using the term *paraphrase.* The WordNet RDF *glossary* however seems to comprise paraphrases and examples, which are two different data types in GermaNet. This point needs clarification. We are not against using the term *gloss* if it is well defined.

Again there is little difference in the kinds and types of relations within wordnets. There are *conceptual relations* between synsets and *lexical-semantic relations* between lexical units. Some wordnet development groups however (see Pavalek and Pala, this volume; Vider, this volume) use the tem *semantic relations* instead of *conceptual relations.* The Czech wordnet developers are using *literal relations* to signify what we call *lexical-semantic relations.*

In addition, EuroWordNet 1 defined a set of interlingual relations between synsets on which at least the members in this project phase agreed. Furthermore this project provided a proposal for a set of intralingual relations which at least some of the new members of the wordnet society in Europe have taken over.

The Estonian wordnet applies a much richer set of semantic relations than e.g. WordNet(see Vider et al., 1999). Furthermore the developers are in need of a set of subtypes for the EWN relation *derived / has_derived / derived_from.*

Furthermore there are differences between the architecture of WordNet (at least the RDF binding), GermaNet and the Czech wordnet.

In WordNet (the RDF version), synsets, glosses and relations (or to be precise, the hyperonymy relation) are organized in different files. In GermaNet (the XML version) the synsets and synset related features are organized separately from the relations, which are called *links* in orientation to the Xlink standard. In the Czech wordnet synsets and relations are organized in one data structure. Glosses are stored in a different file for the simple reason that the English WordNet glosses are used until Czech glosses will be generated (see Pavelek and Pala, this volume). This however, seems to be a minor, merely technical point. At least, GermaNet offers a data structure comparable to the Czech wordnet.

There are only a few if any information types other than the the ones mentioned which are shared by a larger number of wordnets. Subcategorization frames seems to be one candidate. However it might be even more difficult to come to an agreement about the status and the information provided by this data type. This and other information should be treated as particular to any individual wordnet.

7. Compatibility issues

In this section, we will raise several compatibility issues and show how they can be solved within the XML framework We will elaborate on six types of structural differences between WordNet and GermaNet:

1. Objects or relations might have different extensions in both nets, as is the case with the CAUSE relation. In WordNet, this relation holds exclusively between verbs and adjectives. In GermaNet, synsets of all word classes are in the domain of this relation. True compatibility would require a finer granularity of the CAUSE relation in GermaNet. This could be realised by adding an attribute to it. The values of this attribute would lead to at least two subsets of items: one which is extensionally identical with the WordNet CAUSE relation and one which characterises the GermaNet-specific extension.
2. The granularity of a relation differs. For example, WordNet divides the generic part-whole relation into three sub-relations: part (e.g. *arm,body*), member (e.g. *director, staff*), substance (e.g. *glass, glass plate*). Other values might be added to this list. GermaNet, in contrast, uniformly applies the generic relation. We recommend for WordNet or any other wordnet which applies this architecture to add an attribute to a truly generic part-whole-relation which divides the instances into three classes. In GermaNet, this attribute might get a value ANY, until a more fine-grained specification is implemented.
3. There are a few attributes specific to GermaNet, e.g. *StilMarkierung* (=stylistic marker) as an attribute of lexical units. For instance, the German concept *schlafen* (=sleep) has *ratzen*s, pennen*s, knacken*s, pofen*s* as hyponyms which are stylistically marked. These attributes can be INCLUDED in GermaNet and EXCLUDED elsewhere. The same holds for language-specific features of other word nets, e.g. features like *katharevousa* and *demotiki* in Greek.
4. An attribute which is equivalent in both wordnets specifies a different set of values. This holds for the *verb frame* attribute. The German verb frames which are implemented in GermaNet are a closed class. For type checking, it could have been more elegant to define an attribute with a fixed set of values. For compatibility reasons, however, we voted for an element group "frames" with frames as its elements and #PCDATA as data type
5. The adjective domain in GermaNet differs fundamentally from that in WordNet. The domain is ordered hierarchically in GermaNet, whereas WordNet applies an associative similarity relation which groups adjectives in equivalence classes. At present, we do not see any easy solution which would preserve compatibility in this case.

8. Conclusion

We presented the GermaNet data model and an XML binding for it in order to contribute to the difficult process of establishing a standard for at least the core architecture of wordnets. On the way to a standard both conceptual and terminological issues arise. With respect to visualization tools and the semantic web we decided to choose XML in general, and two DTDs in particular, to present our view of the GermaNet architecture.

9. Acknowledgments

The work we report here is in part the outcome of some student projects. We would therefore like to thank Iris Vogel (Heidelberg) and Holger Wunsch (Tübingen) for their valuable contributions. Research on GermaNet was funded by the Land Baden-Württemberg.

WordNet Standardization from a Practical Point of View

Abstract

This article deals with standardization of WordNet data in practice. The format of WordNet databases mentioned here comes as a result of connection with a tool VisDic which enables browsing and editing electronic readable dictionaries. Later in the article, a possibility of embedding WordNet in a common dictionary using this format is described. Finally, a short overview of VisDic tool is presented.

1. Motivation

When we thought about the improvements of WordNet databases we knew that it would be necessary to make a tool which easily enables editing synsets, their relations and links to other wordnets. There has been a tool which met the requirements - Polaris (Louw, 1998). But Polaris was a good WordNet editor just at a first glance. It displayed many functions, but unfortunately also several serious disadvantages: It was a closed project, it was aimed to WordNet databases only and it used its own format for representation of synsets – Import/Export format (Louw, 1998).

What is needed is a program that would enable users to search also in other databases and sources like monolingual and bilingual dictionaries, dictionaries of synonyms or corpora. Thus we needed to find a format for description of possibly any type of lexical resources. The XML format fits perfectly for these purposes. In the next section, we describe the details of this format and motives that led us to the design mentioned below.

2. Format of WordNet Data

A representation of WordNet data comes from the idea that the WordNet database is a dictionary consisting of entries which correspond to the individual meanings. The meaning is described by a set of words. A meaning can also have a gloss consisting of a free text definition of the meaning. The meaning is further derived from synset relations connecting them. There are two types of synset relations (Miller 1993, Vossen 1999):

Internal Language Relations that connect synsets in the range of one language, e.g. hyperonymy, hyponymy, meronymy, holonymy relations.

External Relations which connect synsets among more languages, e.g. EQ_SYNONYM, EQ_HYPERONYM, EQ_HYPONYM.

At this point, it is necessary to make clear how to represent the relations effectively in the computer. The most effective way is to assign a key to each synset which uniquely identifies it. Then the synset can be easily referred by others just by specifying its key. But in WordNet, there already is a value which can be understood as a key, particularly, it is the Interlingual Index (ILI). Then, all relations can be represented just by their names and ILI of the target synset. Moreover, ILI immediately defines the EQ_SYNONYM relation.

The format is further extended by an information about the part of speech of each synset. The next extension divides words in the synset to a literal part and sense number part. The reason lies in the fact, that about 22% of words (e.g. *page*) have more meanings and then it is useful to distinguish them by a sense number.

Fig 1. shows the selected parts of the just described synset representation (VisDic definition). Each row contains a specific information about a synset represented by a tag. The first column contains a level of the tag in a structure. Every tag belonging to a specific level N can be understood as a part of the nearest upper tag having a level N-1. The second column contains a name of a tag. The third column contains its minimal number of repeating in a structure and the fourth column its maximal number of repeating in a structure (–1 means infinity). The fifth column contains the following information about the type of a tag:

N – the tag contains a normal text value

K – the tag contains a key value uniquely identifying the synset, this key can be used by all L, R, and E tags whose definitions follow

L – the tag contains a link to another synset, it is representing a semantic relation

R – is similar to L, but it is not necessary to store the tag, because it can be reversibly inferred by a tag stored in the sixth column

E – the tag contains an information stored in another dictionary, a name of an external tag is contained in the sixth column and a name of a dictionary in the seventh column.

