Abstract

The analogy of a semantic network to hypertext has long been recognized, and a semantic network has been considered as a logical model of hypertext – especially for those hypertexts with typed nodes and links. Moreover, wordnets form the most representative type of semantic networks in the field of Natural Language Processing and semantics in particular. It is obvious that hypertext and wordnets share many common points regarding their fundamental principles and the objectives towards which they both aim. In particular, they are both targeted towards capturing relations that possibly exist between objects and thus providing information of the underlying objects via various types of links used for describing the relations. In this respect, we strongly believe that if semantic networks are viewed beyond strictly linguistically constraints and applications, the results could only be beneficial.

1. Introduction

Hypertext[1] has always been closely related to the idea of freedom to associate, making it to be considered as an alternative means of structuring information. This new promising field provides its users (namely, authors and readers) with effective ways of presenting and exploring information. For authors, hypertext systems offer a high degree of flexibility for connecting pieces of information and presenting it as an assembled collection in an information network. For readers, hypertext provides tools for navigating in these information networks and for exploring them freely. Therefore, hypertext can be a precious dialogic means, facilitating the organization of information according to the user needs.

On the other hand semantic networks form a highly structured linguistic resource enabling a flexible navigation through the lexical items of a language. Wordnet forms a kind of conventional dictionary where semantic information of the terms it contains is represented. The main structural entities of wordnets are language internal relations through which words are linked based on their semantic properties. The main contribution of wordnets in lexicography is the systematic patterns and relations that exist among the meanings that words can be used to express. In this respect wordnets as a particular type of semantic networks resemble much hypermedia as far as the structural organization of information is concerned.

The paper is organized in the following way. Section 2 provides a brief overview of structure in semantic networks. In section 3, we reason about the ability of hypertext to structure information. Section 4 focuses on the similarities that hypertext and wordnets share, claiming that semantic networks can be viewed as hypertext. Finally, section 5 refers to the benefits that these two research areas may have if they are seen as a whole.

[1]Initially, hypertext dealt only with the manipulation of text. Nowadays, one can shape information structures containing pictures, video, sound, etc. Hypermedia – a contraction of the words *Hypertext* and *Multimedia* – is a name invented to stress this change of emphasis.

2. Structure in Semantic Networks

Wordnets form the most representative type of semantic networks in the field of Natural Language Processing and semantics in particular. Motivated by theories of human knowledge organization, wordnet emerged as a highly structured language repository, where words are defined relatively to each other. Unlike machine-readable dictionaries and lexica in book format, wordnet makes the commonly accepted distinction between conceptual-semantic relations, which link concepts and lexical relations, which link words (Evens, 1988). Thus, despite their resemblance to typical thesauri, wordnets in general clearly separate the conceptual and the lexical levels of language, and such a distinction is reflected via semantic-conceptual and lexical relations that hold among synsets and words respectively. Wordnets form semantic dictionaries that are designed as networks, partly because representing words and concepts as an interrelated system seems to be consistent with evidence for the way speakers organize their mental lexicons (Miller, 1998; Kay, 1989).

Wordnets' hierarchical structure allows a searcher to access information stored in lexical chains along more than one path, semantics being among them. Conceptual structures are modelled as a hierarchical network enabling a graphical representation of the lexicalized concepts when the latter are denominated by words (Priss, 1998). The theoretical analysis shows dependencies among semantic rela-

tions, such as inheritance of relations from sub-concepts to super-concepts. Therefore, related senses grouped together under the same lexical chain form preliminary conceptual clusters. Words belonging to the same lexical chain are connected via language internal relations, each one denoting the type of relation that holds among the underlying word meanings. Some of the language relations are bi-directional in the sense that if a link holds between term A and B then a link also holds between term B and term A. However, bi-directionality of the relations strongly depends on the language particularities and semantic properties of the underlying word meanings.

In order to account for particularities in lexicalized concepts, tags are assigned to each lexical relation denoting specialized semantic characteristics of a word's meaning. Tags can be viewed as a means of semantic constraints posed upon semantic relations that link word meanings rather than word forms. Moreover, tags provide information about which of the semantic properties represented in a lexical chain are inherited to its components. In this respect, words represent an atomic and unbiased level of individuality that becomes meaningful via anchoring of semantic relations. As Hasan (Hasan, 1984) pointed out, any word in a chain can be related to multiple other words in that chain. All lexical relations form a graph where cycles are disallowed since after all they contribute very little of any new information.

Summarizing, the structure of lexical data within wordnets is what differentiates the latter from traditional lexicographic aids (both dictionaries and thesauri). The motivation behind construction semantic networks in the form of a graph relies on the fact that lexical data becomes meaningful only via predefined linguistics structures. Navigation through the content of wordnets becomes feasible via language internal relations, which form the main notion around which structure is defined.

3. Hypermedia Principles of Structure

The term of hypertext cannot be explicitly defined since one can approach it by different directions. More specifically, there are those who claim that hypertext can be viewed as an interaction paradigm, referring to the manipulation of "pointing at a link and clicking it" in order to follow it. Additionally, there are others maintaining that "hypertext deals with the organization of information", regarding not only data but also structure as first-class user abstractions. Finally, there is another user group that considers "structure more important than data", making hypertext more structure-based technology than data-dependent.

Adopting the "primacy of structure over data" (Nürnberg et al., 1997), hypertext can be seen as a technology well suited to exploring different kinds of representational structures (Marshall, 1987). Viewing different parts of information as objects, users, often referred to as readers, can navigate through it in a more effective and convenient fashion. Additionally, authors can manipulate information according to their needs (Kyriakopoulou et al., 2001). Therefore, hypertext can be regarded as an informal mechanism, which describes the attributes of these objects and captures relationships that possibly exist between them. Such a characteristic made hypertext become known as an alternative way of structuring information.