Fig. 2 shows the corresponding DTD. At the first sight you can see the difference between these two descriptions. VisDic definition does not contain any information about attributes. Therefore, all tags are understood as elements from a DTD point of view. On the other side it is not crucial to specify which information should be understood as an attribute and which as an element, because all elements which have not any children should be considered as attributes from a low level processing. VisDic definition can be thus understood as a description of XML which comes from a binary representation of a database, it exactly describes a tree structure of XML, while DTD defines more data types and is more readable for humans. The difference between VisDic definition and DTD is comparable to a difference between C and Prolog programming languages.

VisDic tool that will be described later uses the simplified VisDic definition of an XML database.

Fig 2. DTD of WordNet Database (selected tags)

3. Advantages of VisDic definition

Looking at Fig. 3 we can see the example of two synsets stored in a typical database: {psychological feature:1} (P) and {cognition:1, knowledge:1} (C). Notice the following facts:

HYPERONYM tag of C contains exactly the same ILI value (*00012517-n*) as is present in ILI tag of P. This implies, that P is a hyperonym of C. A searching of the hyperonym is reduced just to a looking up a single value *00012517-n*, which **reduces the time for searching**.

There is no HYPONYM tag. An information that C is a hyponym of P is already present in the fact, that P is a hyperonym of C. Searching for all hyponyms of P is then converted to looking up all synsets having their HYPERONYM value the same as ILI value of P. In most cases, the synset has only one hyperonym, but it can have tens of hyponyms. Then, using reversible tags as HYPONYM **reduces the size of a database**.

If we look at Fig. 1, we can see that the gloss is present in the external file called *wn/ili/wn_ili*. There is a good reason for that. There are wordnets that do not have their own glosses at the time. Until these glosses will be added, it is good to use glosses which already exist even in another language. Therefore this external link points to a special file, where all English glosses are stored. All wordnets then can point to this place and automatically load a gloss when necessary - the format allows to **link dictionaries**.

If it is necessary the user can add its own tag, such as gloss in his language, to his own WordNet and the changes take effect immediately without a need of any further processing, such as a recompilation of the WordNet database - the format is **easily extensible**.

```
<SYNSET>
  <ILI>00012517-n</ILI>
  <POS>n</POS>
  <SYNONYM>
    <LITERAL>psychological feature
      <SENSE>1</SENSE>
    </LITERAL>
  </SYNONYM>
</SYNSET>
```

```

  </SYNONYM>
  <HYPERONYM>00012517-n</HYPERONYM>
</SYNSET>
```

Fig. 3. Two synsets represented in VisDic definition

4. WordNet Embedded in Another Dictionary

There are very few relations which cannot be represented in VisDic format definition: DERIVATION, ANTONYM (for literals only), IS_DERIVED_FROM, HAS_DERIVED, PERTAINS_TO, IS_PERTAINED_TO, HAS_INSTANCE and BELONG_TO_CLASS. The reason is, that these relations do not connect two synsets, but in the most cases two literals. Synsets are uniquely identified by their ILI values, but there is no way to refer to their parts – particularly literals. Although most of WordNet data do not contain these relations it is necessary to think about how they can be represented.

One possible solution of this problem would be to specify the second key (in VisDic definition say the type of a tag K2), which makes a unique identification of each literal and sense pair. The literal relations can be then labelled by L2 or R2 type of a tag. The difference between synset links and literal links should be then distinguished (synset links have L and R type of tags). The corresponding part of VisDic definition of synonyms from Fig.1 should be then replaced by data represented by Fig.4.

```
1 SYNONYM                1      1 N
  2 LITERAL              1     -1 N
    3 ID                 1      1 K2
    3 SENSE              1      1 N
    3 IS_DERIVED_FROM    0     -1 L2
    3 HAS_DERIVED        0     -1 R2 SYNSET.SYNONYM.LITERAL.IS_DERIVED_FROM
    3 DERIVATION         0     -1 L2
    3 PERTAINS_TO        0     -1 L2
    3 IS_PERTAINED_TO    0     -1 R2 SYNSET.SYNONYM.LITERAL.PERTAINS_TO
    3 ANTONYM            0     -1 L2
```

Fig. 4. Additional information in VisDic definition for literal relations

It looks quite well but now consider, that we would like to link WordNet database to another common dictionary. Most of common dictionaries are sorted by words which correspond to the literals rather than the word meanings. Word meanings in WordNet typically contain more literals. Therefore, if we would like to refer to the word *cognition* from an example in Fig. 3 we should use a SYNSET.SYNONYM.LITERAL.ID tag instead of SYNSET.ILI tag, because ILI value comprises both *cognition* and *knowledge* literals.

Now think about the real situation, when both WordNet and the other dictionary are being edited. While ILI values of synsets are strictly given, the literals' ID's are very often modified. E.g., when a user deletes the literal from a synset, adds another literal to this synset and finally realizes that the first one was correct and replaces it back, the ID will not be the same. Therefore, during every simple change in a synset, it is necessary to update all the references to the literal. It is possible to maintain ID numbers within WordNet as a compact dictionary, but it is hard to keep consistent more different dictionaries. In our view, this is one of two reasons why this approach should not be followed.

The second reason is that common dictionaries usually contain more information about a specified word, that WordNet does. Except for a simple information such as origin of the word, morphological data (genitive form, plural form), typical collocations, etc., every verb in a common dictionary can display its valency, which may represent quite a complicated structure. From that point of view it is much easier to store relations between literals in the other dictionary. Each word description then can contain an identification of a synset (given by ILI) which specifies which word meaning it belongs to.