Autonomous units of data (e.g. text, images, etc.) can be connected non-linearly creating a structure that has the form of a graph. Apparently, such type of organization and representation of information benefits not only the readers but also the authors, each one by their own point of view. More specifically, readers can retrieve the information they want in the right order serving more easily their particular needs, whereas authors can organize their ideas more efficiently by creating relationships (links) between parts of data (nodes). Thus, hypertext can be a precious dialogic means that offers more flexibility and the freedom of choice to the users according to their preferences, the level of comprehension, and other determined factors.

The analogy of a semantic network to hypertext has long been recognized (Conklin, 1987), and a semantic network has been considered as a logical model of hypertext – especially for those hypertexts with typed nodes and links. As it is widely known, a semantic network is a knowledge representation scheme consisting of a directed graph in which conceptual units are represented as nodes, and relations between the units are represented as links. The graph becomes semantic when each node and link is assigned a particular type, making it meaningful. The essential idea of semantic networks is that the graph-theoretic structure of relations can be used for inference as well as understanding (Lehmann, 1992). In this paper we claim that semantic networks may be profitably viewed as hypertext.

Trying to model different user needs in hypertext, the notion of domain appeared, defining special structural abstractions with specific properties as well as a set of behaviors. The role of structural abstractions is to capture and generalize the knowledge of different problem domains, whereas behaviors are described as computation over structure which is considered as a crucial parameter for the semantic of hypertext structure (Leggett and Schnase, 1994) (see table 1). For example, the idea of taxonomic domain was coined by biologists wanting support for the task of creating taxonomies of the species they were researching (Nürnberg et al., 1996). Similarly, within the last decades, various domains, such as navigational (Halasz, 1987), spatial (Marshall et al., 1994), argumentation (Conklin and Begeman, 1987), etc., have emerged. Since semantic networks and hypertext are closely related, the former ones may be considered as a new domain. The issue in hypertext upon the introduction of a new domain is not to express the domain structure using some general model of structure, but to provide users with domain specific structure to directly work with.

Taking the aforementioned into consideration, it is inferred that the need for domain existence in hypertext is essential. Towards the better exploitation of the properties provided by a particular domain, tools can be developed in order to utilize these specific structures. In this way, users can have the opportunity to work with these tools in order to perform syntactic and/or semantic checks, and maybe to perform structural computations that are only relevant within the domain. Therefore, semantic networks can possibly take advantage of these features improving the infor-

Domains	Structural Abstractions	Behaviors
Navigational	node, link, anchor	follow link, generic links
Taxonomic	taxonomy, taxon, specimen	open taxon, compare, auto generate, detect double categorizations
Spatial	item, space, implicit structure	spatial parse
Argumentation	issue, position, evidence	support link, oppose link, circular argument detection
Wordnet	synset	?

Table 1: Example domains in hypertext.

mation management and graph organization.

4. Approaching Wordnet via Hypermedia

Hypertext and wordnets share many common points regarding their fundamental principles and the objectives towards which they both aim. In particular, they are both targeted towards capturing relations that possibly exist between objects and thus providing information of the underlying objects via various types of links used for describing the relations. Therefore, the main characteristic of wordnets and hypertext systems is the ability to create associations between semantically related information items. On the one hand, these associations imply purposeful and important relationships between associated materials, whereas on the other hand the emphasis upon creating associations stimulates and encourages habits of relational thinking of the user (Landow, 1987).

Relations form the notion around which both semantic networks and hypertext are organized. In the case of semantic networks, relations are denoted explicitly between the lexical units they contain via predefined lexical links, and capture information on the semantic properties of words. In the case of hypertext, although the notion of association can be met in all hypertext domains, the navigational domain with the use of *links* is more closely related to it. Consequently, lexical relations form the fundamental entity of semantic networks the same way as associations in hypertext form the basic structural element around which domains are modeled.

In both cases, information objects (either lexical or not) are heavily structured in order to enable users of wordnets or hypertext navigate through the information they contain successfully. Structure is achieved via internal links, which form the basis on which information is stored and expressed. However, links in semantic networks and hypertext are until recently viewed as two distinct elements and no attempt has been made towards comparing the two. We report on the similarities that exist between hypertext relations and semantic links in an attempt to model the latter in hypertext systems.

In order to support this linking activity in an effective way, hypertext researchers have created a flexible link structure incorporating different levels of functionality. More specifically, in hypertext one can create single or bi-directional links, binary or n-ary links, links to links, automatically activated links, etc. Similarly, links in wordnet are bi-directional and there is generally no restriction on the number and types of links they could be included in it as long as the relatedness between the information items is properly and adequately expressed. Bi-directionality of links indicates that if an object A is somehow related to an object B then object B is again related via the same or another relation to the object A.

However, since bi-directionality might not always be the case in wordnets, special tags need to be attached to the relations to denote their single direction. Namely, tags are being used on semantic network relations to indicate that a lexical item is related to another via a particular type of link but not vice versa. Tags are attached to each link separately and act like constraints on the information provided by the link. However, in the case of hypertext, due to the existence of many specialized domains, the notion of tags is used implicitly.

Furthermore, besides creating associations among semantically related information items, another characteristic shared between hypertext and semantic networks is inheritance. This feature implies that properties of the father are inherited to the children. More specifically, the notion of generalization and specialization forms the principle on which relations are expressed. Specialization and generalization define a containment relationship between a higher-level entity set and one or more lower-level entity sets. Specialization is the result of taking a subset of a higher-level entity set to form a lower-level entity set, whereas generalization is the result of taking the union of two or more disjoint (lower-level) entity sets to produce a higher-level entity set.

Inheritance in wordnets is described via the *H/H tree* that is the complementary hypernymy/hyponymy relations. This type of relationship between objects result in viewing wordnets like tree-structured sources of information, and thus not allowing circular loops. As far as hypertext is concerned, these organizational structures exist in the taxonomic domain under the respective terminology of *supertaxon* and *subtaxon*. The subtaxon is associated with the supertaxon via an "is-a" relationship, inheriting all the characteristics that the latter might have. In particular, the user can classify objects (known as specimens) into sets according to their features, search within the members of a set to find relationships or discreet subsets, and create new sets from the already existing ones.