Fig. 5 shows a VisDic definition for a simple common dictionary with a link to a WordNet database stored in the ENTRY.SYNSET tag. The format is followed by an example of two entries of this dictionary. Notice that all literal relations are stored in this dictionary instead in WordNet itself (especially ANTONYM relation, for example). The external tag ENTRY.SYNSET allows to work with the corresponding WordNet synset, as if it were included in the common dictionary. In the first synset it is linked via 06193747-n value, in the second one, the value of external synset is 05847495-n.

```
1 ENTRY                   1       1 N
  2 ID                    1       1 K

Fig. 5. Example of a common dictionary embedding the WordNet data

5. VisDic

VisDic is a program tool which allows to browse and edit common dictionaries, corpora and also databases like WordNet. All of these resources are based on elementary structures – common dictionaries consist of entries, while WordNet is made of synsets.

The user can view more dictionaries at the same time. Each has its own sub-window consisting of three parts. The topmost one is a query box. The middle one contains all found entries and the last displays a view of a specified entry. This window is represented by a graphical item called notebook which allows to view the entry in more ways. VisDic window with two active dictionaries can be seen in Fig. 6.

The query consists of an XML tag specification, = character and a value specification, e.g. if a user likes to find all the nouns in WordNet, he has to type *SYNSET.POS=n*. One of tags can be understood as the default one. Then the tag specification and = character can be omitted, e.g. if *SYNSET.SYNONYM.LITERAL* is defined as the default tag for WordNet database all the occurrences of a word form, say *side*, can be found by typing just *side*. Queries can be grouped by logical OR (*||*) or AND (*&&*), the value can be prefixed by ^ character, which means to find all entries beginning with the value phrase, or suffixed by *$* character, which means to find all entries ending with the value phrase.

The more complete description of VisDic can be found in (Pavelek, 2002).

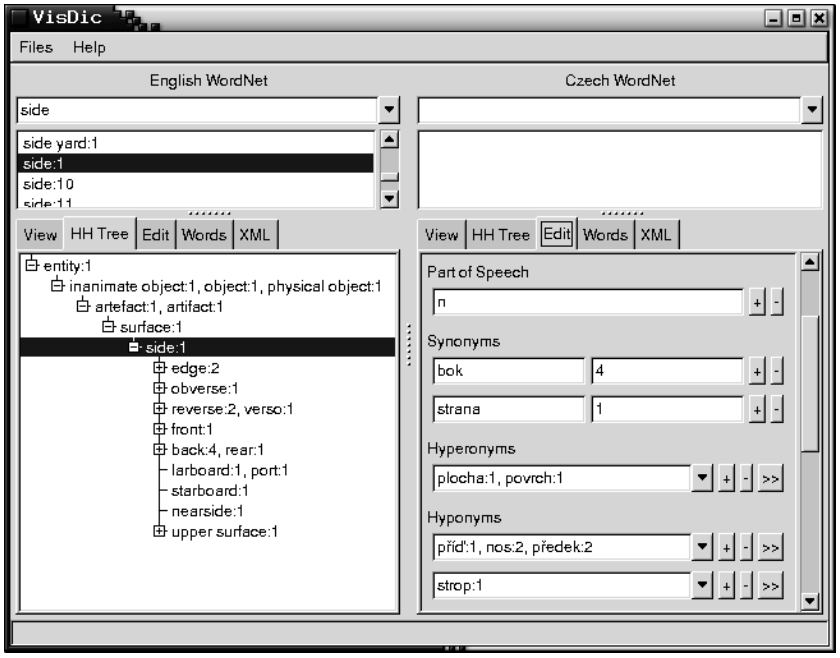

Fig 6. VisDic

6. Conclusions

The suggested format fully corresponds to the XML format as it is used for the data representation. Although we do not use a proper DTD specification fulfilling the requirements of the standard DTD in XML, the presented definition is quite similar to it and though it does not use some features that XML offers in general we think that it is well suited not only for wordnets, but also for other lexical resources as well, such as explanatory dictionaries, bilingual dictionaries, dictionaries of synonyms, corpora, etc. The format used within VisDic tool enables a user to browse and edit easily any type of database stored in it.

The conclusion that can be drawn from this exercise is the following:

The standards can be arrived at either from top (this is not our case) or from the bottom which is the solution presented here. The experience seems to show that real standards develop from the practical use shared by many users. Then the modifications from the top can be applied and adopted if the users can agree upon them.

Abstract

The requirements in building a multilingual ontology of the EuroWordNet kind are frequently conflicting and if not considered in the first stages of the project, later harmonizing might be extremely difficult if possible at all. To ensure as early as possible usability, the incrementally developed lexical stock of each individual wordnet, should cover the most frequent vocabulary of the language. On the other hand, given that this is a multilingual lexical resource, special care should be addressed to the compatibility problems. Specifically, there are two main compatibility issues to be considered: there should be a cross-language conceptual coverage, meaning that each monolingual lexicon should globally deal with the same conceptual areas or domains and the interpretation of the defined relations should be the same in any monolingual ontology considered by the multilingual harmonized ontology. This is why, drawing as much as possible from the EuroWordNet lessons, we decided to address these issues at the very beginning phase of the BalkaNet project.

1. Introduction

BalkaNet [1] (Stamou et al, 2002) is an EC funded project (IST-2000-29388) that aims to develop in accordance with EuroWordNet philosophy a core multilingual resource for the following Balkan languages: Greek, Turkish, Romanian, Bulgarian, Czech and Serbian. As in EuroWordNet, the monolingual lexical ontologies are projected onto an interlingual set of concepts (ILI), the correspondences being established by means of complex equivalence relations (eq-synonymy, eq-near-synonymy, eq-has-hyperonym, eq-has-hypernym etc).

The requirements in building a multilingual ontology of the EuroWordNet kind are frequently conflicting (Rodriguez et al, 1998) and if not considered in the first stages of the project, later harmonizing might be extremely difficult if possible at all. To ensure as early as possible usability, the incrementally developed lexical stock of each individual wordnet, should cover the most frequent vocabulary of the language. On the other hand, given that this is a multilingual lexical resource, special care should be addressed to the compatibility problems. Specifically, there are two main compatibility issues to be considered: there should be a cross-language conceptual coverage, meaning that each monolingual lexicon should globally deal with the same conceptual areas or domains and the interpretation of the defined relations should be the same in any monolingual ontology considered by the multilingual harmonized ontology. This is why, drawing as much as possible from the EuroWordNet lessons, we decided to address these issues at the very beginning phase of the BalkaNet project.

The first part of the paper will address the approach we took for the selection of the initial lexical stock to be included into the Romanian core wordnet so that to observe multilingual design criteria and cross-language compatibility issues. The synsets (in two or more languages) that are mapped onto the same ILI concept are implicitly semantically linked. The nature of these cross-lingual semantic links, which we call *translational links*, depends on the links between the ILI concept and the synsets in the monolingual wordnets. One way to check consistency of the ILI projection of the individual wordnets is comparing the translation links with the translation equivalents licensed by a parallel corpus. This issue will be discussed in the second part of the paper.

2. An overview of the language resources

The Romanian wordnet started, as in the case of other languages in this project, from scratch. However, in order to ease the work and make the process as reliable as possible we built on various valuable language resources and several tools we developed for their exploitation. In the following there is a brief account of these building blocks, each of them being largely described elsewhere.

2.1. Corpora

Within the Multext-East and TELRI European projects (Erjavec et al. 1997), (Dimitrova et al., 1998), (Tufiş, Bruda, 1997), (Tufiş et al. 1997, 1998, 1999) there were created one 7-language heavily annotated parallel corpus based on Orwell's famous novel "1984" and one 25-language heavily annotated parallel corpus based on Plato's "The Republic". The annotation initially used was TEI compliant, but it was later on converted into CES (Ide, 1998). These are two relatively small corpora (about 110,000 tokens in each language) but given the accuracy of tagging and interlingual sentence alignment (hand validated) they were extremely useful for various applications ranging from building language models for morpho-syntactic tagging (Tufiş, 1999) and document classification (Tufiş et al., 2000) to automatic sense

[1] Further information can be obtained from the project's web site http://dblab.upatras.gr

discrimination (Erjavec et al., 2001). Besides the multilingual corpora we constructed two other much larger monolingual corpora: a literary corpus based on various novels (containing about 1,500,000 tokens) and a journalistic corpus (containing more than 100,000,000 tokens). Both corpora were automatically tokenized, tagged and lemmatized.

2.2. Lexicons and dictionaries

One delivery of the Multext-East project was a large wordform lexicon (more than 450,000 entries) containing triples <wordform, lemma, morpho-syntactic_code>. The encoding used in this lexicon is compliant with the Eagles recommendations for morpho-syntactic annotation and is largely documented in (Tufiş et al. 1997).

The reference dictionary we used for our analysis is The Explanatory Dictionary of Romanian (DEX,1996), work of the Romanian Academy Institute of Linguistics. This most authoritative lexicographic source for contemporary Romanian was partially digitized and converted into a lexical database (XML encoded) by RACAI under the European Project CONCEDE (Tufiş et al.1999). This core XML-dictionary has been extended to the full content of the printed dictionary by a follow-up project funded by Romanian Academy.

Another extremely useful lexical resource we relied on was the Romanian Dictionary of Synonyms-RDS (Seche, Seche 1997), which was transposed into electronic form by the NLP group at the University A.I. Cuza din Iaşi. The electronic form of RDS has been converted into an XML format so that the same query interface we developed for DEX works also with RDS.

From the multilingual parallel corpora mentioned before and using our translation equivalents extraction program (Tufiş, Barbu 2000, 2001a, 2001b) we constructed a bilingual Romanian English dictionary (also XML-encoded). This bilingual lexicon has been hand validated and extended with new entries from several public domain sources.

Finally, an extremely valuable resource was the ILI of the EuroWordNet, exported in XML format by means of the VisDic editor produced by the Masaryk University of Brno (Pavelek and Pala, 2002).

All these resources have been integrated by means of a series of tools developed for the purpose of the BALKANET project. They are user-friendly and allow for editing and mapping the Romanian synonymy series in RDS to the sense definitions in DEX and ILI records from EuroWordNet. The output of these tools is further subject to primary local consistency checks (such as detecting word sense appearing in more than one synset) and generated as an XML-encoded file appropriate for import in VisDic. We will provide a brief overview of these tools in Section 5.

3. Lexical stock selection

In order to ensure practical utility for the core wordnets to be delivered by the BALKANET project and to facilitate further extensions towards as large as possible coverage for the languages concerned, the project consortium decided to start the development process with a common set of concepts likely to be lexicalized in all the project languages. This special set of concepts, called *Base Concept* Set, was selected from the EuroWordNet interlingual index for reasons convincingly argued in (Vossen, 1998). The Base Concept Set contains 1310 concepts, each of them being attached a gloss and a Top Ontology Description (see Vossen, 1998). All project partners developed in a harmonized way the synsets in their languages corresponding to the Base Concepts. After this step, the monolingual wordnets will be further developed in a top-down approach starting with the synsets already mapped onto the Base Concepts.

Let us give a few definitions for some notions that will be used in the following.

When we place ourselves in a monolingual environment we speak about *senses*, *meanings* and *synsets.* A word has one or more *senses.* A sense refers to one *meaning.* In EuroWordNet the senses of a word are numbered according to their frequency and a sense of a lemma is denoted by appending the sense number to orthographic form of the lemma in case. A set of such numbered senses (eg. action2 activity1 activiteness1) referring to the same meaning is called a synset, which itself stands as a denotation of the common meaning of the senses in the synset. A meaning has a gloss that obviously applies for all senses in a corresponding synset.

When we want to abstract away from one language, we speak about the *concepts* referred to by the *word meanings*. So, we may speak about concepts with or without the reference to a specific language. Therefore, in trying to establish cross-lingual dependencies, via an interlingual index, it is convenient to refer to the entities used for this purpose as *concepts.* A concept is a language independent cognitive construct, which in EWN is always lexicalized at least in one language. A concept is further refined in terms of basic semantic distinctions (semantic features, sometimes referred to as semantic fields) so that one could speak about concept clustering along the basic semantic features.

According to these definitions we will use the term *Base Meaning* to refer to a basic (language specific) meaning in terms of which other word meanings can be defined and *which is directly mapped on a Base Concept*.

In EuroWordNet, and thus in BALKANET, ILI is defined as an unstructured collection of concepts represented by records of the form (<ILI-index> <ontological description> <gloss> {<domain>}). The initial ILI has been constructed from Wordnet1.5 and thus the gloss of each concept has been imported directly from the English synset referring to the meaning conceptualized in ILI.

According to the aims of the project regarding the interlingual coverage, language representativity, maximum usage of the core wordnet and scalability we started a series of quantitative analysis on a very large corpus made of several novels and a collection of journalistic texts, collected from the web. The corpus (containing more than 100 million words) was automatically tagged, lemmatized and the content words of interest (common nouns, verbs, adjectives and adverbs) were counted and sorted according to their frequency. We extracted this way, a list of more than 30,000 Romanian lemmas. Based on the frequency in the running texts, this list was divided into three parts, corresponding to the first 10,000 most frequent lemmas (I), the next most frequent 10,000 lemmas (II) and rest of the lemmas (III).

In deciding which is the most important subset of a lexical stock for a language, the frequency in running texts

is considered by many lexicographers to be a very subjective criterion. Among the strongest arguments they would come with is the volume and representativity of the texts included into the corpus subject to the quantitative analysis. With more and more texts available on the net, the size of the data is not anymore a significant issue, but the representativity remains a systematic complain. The exact definition of what representative texts should be included into a corpus for quantitative data analysis is a long-standing debate and we won't get into this. Considering that our data consisted, almost entirely, of journalistic texts, the representativity issue could certainly be raised. The Frequency Dictionary of Romanian Words– FDRW (Julliand et all., 1965) published long time ago, based on a balanced corpus of 500,000 words of Romanian literature, legal texts, poetry and journalism contains a list of most frequent 5,000 lemmas. In spite of being quite contested, it is still used by many Romanian linguists as a reference. The comparison we made revealed that most of the 5000 words in FDRW were also in our list, although not with the same frequency ranges.

As frequency in running texts is a disputable criterion for deciding what words should be encoded into a core dictionary/thesaurus/ontology we considered that this criterion should be complemented with others, less controversial in the world of traditional lexicography.

Among the criteria one could find pleas for, we opted for two that we could easily turn into operational selectors. The one is the number of senses a headword would have in a reference dictionary. The second one is the number of word definitions that use the headword in case. A third criterion, not considered yet, might be the number of derivatives of a given headword (this last criterion is preferred by most Romanian etymologists).

In this phase of the BALKANET project we concentrated our attention to the Romanian nouns and the experimental data reported below refers to nouns. Since the technical procedures do not depend on the specific part of speech, the same would apply for verbs, adjectives and adverbs.

Considering only the first two frequency ranges described above (the first most 20,000 words in the journalistic corpus) we extracted from our Explanatory dictionary more than 8000 entries for nouns and nominal compounds (accounting for almost 35,000 senses) so that the definitional productiveness DP (the number of sense definitions a noun participates in) was at least 3. The list was sorted according to the definitional productivity.