Finally, what should be stressed is that semantic networks and hypertext, despite the characteristics they have in common, they also have quite a few differentiations, mainly stemming from their applications and usage. What we at-

tempted in this paper is to explore the usefulness of both wordnets and hypertext systems beyond the limitations imposed by the applications at which they are targeted. What we claim is that by treating wordnet, as a new domain of hypertext would result in a better understanding of the language structure and consequently human memory and way of thinking. After all, any application is targeted towards human beings and aims at providing a clear description of how information is stored and thus how it should be interpreted. In this respect we strongly believe that if semantic networks are viewed beyond strictly linguistically constraints and applications, the results could only be beneficial.

5. Discussion

As it has been already mentioned, the technology of hypertext is not mainly used for the organization of information but can be considered as a significant means of structuring information. Viewing semantic networks as hypermedia, the power of hypertext is enforced even more, making us infer that any kind of information can be structured under the fundamental characteristics of hypertext. Furthermore, some special structural characteristics of semantic networks can be effectively exploited by hypertext community, resulting in the extension of already existing domains, such as taxonomic, navigational, etc. More specifically, tags might be such a characteristic, providing the hypertext users with the ability to pose semantic constraints upon relations, enabling the distinction among different types of whichever kind links.

On the other hand, taking advantage of the structural characteristics of hypertext while developing semantic networks can prove quite beneficial for both the lexicographic and linguistic communities. In particular, hypertext provides ways of organizing information stored in such systems in a meaningful way so that navigation through the stored data is facilitated. By adopting structures implied by the hypertext community in other applications such as lexicography, the potential and performance of the latter can be greatly improved. When it comes to the storage of lexicographic data the need for efficient structures becomes apparent due to the large amount of information that has to be handled and especially due to the dynamic nature of the underlying information. Moreover, even if behaviors exist in wordnets, they haven't been explicitly defined so far, resulting in less comprehensive usage of the underlying data.

Language forms the mean through which communication is achieved and as such its processing undergoes through various structural decisions that need to be taken prior to storing and incorporating lexicographic data in applications. In this paper we attempted a preliminary comparison among structural characteristics of semantic networks with hypertext and as a conclusion we claim that the abovementioned areas share a few common points in terms of data representation, storage and navigation. What we imply is that semantic networks and hypertext are by no means equivalent in terms of structure. Conversely, what we suggest is that by tracing points between the two and by adopting structural characteristics of other domains can only be beneficial for both sides.

Abstract

This paper addresses the need for domain-specific resources in NLP applications. The motivation for this work emerged from the current limitations of WordNet when the latter is adopted in a domain-specific applications and environments. Moreover, we report on methods and techniques for extending and tuning WordNets for domain-specific usage. We envisage a unifying WordNet structure, that will be easily extendable and customizable and also has the ability of incorporating other lexical and semantic resources with minimum effort. Finally, we discuss on the advantages of a unified WordNets structure over various types of applications that require extensive usage of NLP applications.

1. Introduction

Lexical resources used in natural language processing have evolved from handcrafted lexical entries to machine-readable lexical databases and large corpora. Much effort is being applied no the creation of electronic lexicons and electronic linguistic resources in general. However, the above resources are expensive to build, and instead of creating new ones from scratch, it is preferable to adjust and extend existing ones.

One linguistic resource of great interest is WordNet (FellBaum, 1998). WordNet is a general-purpose concept ontology, which has been developed a Princeton University, and resembles the way that humans store and organize information in their memory. It can be used both as an on-line dictionary or thesaurus for reference purposes, and as a taxonomic lexical database. WordNet is a resource of high quality and is freely available over the Internet, thus it has rapidly become one of the most widely used tools in language engineering, research and development.

However, as many technical words or word meanings cannot be found in general semantic databases such as WordNet, Natural Language Processing (NLP) in specific domains requires specialized semantic lexica. A major difficulty in using WordNet or any other general NLP resource in a specific domain is that much of the specialized semantic attributes (terminology, semantic relations, domain-specific relations etc) of the domain is not present. In this paper we describe the requirements of domain-specific wordnet development. First, we describe shortly the application usage of wordnet. We then explain the need for domain-specific NLP resources. Next we present techniques and methodologies that are used till now for the development of domain-specific wordnets. Finally, we present our approach towards developing domain-specific wordnets. Finally, we outline some early conclusions regarding the necessity for building domain specific WordNets and their usefulness in various applications.

2. WordNet applications

WordNet has been identified as an important resource in the human language technology and knowledge processing communities. Its applicability has been cited in many papers and systems have been implemented using WordNet. Almost every NLP application nowadays requires a certain level of semantic analysis. The most important part of this process is semantic tagging: the annotation of each content word with a semantic category. WordNet gives a solution to the above problem and has been used in various applications including Information Retrieval, Word Sense Disambiguation, Machine Translation, Conceptual Indexing, Text and Document Classification and many others.

3. Need for domain-specific resources

A problematic issue is that general semantic resources like WordNet do not cover many terms and concepts specific to certain domains, and also include many unnecessary (general) concepts and relations. Therefore these resources need to be tuned to a specific domain at hand. This involves selecting those senses that are most appropriate for the domain, as well as extending the sense inventory with novel terms and novel senses that are specific to the domain (Buitealar, 2001; Turcato et al.,2000). Another problem is that in a specific domain only a subset of the semantic relations defined in the general semantic resource hold. Also many technical words or word meanings cannot be found in general resources. Partial overlaps can be found, but the domain specific description is likely to be more precisely defined and reliable.