Noun	**Definitional productivity**	**Number of definitions**	**FRECV$_{range}$**
acțiune	2279	13	I
persoană	1979	9	I
parte	1882	94	I
formă	1286	21	I
obiect	1204	16	I
fapt	1044	11	I
apă	743	29	I
• • •	• • •	• • •	• • •
rasism	3	1	II

Table 1: scoring the headword candidates

For all these nouns we extracted EN translations from our translation equivalence dictionary. The procedures for automatic extraction of translation equivalents from parallel corpora as well as the sense discrimination procedure are largely described in (Tufiş&Barbu, 2001a,b), (Erjavec et al, 2001). As the translation equivalents found by our extractor are limited by the available parallel corpora we have, provisions were made for automatic updating of the Ro-En dictionary with web resources.

All pairs containing an English word (or a synonym of it) in the English synsets corresponding to the base concepts were also associated with the corresponding top-ontology description. Practically for all English words corresponding to the base concepts there were found translations in our translation lexicon and these translations appeared in the upper top of our 8000-noun list. Those few EN nouns not translated in our lexicon were given manual translations. Because our translation equivalence lexicon is based on sense equivalence in context, transferring the ontological description from one EN word to its equivalent translation was considered to be a legitimate option. Thus, at the end of this step we collected a list of Romanian nouns associated with one or more English translations out of which at least one was present in the base concept list. Each such an association was further enriched with additional information extracted from other resources:

a) the RO word was attached with all its definitions extracted from the Explanatory Dictionary of Romanian;

b) the EN word was attached with its entry in the WordNet1.5

The Romanian Dictionary of Synonyms (RDS), digitized and encoded as an ACCES database by University A.I. Cuza of Iaşi, was used to extract the synonymy series for the selected RO words. In RDS some members of the synonymy series are provided with usage information (old, regionalism, specific area of usage, domain, etc). Preliminary discussions lead to the idea to eliminate all the words marked as such (based on the assumption that we would like to construct a lexical stock for general use in contemporary Romanian). However, if later on this filtered out words (together with their usage information) would be necessary, their recovery was ensured. The synonymy series were taken as possible Romanian synsets and added to the RO-EN associations described above.

We have thus assembled the basic linguistic material that the lexicographer should use in making the decisions (linking) necessary for building the noun subset of the core Romanian wordnet. All this information is currently available in a java-based editor, showing in different frames, the following information (see figure 1):

- the list of the base concepts (upper-left frame), identified by the ILI record and an English word in the synset mapped on this concept (ex. *life_3_03941565-n*)
- the synset (life_3 living_1), its gloss and top-ontology description, possible translations and association boxes (right-upper frame)
- the numbered sense definitions from the Explanatory Dictionary of Romanian for the selected translation (left-lower frame);
- synonyms of the selected Romanian translation word (right-lower frame)

- pop-up menus for selecting the relevant sense numbers and the equivalence relation to the ILI concept.

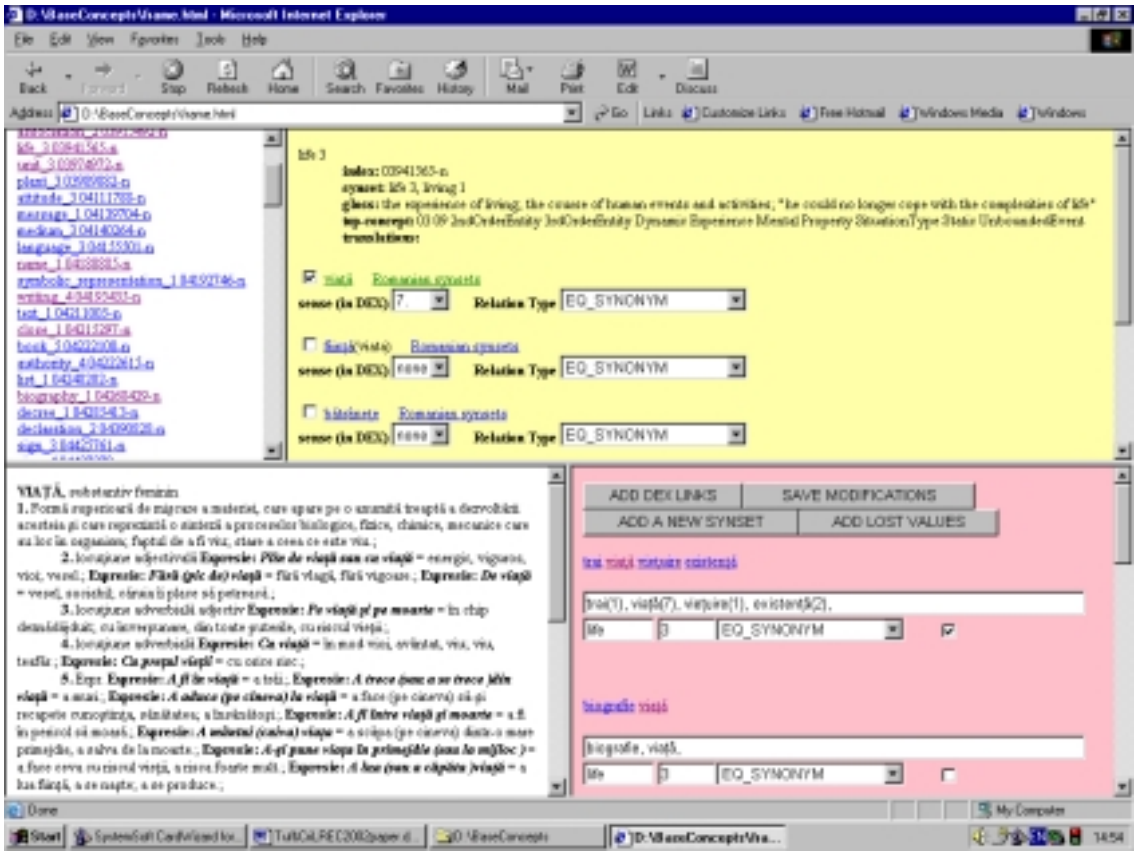

Figure 1: The editor for building synsets for the base meanings

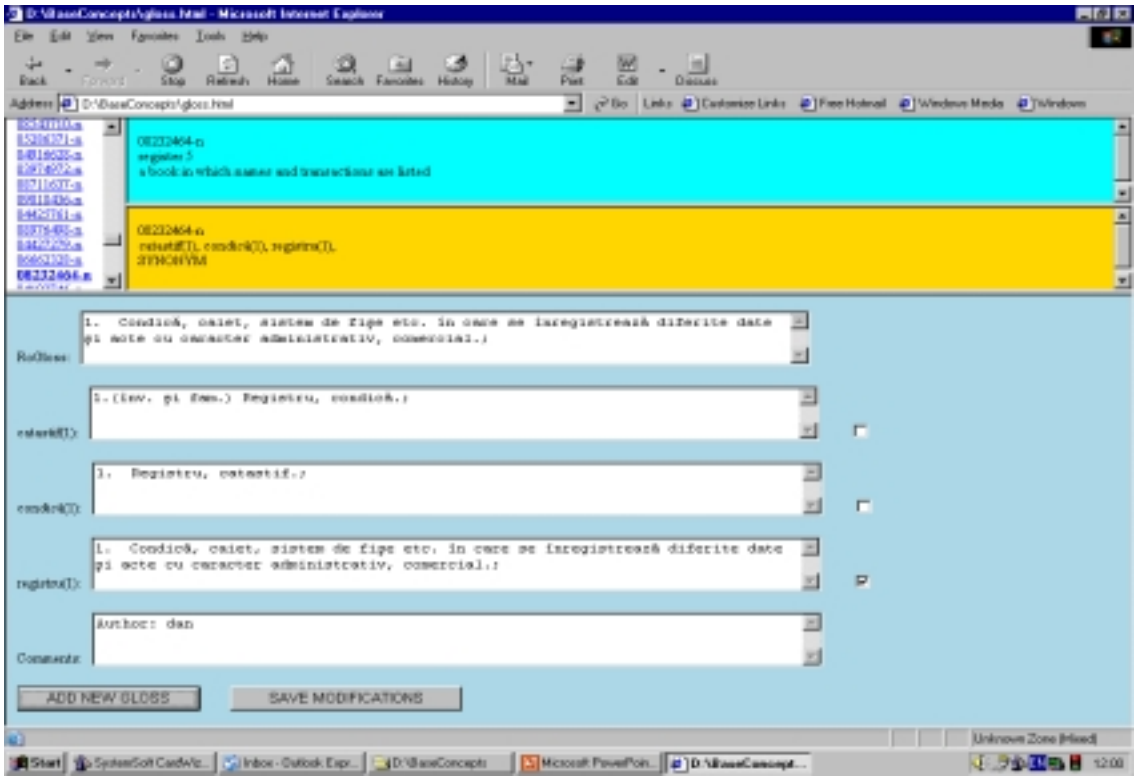

Figure 2: The editor for gloss assignment

The editor has been instantiated into 10 differently populated copies, each containing a different set of base concepts. Each incarnation of the editor has been given to a different expert who was in charge of building his/her set of Romanian synsets and map them onto the appropriate base concepts. When this building phase was finished we performed a few simple error-checking such as:

- all literals appearing in a synset should have attached a sense number
- no sense (literal and sense number) should appear in two or more synsets
- each synset should have an equivalence relation to a unique base concept.

Once the synsets were constructed and mapped onto base concepts, the second phase was to add a Romanian gloss to each Romanian synset. In the vast majority of cases, the definitions extracted from DEX corresponding to the senses in a synset were different in wording so, the lexicographers had to chose the best definition, closest to the definition of the corresponding base concept. The Figure 2 shows that the base concept 08232464-n corresponding to the 5th sense of the English word *register* (a book in which names and transactions are listed) corresponds in Romanian to the synset (catastif_1 condică_1 registru_1). The selected senses for the three Romanian words have in DEX different definitions. By checking the box to the right of the third definition (lower frame in Figure 2) the lexicographer decided that the definition given to *registru_1* is the one to be attached to the synset.

It is worth mentioning that during the gloss assignment phase it became apparent that several synsets were not correct, requiring modifications. In some cases, the Romanian Explanatory Dictionary includes under the same definition two senses that are differentiated in ILI as two distinct concepts. In such cases, the general strategy was to split the Romanian definition and attach the relevant part as a gloss.

4. A proposal for cross-lingual validation of the ILI mapping

As we said before, one of the main objectives of the BALKANET project (which adopted a merge model approach) is to ensure as much as possible overlap between the concepts lexicalized in the concerned languages. A significant overlap may be hampered either by conceptually different lexical stocks for the different languages or by inconsistent projection of the monolingual concepts onto the ILI concepts. In order to ensure conceptual similarity for the lexical stocks across various languages, the development of the monolingual ontologies started in two different, but convergent ways: the minimalist one was to provide direct translations of the EuroWordNet Base Concept Set; the second way (language-centric) was to produce a ranked list of most important (according to prescribed lexical criteria) words in each language and to include in the monolingual wordnets at least those words, the meanings of which would cover the Base Concept Set. Irrespective of the approach taken towards ensuring lexical stock similarity across languages, we had to consider means for automatic check of the correctness of the mapping of the monolingual synsets over the ILI concepts. To this end we will describe in some details a proposal for an automatic consistency checking.

Our approached is based on the notion of translation equivalence over bitexts, on bilingual lexicons automatically extracted from parallel corpora (Tufiş, Barbu, 2001 a,b) and on sense disambiguation (Erjavec et al., 2001).

The parallel corpus we used in our experiments is the "1984", based on Orwell's famous novel, developed in the MULTEXT-EAST project, further cleaned up in the TELRI and CONCEDE projects. The corpus contains professional translations of the original novel in 6 languages (Bulgarian, Czech, Estonian, Hungarian, Romanian and Slovene), all aligned at the sentence level to the English original. Each monolingual part of this 7-language parallel corpus is segmented, tagged and lemmatized and also carefully hand validated.

From the 6 (integral) bitexts (CEE language texts aligned to the EN original) there were extracted bilingual lexicons (XX-EN, with XX one of the six CEE languages) and furthermore a 7-languages lexicon with EN as a hub. By removing all the non 1-1 alignments in the bitexts and using the EN sentence Ids as anchors, a partial (about 92% of the whole text) 7-lingual 1-1 alignment (EN-BG-CZ-EE-HU-RO-SI) was computed. The 7-language aligned corpus allows for extracting any of the 21 possible (partial) bitexts. A number of 104 nouns appearing in the English part of the multilingual corpus (altogether 3316 instances were hand annotated and used as a gold standard for our sense clustering algorithm (Erjavec, 2001).

As BG, CZ and RO are languages of the BalkaNet project from the present data, our methodology could be used for checking the ILI-mapping consistency for any of the RO-EN, RO-CZ, RO-BG, EN-CZ, CZ-BG and BG-EN pairs of wordnets. In the current phase of the project we are able to consider only the interlingual mapping of the base concepts. Let us generically denote the language pairs subject to checking as XX-YY. The basic methodology is as follows:

1) From the XX-YY bitexts we extracted the XX-YY lexicon (http://www.racai.ro/~tufis/BilingualLexicons/AutomaticallyExtractedBilingualLexicons.html). The bilingual lexicon contains not only the translation pairs but also, for each entry the aligned sentences that licensed the translation equivalence relation. This lexicon is purged so that it contains only words that have (in the respective monolingual wordnets) at least one sense mapped on a base concept set. Put it otherwise, any pair (W_{XX} *translated as* W_{YY}) of the purged lexicon has the property that W_{XX} or W_{YY} or both have at least one sense in the language-specific base meaning set.

2) Let it be (W_{XX} W_{YY}) a translation equivalent. Let us denote with S_{WXX} the synsets in language XX containing the W_{XX} word (actually one sense of it) and S_{WYY} the synsets in language YY containing the W_{YY} word (actually one sense of it). Starting in the XX monolingual wordnet from the synsets in S_{WXX}, via ILI, one ends in the YY monolingual wordnet with the XX-synsets having translation links to YY-synsets. Let us call this set as S'_{WYY}. S_{WYY} and S'_{WYY} should have at least one synset in common. Please note that if the intersection of the two sets of synsets is non-empty, the described procedure ensures semantic tagging of the (W_{XX} W_{YY}) pair with one or more ILI-concept tags. If the intersection contains exactly one synset, its corresponding ILI record-number

could be used to semantically tag both W_{XX} and W_{YY}. With intersection containing more synsets, we still are able to reduce the semantic ambiguity of the considered words. In case the intersection is empty, we might have one of the following possible explanations:

2.1) (W_{XX} W_{YY}) is not a valid translation pair; by checking the sentences that licensed the extraction of this translation pair one could confirm or refute this possibility; please note that an error here might be due to the extraction algorithm or to a problematic human translation (for instance it is not uncommon that even professional translators would sometimes translate one word by a non-eq-synonym for various reasons like contextual semantic gaps or stylistic preferences)

2.2) (W_{XX} W_{YY}) is a valid translation pair and the two words share a meaning assigned to a concept which is not in the base concept set.

2.3) the interlingual mapping of the W_{XX} and W_{YY} is "wrong"; being "wrong" might be a real mapping error in the XX or YY language (or in both) or it might be motivated by a lexical gap in one of the languages concerned (or both); the lexicographer might have overcome the lexical gap by using a complex equivalence relation (not the eq-synonym); in the second case, one might get insights on possible concept clustering at the ILI level (creating so-called *soft-concepts*).

We claim that this procedure allows us to estimate both the cross-lingual coverage and the correctness of the interlingual mapping of the two considered monolingual wordnets. The procedure allows not only for estimation but also for pinpointing the incomplete or missing synsets as well as inconsistencies in mapping the synsets onto ILI concepts and gives hints on soft-concept clustering.

4.1. Condiments, spices, sauces and other ingredients

Let us consider the fragments of the Ro-Wordnet and WN1.5 shown in the Figure 3. The arrows represent hyponymy relations in the two wordnets. The gray heavy lines represent translational links between the synsets in the two languages, meaning that the respective synsets are mapped onto the same ILI concept. The heavy dashed line represents a translational link that is reported as wrong during the cross-validation of the two wordnets. The reason for this comes from the violation of what we called the *hierarchy preservation principle*. The inconsistency is signaled because in language RO the hierarchical relations (hyponym) between $^{M}mirodenie_{RO}$ H $^{M}condiment_{RO}$ as well as $^{M}ketchup_{RO}$ H $^{M}sos_{RO}$ are not verified in language EN by the equivalent pair meanings ($^{M}spice_{EN}$ $^{M}condiment_{EN}$) and ($^{M}ketchup_{EN}$ - $^{M}sauce_{EN}$)(in EN they are sisters). If the structuring in WN1.5 is taken to be the Truth, this example shows that *the hierarchy preservation principle* is not true. On the other hand, if it would be reasonable to consider that WN1.5 is amendable (for instance making $^{M}mustard_{EN}$ and $^{M}ketchup_{EN}$ direct hyponyms of $^{M}sauce_{EN}$) then the *hierarchy preservation principle* might be a very powerful consistency check.

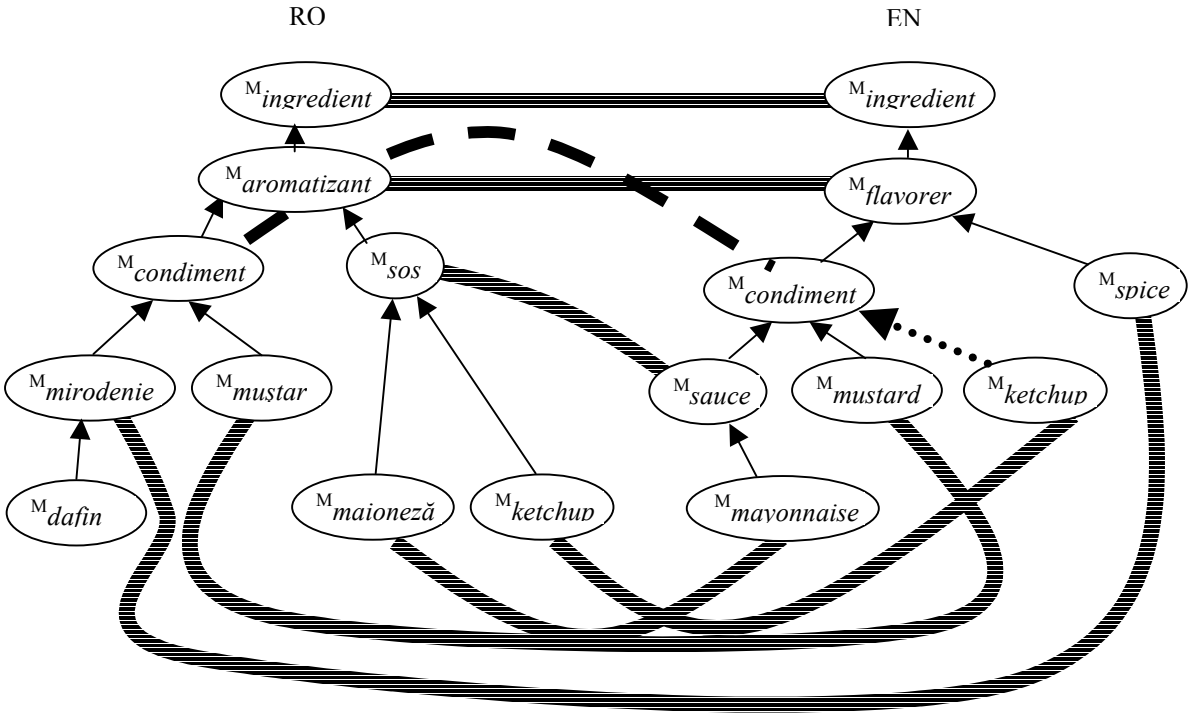

Figure 3: Translational links and consistency checks

5. Conclusions and further work

The approach on consistency checking based on translation equivalents in multilingual parallel corpora has some methodological similarity with (Resnik et al., 1999) on the multilingual corpus built up from many translations of the Bible. Speaking about useful sense distinctions (for machine translation for instance) Resnik (personal communication) identifies *strong sense distinctions* of one word in a source language as those that are lexicalized as

different words in the target languages. When some senses carried by a source word are found in a target word the distinction between them is called a *light sense* distinction. In the area of machine translation trying to disambiguate among light distinctions is not a very productive enterprise and therefore being able to identify, for a given pair of languages, which are the strong/light sense distinction might be extremely useful for machine translation. Our approach could be used to enhance the strong/light dichotomy with a third dimension: *fuzzy sense* distinction. This term is strongly related to that of *soft concept* used in EuroWordNet for clustering different ILI concepts that are lexicalized in two or more languages by words considered to be legitimate translations of one another.

In the next phase of the project, in order to extend the monolingual Romanian wordnet up to the level of the promised size, our strategy will be language-centric meaning that the new entries will be the top ranked words selected from our noun/verb/adjective/adverb lists sorted as described in the section 3.

Abstract

Construction of the Hungarian WordNet began in 2000. The project presently focuses on the nominal part. Our principal approach is to use Princeton WordNet as the basic structure, to which Hungarian nouns are attached. We are applying two methods to accomplish this: manual disambiguation for the more abstract levels, and automatic methods, including heuristics developed by earlier projects, in order to attach the remaining more specific senses. Results from these methods are integrated into a core structure, which will be enriched using further electronic linguistic resources.

1. Introduction

The construction of the Hungarian WordNet has started from scratch, unlike many components of the EuroWordNet project (Vossen, 1999), whose creators could rely on already existing lexical resources (Kunze et al., 1998). We employed the initial hypothesis that nominal hierarchies in English and Hungarian should be similar, at least for certain domains. This enabled us to attach Hungarian nominal entries of a Hungarian-English bilingual dictionary to Princeton WordNet 1.6 (WN) synsets. In this way, the English nominal hierarchy of WN serves as a skeleton structure to support the construction of the core Hungarian nominal WordNet. This approach was also used in the initial stage of the construction of the Spanish and Catalan WordNets (Farreres et al., 1998; Atserias et al., 1997). Furthermore, examining the Hungarian nominal taxonomies extracted from a Hungarian monolingual dictionary, we have found that hierarchies for the specific nominal domains (nouns denoting objects) tend to be similar to those found in WordNet.