As a result of these difficulties with existing generic resources, NLP system builders have tended to handcraft resources for each application domain, or have looked at techniques for automatically or semi-automatically constructing lexicons of various sorts from texts in the domain.

The main problem is how can we develop domain-specific resources either from scratch or by using existing resources with minimum effort.

There are two main problems. The extension/expansion of existing general resources and the

adaptation of these resources to a specific domain and how can we acquire the above with minimum effort. In particular, the first problem regarding extending already existing lexicographic resources with domain-specific terminology requires a lot of manual work since additional information needs to be attached to the contents of the resources emerging from the underlying domain of interest. This would imply that large corpora from various terminological domains should be used in order to perform a semantic annotation of the terms they comprise of. In the second case, adapting existing resources toi particular applications would require not only enriching those resources with specialized terminology but it would also need partial restructuring of the resource so that the new content is sufficiently represented in a meaningful way.

In the case of wordnets the solution that implies the development of domain specific semantic networks seems as the best way of solving many problems imposed by the lack of such resources from various NLP applications. In the following sections we briefly report on the work conducted so far in this area and we continue with a description of our approach towards the necessity of domain specific terminological resources.

4. Building Domain-Aware WordNets so far

It is obvious from the above how important is the need for domain-specific NLP resources in general, and particularly for domain-specific wordnets. Several methods for the creation of domain-specific resources have been applied ranging from:

- Creation from scratch, to
- Data Extension of generic WordNets for a specific domain and
- Structure Extension of generic WordNets for a specific domain.

More specifically, the methodology adopted for each of the abovementioned techniques is described as follows:

4.1. Creation from Scratch

One solution, and apparently the most costly, is to handcraft domain-specific wordnets from scratch for any specific-domain. Building wordnets by hand requires significant amount of time and effort even for restricted domains. Furthermore this effort is repeated when a system is ported to another domain. The above leads us to automatic or semi-automatic approaches for building wordnets and other NLP resources using already available existing generic resources.

4.2. Data Extension of generic WordNets for a specific domain

The adaptation of existing resources to a specific domains includes selecting those terms and meanings that are relevant for the domain, adding new terms and meanings that are missing from the existing resource, removing relations that are irrelevant or incorrect in the specific domain, keeping relevant relations and adding missing ones (Buitelaar & Sacaleanu, 2001,2002;Turcato et al.,2000).

4.3. Structure Extension of generic WordNets for a specific domain

Another solution to the problem is to extend existing generic wordnet structure incorporating in it semantic distinctions from external resources such as ontologies, semantic taxonomies, domain-specific corpora etc. One approach is to add an ontology layer, which refers to specific domain attributes and characteristics and thus relates the domain with the linked concepts (Vossen, 1998; O'Sullivan et al., 1995). Another way is to link concepts with relevant document collections or corpora and find a way to compute the weights of their topic signatures (Agirre et al., 2001). Automatically build an hierarchy of terms using terms extracted from documents of a specific domain, combine it with existing hierarchies in wordnet and by fusing and clustering we can derive a condensed tree that has maximum coverage due to the extension, but only contains distinctions and classifications that are relevant and desired (Vossen, 2001).

There have also been attempts to integrate the information of generic lexical databases with existing ones (Magnini & Speranza, 2001).

5. What is missing from WordNet?

The success of WordNet has determined the emergence of several projects that aim the construction of WordNets for other languages than English or to develop multilingual or specialized WordNets or to extend existing WordNets for specific domains or to incorporate WordNet in various NLP applications. Through these attempts many WordNet's advantages have been discovered and some weaknesses have appeared. According to *(Harabagiu et Al. 1999)* the main weaknesses of WordNet cited in the literature are:

1. The lack of connections between noun and verb hierarchies.
2. Limited number of connections between topically related words.
3. The lack of morphological relations.
4. The absence of thematic relations/ selectional restrictions.
5. Some concepts (word senses) are missing.
6. Since glosses were written manually, sometimes there is a lack of uniformity and consistency in the definitions.

Until now there has been a lot of research for methods and techniques for WordNet development, customization, multilinguality, alignment with existing resources etc. However all the attempts concentrated on everything that was related to the content of WordNet and WordNet's lexical and semantic coverage, leaving behind everything that is related to the data model of Wordnet and WordNet's structure (the way that WordNet's data are stored and manipulated).

From a WordNet's developer perspective the main disadvantage of WordNet is that WordNet is almost a black box. The WordNet community is increasing year by year, but till now there are no standards about WordNet structure. With a standard WordNet structure and all the methods and techniques that are already available for WordNet construction, extension, alignment with other NLP resources and link with other language WordNets will road the map for a new perspective towards wordnets and their usage in every day NLP applications.

6. Requirements for Domain-Specific WordNets

In this section we describe the requirements that a domain-specific WordNet must satisfy. Many of these requirements are also addressed to generic WordNets.

One key point is the integration of domain-specific wordnets with generic ones. On the one hand the domain-specific wordnet is a specialized resource, whose content is supposed to be more accurate and precise for the domain that it was designed; on the other hand, the generic wordnet guarantees a more uniform coverage as far as high level senses are concerned. There must be a flexible and modular integration procedure, which will give the ability many domain-specific wordnets to co-exist with one generic one. This procedure shall manage inconsistencies and overlaps between the different resources. Co-existence of lexical resources that are targeted towards various domains has many advantages.

First and foremost, it enables the comparison of concepts used in both genetic and domain specific vocabulary. ,It can also contribute towards the ease identification of the domain in which a concepts belongs to. However, the most important feature of such resources is the potential of using a domain specific semantic resource for various types of applications. The latter results in a global lexicographic resource of great usefulness in many tasks and applications.

A problematic issue in the field of NLP is that it does not often suffice to depend on any single resource , either because it does not contain all required information or the information is not organized in a way suitable for the purpose. So merging of different resources is necessary. Many different NLP resources are available to the NLP community e.g. corpora, morphological lexicons, semantic lexicons, ontologies. Many applications will benefit from the integration of such resources with WordNet (Kwong, 1998). So there shall be a flexible structure that will provide fully-automatic or semi-automatic mechanisms for the incorporation of such resources in WordNet.