Linking Hungarian words to WN synsets is accomplished in two ways. First, a software environment has been created to support the manual disambiguation of Hungarian nouns against WordNet. This is a top-down procedure advancing from the abstract to more specific levels in the WordNet hypernym structure, resulting in the manual construction of the more abstract levels of the core Hungarian WordNet.

Secondly, various heuristics, mostly developed in earlier projects, are applied to produce sets of candidate links between Hungarian nouns and WN synsets automatically. These methods rely on information found in the bilingual and monolingual dictionaries, plus the information already available from the parallel manual disambiguation procedure. Finally, results of all the different methods are manually checked and integrated.

Attaching further nominal entries from a larger bilingual dictionary, a thesaurus, and entries and definitions (serving as glosses) from a monolingual dictionary will enrich the resulting skeleton Hungarian WordNet structure, connected to the English WN.

In the following section, we will give a review of the electronic resources we use in our work. Section 3 gives an overview of the various automatic and manual methods used in the project. Integration of the information from different sources and the possibilities for further extensions are also discussed. Finally, our conclusions are provided in Section 4.

2. Acquiring taxonomies from various dictionaries

We have several electronic resources at our disposal: English-Hungarian bilingual dictionaries, a monolingual Hungarian explanatory dictionary, a Hungarian Thesaurus, and, of course, WordNet 1.6. MorphoLogic's English-Hungarian bilingual electronic dictionary contains entries for 17,801 Hungarian nouns with 12,440 English translations included in WordNet. The dictionary has been converted into a database of English-Hungarian word pairs with symmetrical translation relations (Prószéky et al., 2001). The entries of the Hungarian side constitute the basic set used for the various attachment procedures (see: Section 3).

A significantly enlarged version of the *English-Hungarian Dictionary* (Országh–Magay, 2001) will be used for further improvement of the Hungarian WN structure. It contains over 150,000 Hungarian entries, with English translations covering more than 80% of WordNet's entries. An electronic version of the Hungarian explanatory dictionary *Magyar Értelmező Kéziszótár* (ÉKSz) (Juhász et al., 1972) has been converted into XML format. This dictionary contains 42,942 nominal entries, corresponding to 64,146 definitions. 31,023 of them are annotated with usage codes, representing either the semantic domain (sport, medicine, science, religion etc.), or the language usage (technical, slang, vulgar, intimate, etc.). Through the smaller bilingual dictionary, 10,507 headwords have English translations in WN. We also have at our disposal a Hungarian electronic thesaurus. The *Magyar Szókincstár* contains 25,500 entries with synonyms and 14,400 entries with antonyms. Entries are linked to separate sets of synonyms for various senses. Most of the synonym and antonym words are annotated with language usage labels.

To help the construction of the Hungarian nominal WN, information is acquired from the monolingual dictionary in several ways. First, programs were developed to parse each dictionary definition and extract semantic information. In 83% of all the definitions, genus words were identified, which can be accounted for as hypernym approximations of the corresponding headwords. For example, the following ÉKSz entry will tell us that the *koala* is a kind of *mammal*:

koala: *marsupial* ***mammal*** *resembling a bear, native in Australia*

In about 1,700 cases, the identified genus word was either a group noun, or a word denoting a "part" relationship. Let us consider as an example the ÉKSz entries for *alphabet* and *face:*

alphabet: *The* ***set*** *of letters used for…*

face: *The* ***part*** *of the head that…*

Using morpho-syntactic information, the meronym or holonym word (in the example above: *letter, head*) could be identified instead of a genus word. This method provided holonym/meronym word approximations for 2.7% of all the headwords (only distinguishing between "part" and "member" subtypes of holonymy, as opposed to the 3 types represented in WN (Miller, 1990)). A further 13% of the definitions consisted only of a single noun. These are synonyms for the corresponding sense of the headwords, which are mostly rare variants or compounds.

These simple methods provided us with hypernym, holonym and synonym words for 98.9% of all the nominal dictionary entries. Such information extracted from machine-readable dictionaries can be used to build hierarchical lexical knowledge bases (Copestake, 1990), or semantic taxonomies (Rigau et al., 1998). The extracted genus word approximations can yield a hierarchical taxonomy of the nominal dictionary entries, organized by hypernym relations, providing a very versatile resource for the construction of our Hungarian nominal WN. However, in order to get hypernym relations between senses, the identified genus words have to be disambiguated, which means the hypernym sense must be separated from the senses corresponding to the genus word.

We are experimenting with several heuristics, relying on the work by Rigau et al. (1997) and Copestake (1990) to achieve an automated process of genus word disambiguation. About 70% of the genus terms are monosemous in the monolingual dictionary. In these cases the hyponym senses are attached to them directly.

Another heuristic utilizes the usage codes available for about 30% of the candidate senses Semantic codes, if available, can be tested for compatibility between the hyponym and the candidate hypernym senses. The pragmatic codes are also put to use: senses annotated as slang, vulgar etc. are more unlikely to be used as genus terms.

A third heuristic assigns the first sense occurring in an entry, relying on the fact that senses are ordered by usage frequency, and the most used senses are more likely to be used as hypernyms.

A fourth heuristic tries to measure semantic similarity among definitions by means of determining the number of lemmas shared by both definitions.

A fifth heuristic will rely on the conceptual distance formula, which measures semantic similarity between concepts using WordNet as a hierarchical knowledge base (Rigau et al., 1997). Application of the conceptual distance formula is discussed in more detail in Section 3.2.2.

Each heuristic will assign a score for the candidate senses, and the ones bearing the highest score will be linked to the hyponym senses. As work is still in progress for the disambiguation, it is early to report on the precision of the algorithm. Moreover, considering reports on previous works, it is likely that further manual and automatic assortment and/or verification of the resulting hierarchies will be necessary in order to attain a well-structured taxonomy (Rigau et al., 1998).

Some sample subsections of the resulting taxonomies were examined in order to investigate semantic similarities and differences between the parallel structures of the Hungarian hierarchy and WordNet. The most frequent difference originates from the fact that the hypernym trees in WN are quite detailed, often having 7-9 levels, while the Hungarian hierarchies tend to be more shallow, usually consisting of only 3 or 4 levels. The situation seems to be similar to previous projects constructing lexical hierarchies from machine readable dictionaries, for example in the Czech WordNet project (Pala & Ševeček, 1999).

Based on the samples examined, besides the lexical gaps on both sides, the two hierarchies seem to differ most at the higher, most abstract levels, where the Hungarian taxonomies are often unelaborated or confusing, and containing circular references. Nevertheless, we have not found evidence strongly contrasting our basic hypothesis, and our approach of attaching Hungarian nouns to the WN hierarchy seems maintainable for the initial stage of our work.

On the other hand, these facts have encouraged us to start linking Hungarian nouns manually, starting from the topmost WN levels, and to apply automatic linking procedures for the more specific senses.

3. Manual and semi-automatic procedures