WordNet has been criticized for its lack of relations between topically related concepts. The enrichment of WordNet's concepts with topic signatures and the application of topic relations open the avenue for interesting ontology enhancemenrs, as they provide concepts with rich topical information (Agirre et al., 2001). For instance, similarity between topic signatures could be used to cluster topically related word meanings. Word sense disambiguation methods could profit from these richer ontologies, and improve word sense disambiguation performance.

WordNet's concepts shall be enriched with additional semantic and non-semantic attributes. Some of these attributes may be word usage examples, words that accompany a concept in a specific meaning, morphology information, domain-specific information about the concept. For example if we meet the word 'world' with the meaning of 'people' we cannot find this word in plural. The above attributes may also be links to corpora or other incorporated resources. By the same way attributes shall be applied to relations, too. For instance some relations may exist under certain constraints in a domain-specific context, and there must be a way of identifying domain-specific relations that do not exist in generic or in other domain contexts, or generic relations that are also applied in domain-specific context. One such examples concerns the application of wordnet during language teaching tasks in which phonetic information could be added.

The WordNet structure shall be organized in a way that will allow the insertion of additional relations between concepts, additional attributes both for concepts and relations and constraints both for attributes and relations without affecting existing data and with a way that will be as easy and effective as possible.

Another feature that shall be made available to WordNet is the definition of the behavior of relations regarding the domain that the wordnet is designed for and the application usage of the WordNet. Following this approach different applications in a specific domain have the ability to share common data. This means that if somebody developed a domain-specific WordNet for domain A in order to use it in his document classification application and another one plans to develop a query expansion system for an information retrieval application he can use the already developed WordNet in the same way only by changing for instance the behavior of the synonymy relation which will now be used for searching in documents with the synonyms of a given word. In other applications for instance the hyperonym relation may be used for getting more general word meanings than the given one and in other applications may define an upper-level category of classification of documents.

An Ontology Layer should be present on the upper level of the semantic features of a language for the transfer of domain specific semantic characteristics and distinctions relative to the domain to the underlying concepts. However, it might be more effective if the concepts belonging to the upper level had as additional features the abovementioned distinctions and thus all terms related to these inherit these distinctions and features. . The above resembles much the wordnet-type of information storage and representation and would result in a more flexible semi-automatic extraction and development of domain-specific ontologies based on wordnet information.

All the above leads us to the conclusion that there is an imperative need for a flexible and unifying WordNet structure. The whole WordNet community shall concentrate in the standardization process of WordNet structure. The structure must be able of defining concepts, relations, attributes for both of them, flexible linking with existing NLP resources and components. It also must be easily customizable and extendable, allow the co-existence of generic and specialized wordnets providing mechanisms for domain resolution and identification. Such an approach will make easier the process of multilingual wordnet linking and will also provide an unifying approach to any NLP problem that wordnet is called to solve. Since the research concerning wordnet itself and its applications has grown extremely in the past years a standard structure will just provide wordnet an easy and effective way in everything concerning wordnet from wordnet development to wordnet usage in NLP applications.

With the need of the standardization of structure comes the need for a wordnet protocol, which will describe all the operations, methods, functions that wordnet offers. The existence of a wordnet protocol means that everyone is free to develop wordnet in the way

they prefer even if it is relational databases, xml files, polaris format files, indexed text files etc, as long as they follow the pre-specified protocol.

The need for a unified structure is requested to solve problems related to wordnet extension as long as other problems emerging from wordnet applications ands need to be solved via a unified and common way. The main idea behind this assumption is the conversion of wordnets into a linguistic resource that would apply to as much as possible to ll members of the NLP community.

The need for a common protocol needs to be solved through a unification of the applications of the already existing wordnets. A common protocol applications envisaged for one monolingual wordnet (e.g. the English Wordnets) could be used in other monolingual wordnets without any previous change required in the structure or content of the latter. Of course this implies that in case one application performs sufficiently for a particular domain then its usage in another domain needs solely the existence of a wordnet for another domain and no extra effort towards structural or content modifocations.

7. Conclusion

We identified the need for domain-specific WordNets and presented some requirements that shall be met both by generic and specialized WordNets. WordNets success in the field of NLP can be even greater but to achieve this there must be standardization concerning both the structure and the protocol, which will be used by applications that use WordNet. This is a long way, and it must be walked with the right steps.

Notes about Labelling Semantic Relations in Estonian WordNet

Kadri Vider

University of Tartu,
Department of General Linguistics
Tiigi 78-204, 50410 Tartu, Estonia
kvider@psych.ut.ee

Abstract

Estonian language is rich in derivation. Most of derivational suffixes have their regular meaning(s) and is very obvious, that source and target words in derivation have regular lexical-semantic relations between them. The problem of what regular derivational suffixes in Estonian lexica cover what kind of semantic relations in Estonian WordNet is discussed in this paper.
Another problem of labelling connected with semantic relations is related to proper nouns. In purpose to use referential character of proper nouns in word sense disambiguation, we need to connect proper nouns with objects carrying the names e.g. 'John ISA man', but not 'John ISA first name'.

1. Introduction

Compilation of Estonian WordNet (EstWN) started in 1997 and the work is still in progress. The work was funded partly by the Estonian Science Foundation and partly in the framework of the Estonian National Programme of Language Technology. Like other wordnets, EstWN is a lexical-semantic database, the basic unit of which is concept. Concepts are represented as synonym sets (synsets) that are linked to each other by semantic relations. In 1998-1999 EstWN was created as a part of EuroWordNet (EWN) and since then we have used semantic relations from EWN, which are more flexible and richer than in the original (Princeton) WordNet. Still, our experience has shown that there are at least some language-specific semantic relations needed. Up to now, the usage of semantic relations was limited by the set provided by Polaris, the EWN editing tool.

Which new words or concepts should be concentrated on to upgrade the EstWN? It is essential that words actually used in text will be added. Results of word sense disambiguation (WSD) task of corpus texts turned out to be a good way of adding missing and new synsets and senses into our wordnet. (Kahusk and Vider, 2002)

Estonian is usually considered to be an agglutinative language, thus belonging to same group as Finnish, Hungarian and Turkish. It is flective language with free word order.

In order to reach the lemma in the text, Estonian needs morphological analysis. The program ESTMORF, in use at present, renders it possible to analyse the productive derivatives and tag suffixes.

2. Semantic relations in EstWN

The existing Estonian WordNet contains nouns, verbs, some adjectives and proper nouns, more than 10,000 synsets all together. The more detailed description of EstWN is given in the final document of EuroWordNet, Estonian part (Vider et al., 1999)

Semantic relation	**No. of links**
has_hyperonym/has_hyponym	19002
belongs_to_class/has_instance	948
near_synonym	354
xpos_near_synonym	246
has_holonym/has_meronym	234
antonym	209
be_in_state/state_of	186
near_antonym	138
involved/role	134
causes/is_caused_by	128
has_subevent/is_subevent_of	36
has_xpos_hyperonym/has_xpos_hyponym	12
xpos_near_antonym	4
xpos_fuzzynym	2

Table 1: Semantic relations expressed in EstWN in the order of frequency.

3. System of Estonian derivation

Wordnet is based on word meaning and from this point of view such lexical feature as derivation should not play a significant role. But a lot of Estonian derivational suffixes have concrete meanings and this fact can be applied in connecting the derivational base and the derivation with a definite semantic relation, dependent on the meaning of the derivational affix.

In Estonian, derivation is mainly a process of appending derivational suffixes, more than 60 altogether, to both declinable and conjugable words. Suffixes can be appended sequentially; up to four suffixes in a row can be appended in some cases. About 8% of the word forms in a running Estonian text are derived words; in journalism and scientific texts the figure is even higher (Kaalep, 1997).

Derivation, a frequent and productive way in Estonian for forming new words, is a process where adding an affix produces a new lexical item having its own inflectional

paradigm. Derivational morphology in Estonian is always connected with changing the meaning of lexeme. The lexical meaning of the derived word is different from the word used as the derivational base, in some productive cases the derived words belong to a different part of speech

Thus it may be concluded that affixes in Estonian belong to the category of semantics, not grammar. Morphologically derivation can be defined as the formation of a new stem by adding an affix to the last morpheme of the stem.

In Estonian, compounding is even more frequently used for word formation than derivation. Compound words comprise more than 12% of the running words in an average Estonian text. The formation of Estonian compounds is quite free and derived words may also constitute a compound. In this paper we consider only such kind of compounds.

We proceed from the assumption that in a lexicon compiled on the semantic basis the semantic association between the words derived from the same stem should be fixed. It should be possible to automate the relation on the basis of meaningful affixes. The question is which relation should be attributed to which affix.

Derived/derived_from/has_derived relations exist in EWN structure (Vossen 1999), but they are clearly too general and ambiguous for such a language abundant in regular and ample derivation as Estonian.

4. Suffixes actual in EstWN data

This chapter deals, first and foremost with the productive derivation types (formation patterns) that have an independent meaning, e.g.

VERB+**mine** – PROCESS[NOUN],

VERB+**ja** – ACTOR,

PLACE[NOUN]+**lane** – INHABITANT

Lexicalised derivation also has quite a clear relation with the derivational base. Only the idiomised derivations have lost the distinct relation with the derivational base (Kasik 1996).

4.1. Verb suffixes

4.1.1. Verb -> Verb derivation

Most frequent verb suffix in Estonian is **-ta**, which has a causative meaning in verb-to-verb derivation, e.g. kulu/ta/ma (spend, expend) *causes* kuluma (go, be spent); levi/ta/ma (distribute, cause to spread) *causes* levima (spread, be disseminated); liigu/ta/ma (cause to move) *causes* liikuma (move); kao/ta/ma (lose, fail to keep) *causes* kaduma (disappear, vanish, get lost); meenu/ta/ma (remember, retrieve, recall, remind) *causes* meenuma (be reminded); kuiva/ta/ma (dry, make dry) *causes* kuivama (become dry); sünni/ta/ma (birth, give birth) *causes* sündima (be born); nõrges/ta/ma (weaken, make weak) *causes* nõrge/ne/ma (weaken, get weak); aren/da/ma (develop, evolve) *causes* are/ne/ma (evolve, undergo an evolution); puru/sta/ma (break, cause to break) *causes* puru/ne/ma (break, separate, be smashed); rahu/sta/ma (calm, make calm) *causes* rahu/ne/ma (calm, be pacified, become stable); unu/sta/ma (forget, fail to remember) *causes* unu/ne/ma (pass out of mind, be forgotten).

Productive verb suffix **–u** constructs intransitive verbs with reflexive meaning, eg. aeglus/ta/ma (retard) - aeglust/u/ma (slow, become retarded); asen/da/ma (substitute, replace) - asend/u/ma (be replaced); eral/da/ma (separate, divide) - erald/u/ma (separate from); eru/ta/ma (stimulate, shake, excite) - erut/u/ma (become excited about); eten/da/ma (perform, give a performance) - etend/u/ma (play, be performed); kahjus/ta/ma (damage, do harm) - kahjust/u/ma (be damaged); katma (cover) – katt/u/ma (be covered); kuhjama (heap, pile, stack) - kuhj/u/ma (be heaped, be piled); moodus/ta/ma (form, constitute) – moodust/u/ma (be formed, be constituted).