We are using both manual and semi-automatic techniques to achieve the task of linking Hungarian nouns to the WN synsets. The manual methods provide a framework of top-down construction of the Hungarian nominal WordNet. The automatic methods rely on the bilingual and monolingual dictionaries, and on the extracted semantic information, applying heuristics developed for the construction of the Spanish and Catalan WordNet (Farreres et al., 1998; Atserias et al., 1997). We chose to test these methods because the resources available to the Spanish and Catalan Research Group are closest to our available resources, considering the participants in the EuroWordNet project (Vossen et al., 1999).

The result of these methods will be evaluated manually, based on random samples. Then all the possible intersections of the sets of results produced by the different methods will also be evaluated, and only the results obtained by the combination that produces the highest accuracy will be considered. We follow this approach, described by Atserias et al (1997), in order to ensure the precision of the core Hungarian WordNet structure.

3.1. Manual disambiguation with the help of the web

A set of Internet-based software tools has been developed for manual disambiguation of the Hungarian nominal entries against WN. The use of the Internet makes it possible for our contributing experts to work independently.

For the users, the system offers a web page, over which the expert can answer questions provided by the central server maintaining the database. (Figure 1) xperts are exposed to dialog boxes: if the word in question does mean the concept outlined below by English synonyms and a definition, then the human expert is supposed to press the Yes button (Nagy, 2001).

3.2. Semi-automatic methods based on heuristics

There are three kinds of automatic linking methods, each relying on different kinds of resources.

The first group of heuristics relies on information found in the bilingual dictionary and the structure of WN, while the second type relies on the genus information extracted from the monolingual dictionary. These constitute heuristics described by Atserias et al. (1997), plus a technique of our own.

The third method relies on the links already produced by the manual linking procedure and the taxonomy acquired from the monolingual dictionary.

3.2.1. Methods relying on bilingual dictionaries

Of the 17,800 Hungarian nouns forming the initial set, about 7,000 have translations in English, each belonging to only one synset in WordNet. These nouns are classified into four groups, based on the nature of the Hungarian-English translation relationships (one-to-one, one-to-many, many-to-one or many-to-many). Then, for every noun in each class a hypothetical link is produced to the unique synset containing the translation(s). Atserias et al. (1997) report on different kinds of precision for the four classes, ranging from 85% to 92% correct connections. Based on preliminary investigations, the average amount of correct links produced seems to be somewhat lower in our case. This is probably owing to the fact that the bilingual dictionary often either refers to senses not found in WordNet, or provides translations that correspond to hyponym senses of the Hungarian noun.

For the Hungarian nouns with polysemous translations in WordNet, the *Variant Criterion* and the 4 *Structural Methods* are being applied. These heuristics try to find common information between the English translations and WN. The *Intersection Criterion*, for example, will assign a Hungarian word to a synset if the synset is shared by at least two of the word's translations. In the Spanish experiments, precision is reported to be between 58% and 85% for these criteria (Atserias et al., 1997).

3.2.2. Methods relying on monolingual dictionaries

The ÉKSz explanatory dictionary contains *Latin* equivalents for about 1,600 nominal entries. These are mostly names of animal and plant species, taxonomic groups, diseases and chemical substances. Since WN 1.6 is very elaborate on Latin translations for such nouns, this provides for a reliable way for the linking of the Hungarian nouns. This method produced links for a small set of about 1,200 Hungarian nouns and corresponding definitions to WN, with the rate of correct connections estimated over 90%.

The second type of our automatic methods that utilize the monolingual dictionary relies on the extracted genus information (see Section 2). Following Atserias et al. (1997), we are applying the *Conceptual Distance formula* for the English translations of each headword-genus, or headword-holonym word pair we identified in the dictionary. The Conceptual Distance formula, introduced by Agirre et al. (1994), selects those two closest concepts in WN which represent the two input words. In the case of headword-genus pairs, the hypernym structure of WN is used as a semantic network for the heuristic, while for the ÉKSz headwords with holonym/meronym word approximations, the structures determined by WN's holonym links are used.

The application of the Conceptual Distance formula not only produces candidate links for the Hungarian words, but can also be used as a heuristic in the sense disambiguation of the Hungarian genus words, thus contributing to the construction of the Hungarian nominal taxonomy (Rigau et al., 1997).

3.2.3. Using information from the manual disambiguation procedure

After the semantic taxonomy is extracted from the EKSz dictionary, it can be used in conjunction with the already available information gained from the previous steps and WordNet's structure to support the manual processing. The order of the manual disambiguation of Hungarian words nouns follows top-down order (starting with abstract senses) of the English WordNet's hierarchy. Thus, once a Hungarian word is linked to a WordNet sense, hyponym words of its various senses can be disambiguated automatically against WordNet synsets, making use of the parallel structures of WordNet and the Hungarian taxonomy.

For example, let us suppose that the Hungarian word *állat* (`animal') has already been linked (either manually or automatically) to the WordNet synset {*animal, animate being, beast, brute, creature, fauna*}. *Állat* has 3 different senses in the Hungarian taxonomy, one of which has a hyponym pointer to (a sense of) the word *ló* ('horse'). The word *ló* has 3 English translations in the bilingual dictionary, which belong to 8 different synsets in WordNet. In order to determine which of those 8 synsets should *ló* be linked to, Conceptual Distance (see Section 3.2.2) is calculated between {*animal, animate being,…*} and the 8 candidate synsets. The candidate synset {*horse*, *equus caballus}* will show the smallest distance from the hypernym synset {*animal, animate being,…*}, thus, *ló* (with the sense determined by the hypernym *állat*) can be linked to {*horse*, *equus caballus*} (Figure 2).

A threshold condition will also be built into the algorithm, which will prevent links to existing but incorrect WordNet senses (i.e. in cases where a Hungarian word has a hyponym sense that does not have an equivalent meaning in WordNet).

3.3. Further steps

After the linking of the Hungarian entries of the bilingual dictionary to the WordNet semantic nodes is complete, further methods can be applied to enrich the resulting skeleton structure.

One way is with the aid of the *Magyar Szókincstár* thesaurus. With semantic disambiguation to decide which sense of a word the synonyms express, synonyms can be added to the Hungarian-English synsets. Antonyms to Hungarian words can also be added (antonymy is a lexical relation, therefore pre-existing WordNet antonym links cannot be used).

Daudé et al. (1999) describes a method for mapping multilingual hierarchies to WordNet using the relaxation labeling algorithm. Mapping the extracted Hungarian taxonomy to the Hungarian core structure using WN would provide the Hungarian WordNet with glosses, in addition to further synonymy and holonymy links.

4. Conclusion

In this paper we have described several methods we are using for the creation of the Hungarian nominal WordNet. A combination of automatic and manual methods is used. The manual method relies on human experts, who are allowed to work independently, constructing the higher levels of the hierarchy. Automatic methods relying on the bilingual and monolingual dictionaries are used to link a basic set of Hungarian nouns to WordNet. A third group of methods, which depend on taxonomies extracted from the monolingual dictionary, supplements this process. Our approach relies on the assumption that WordNet's semantic structure should provide us with an ample framework supporting the initial phase of our work.