The most important derivation in this group is muutma (*change, alter, make different*) - muut/u/ma (*undergo a change, become different*). The source verb of derivation needs an active agent, but it does not render passive or *is_caused_by* meaning to the verbs with reflexive u-suffix. Lexical expression of passivity is not characteristic of the Estonian language. As to Estonian (perhaps French and German as well) reflexivity is one of the missing semantic relations in the EWN verb structure.

4.1.2. Noun -> Verb derivation

The most common semantic categories in derivations of this type are CAUSE, CHANGE, USE, ADD. Verb arguments behave in this case as derivatives, e.g. RESULT, ACTOR, INSTRUMENT. They all hold subtypes of *involved/role* relation. Often such arguments can be met in synonymous phrases or idioms, e.g. kirju/ta/ma, kirja panema (*write, write down, directly "put into letter"*).

(1) Productive suffix **-ta** and its variant **-sta** have factitive meaning, i.e. one of the arguments of the derived verb is the source of derivation as well. The semantic relation between the verb and its derivational base belongs, in this case, to the subtype of *involved/role* relation, e.g. huvi/ta/ma (interest, cause to be interested) *involved* huvi (interest); avar/da/ma (enlarge, expand, extend) *involved* avar (spacious); elav/da/ma (enliven, liven) *involved* elav (living, alive); nalja/ta/ma (joke, jest) *involved* nali (wit, humour, joke, jest); ahel/da/ma (chain) *involved* ahel (chains, chains); halven/da/ma (make worse, worsen) *involved* halb (bad)

(2) Suffixes **–u** and **–ne** have translative meaning. They present autonomic CHANGE (of state or situation); e.g. korts (wrinkle, fold, crease) – korts/u/ma (wrinkle, ruckle, crease, crinkle, scrunch) kõva (hard, firm, solid, stiff) – kõvast/u/ma (harden, indurate, solidify); kõver (crooked, bent, curved) - kõverd/u/ma (curve, crook, bend); külm (cold) – külm/u/ma (freeze, change to ice); lahus (solution) – lahust/u/ma (dissolv, resolve); niiske (damp, moist) – niisk/u/ma (moisten, dampen); puit (wood) – puit/u/ma (turn into wood, lignify); raev (rage, fury)- raev/u/ma (become furious, see red); rasv (fat, lardy) - rasv/u/ma (fatten, batten, grow fat); rohi (grass) - roht/u/ma (overgrow with grass); suund (direction) – suund/u/ma (head, travel in a direction); kitsas (narrow) – kitse/ne/ma (narrow, contract); halb (bad) – halve/ne/ma (worsen, decline); harv (sparse, thin) – harve/ne/ma (thin out); kauge (far) – kauge/ne/ma (recede, move away)

Existential verbs, where derivation changes only the part of speech should be brought out as a separate group.

4.1.3. Modifying derivation

Derivations formed with the help of affixes modifying the verb have a hyperonym/hyponym relation with the derivational base, for the affixes mentioned above only modify the way of action. The best label for describing such a relationship is troponymy.

Frequentatives (expressing repetition of an action, e.g. hüppama (jump)- hüp/le/ma (hop, skip, jump lightly); mulks (gurgle) - mulks/u/ma (bubble up); tukse (throbbing) - tuks/u/ma (pulsate, throb, pulse); momentanes (express the singleness or suddenness of an action, e.g. tuks/u/ma (pulsate, throb, pulse) - tuks/ata/ma (give a throb)) and continuatives (show the continuity and permanence of an action, e.g. mängima (play) - mängi/tse/ma (dally, trifle, play)) can be differentiated by the affixes.

4.2. Noun suffixes

In case of argument-nominalization the derivative is expressed in the function of one argument of the derivational verb. The more widely-spread arguments include ACTOR, RESULT, INSTRUMENT, OBJECT, PLACE.

4.2.1. Action derivatives

The suffix of absolute productivity **-mine** changes only the part of speech of the derivational base. With the help of this suffix every verb can be changed into a noun, which has cross-part of speech synonym relations, e.g. alustama (begin, start, commence) *xpos_near_synonym* alusta/mine (beginning, start, commencement); harjutama (drill, exercise, practice) *xpos_near_synonym* harjuta/mine (practice session, exercise).

Abstract and metaphorical meanings of the verb should not be bound to the suffix **-mine** but only the ones expressing a definite action.

Due to absolute productivity we have included only such mine-derivatives in the EstWN that were founded in corpus texts.

4.2.2. Personal derivatives

Actor's suffix **–ja** is also a very productive suffix, the application of which is universal for all kind of action, e.g. ehitama (build, construct, make) *involved_agent* ehita/ja (builder, constructor); esindama (represent, be a delegate for) *involved_agent* esinda/ja (representative); juhatama (head, lead) *involved_agent* juhata/ja (leader); kasvatama *involved_agent* kasvata/ja, koristama *involved_agent* korista/ja, kütma *involved_agent* küt/ja, laulma *involved_agent* laul/ja. Some of the ja-derivatives can besides the live agent also express appliances, e.g. ajamõõt/ja (timekeeper); voolumõõt/ja (ammeter); raadiosaat/ja (radio transmitter).

The most productive affix in forming generic names from proper names is **-lane**. The biggest group of lane-derivatives refers to persons by their origin, e.g eest/lane (Estonian); ameerik/lane (American); hiin/lane (Chinese); indiaan/lane (American Indian).

Terms of biological taxonomy form another big group, which could be formed with the help of suffixes **-lane** e.g. kass (cat) - kas/lane (feline, felid); koer (dog) - koer/lane (canine, canid); and **-line**, e.g. kabja/line (perissodactyl mammal); kiletiiva/line (hymenopterous insect); kõrre/line (graminaceous plant).

A productive affix in forming business titles is **-ur**, e.g. kaevama (dig) - kaev/ur (digger, miner); kala (fish) - kal/ur (fisher, fisherman); juus (hair) - juuks/ur (hairdresser); valvama (protect) - valv/ur (defender, guardian, protector).

Feminine suffixes **-nna, -tar** are also productive, e.g. luuleta/ja (poet) - luuleta/ja/nna (poetess); sõber (friend) - sõbra/nna, sõbra/tar (girlfriend). Estonian morphology lacks feminine markers, feminine suffixes exist only in noun derivation. The problem is not new, as in his first papers about EWN-1 Vossen declared that the semantic category WOMAN got lost in converting the Vlis (Dutch) database relations into EWN ones.

4.2.3. Place and set derivatives

All **-la** derivatives refer to a place and indicate a specific place (building, room), e.g. haige (sick person, sufferer, patient) *involved_location* haig/la (hospital); levima (spread, be disseminated) *involved_location* levi/la, parkima (park) *involved_location* park/la (parking lot, car park); suvitama (summer) *involved_location* suvi/la (summer house); sööma (eat, take in) *involved_location* söök/la (lunchroom, eating house).

-kond is a productive suffix expressing collectivism, e.g elanik (inhabitant) *has_holo_member* elanik/kond (population); inimene (human, man) *has_holo_member* inim/kond (humankind, mankind); võistleja (contestant) *has_holo_member* võist/kond (team, squad).

Apart from the kond-suffix, suffix **-stik** refers to the group or set of things or fenomena, e.g. kõrge (high) *has_holo_member* kõrgu/stik (highland, upland); leht (leaf) *has_holo_member* lehe/stik (leafage); mägi (mountain, hill) *has_holo_member* mäe/stik (mountain range); nimi (name) *has_holo_member* nime/stik (list, listing); rahvas (people) *has_holo_member* rahva/stik (population); seade (mechanism) *has_holo_member* seadme/stik (machinery, equipment); taim (plant, plant life) *has_holo_member* taime/stik (vegetation, flora).

4.2.4. Property derivatives

Productive suffix **-us** makes it possible to form property names from most of the adjectives, changing only the part of speech, e.g. intensiiv/ne (intense) – intensiivs/us (intensity, intensiveness); musikaal/ne (musical) – musikaals/us (musicality, musicalness); soola/ne (salty, salt) – soolas/us (saltiness, salt); keeru/line (baffling, knotty, problematic) – keerulis/us (complexity, complexness); lopsakas (buxom, chubby, plump) – lopsak/us (fleshiness, obesity); vürtsikas (hot, spicy) – vürtsik/us (spicery, spiciness)

Suffix **-ndus** forms abstract names of substances or fields of action from concrete nouns, e.g. kauba/ndus (commerce); kirja/ndus (literature); koka/ndus (cookery, cooking, cuisine); maja/ndus (economy); metsa/ndus (forestry); teeni/ndus (service); veondus (transportation, shipping).

4.3. Adjective suffixes

It is difficult to group adjective suffixes by meaning because most of the suffixes can express several

meanings. Very often it is dependent on the derivative base.

The adjectives formed from the nouns often convey a comparative or possessive meaning, e.g analoogia (analogy) – analoogi/line (analogous); kriitika (criticism, critique) – kriiti/line (critical); värv (colour) – värvi/line (coloured); kasu (use, good) – kasu/lik (useful); noorus (youth) – noorus/lik (youthful).

The EWN derivational relations *derived/has_derived/derived_from* and *pertains_to/is_pertained_to* are namely prescribed for adjective suffixes.

5. Semantic relations of proper nouns

The main inspiration for our WSD system *semyhe* is Agirre and Rigau (1996) similar system that disambiguates the English noun senses based on WordNet hyponym/hypernym hierarchy, taking into consideration the distances between the nodes corresponding to the word senses in the WordNet tree as well as the density of the tree (Vider and Kaljurand, 2001).

In order to improve the operation of the program, the density of the words, that will be disambiguated should be increased. Up to now proper nouns were left out of disambiguation and they comprised 30% of the 0-analysed nouns. As our WSD system uses EstWN, it is essential that proper names encountered in the texts be added to it. Fortunately the EWN database structure includes a type of entry meant for proper names — *word_instance*.

Hyponymy is a relation between classes of entities. Individual entities, presented in texts as proper nouns and in EWN structure as *word_instance* entries, can also be said to belong to some class. To distinguish this relation from hyponymy it is labelled *has_instance/belongs_to_class* in EWN (Vossen, 1999). It is good because it makes it also possible for the WSD system to find out referee among *word_meaning* entries. Thus WSD system can make more precise decisions about the right word meaning, because meaningful context is more dense. Therefore we added all proper nouns existent in the WSD training corpus to EstWN and linked *belongs_to_class/ has_instance* relation to *word_meaning* entries (see Table 1).

Now the question is which proper noun links to which *word_meaning* entry. It seems only natural to link e.g. capital *has_instance* Tallinn, river *has_instance* Volga. It is also possible to link e.g. male, male person *has_instance* John. But is it right to link family *has_instance* Smith, for family refers to a social group, not a person?

Most proper nouns listed in the EstWN refer to a person. The next group as to the frequency is toponyms that refer to a location or place (city, state, land, region) or natural objects (river, mountain, lake, island etc).

6. Conclusions

In the Estonian language derivation is not a feature of morphology. As to the richness of meaning of the Estonian derivation system, the semantic relations existent in the EWN and labeled as *derived/has_derived/derived_from* clearly too scarce. Making use of the recognizability of the suffixes, it is possible to link the derived words with the derivational base words (semi)automatically, specifying the semantic relation on the basis of the meaning of the derivational suffix.

Specifying the semantic relation of proper nouns is of vital importance to increase the conceptual density in solving the wordnet-based WSD task. One should only be careful and persistent in achieving the target concept.

Applied Linguistics Department, Philological Faculty, Saint-Petersburg University
Universitetskaya nab. 11, Saint-Petersburg, Russia
azic@bsr.spb.ru , asinopalnikova@yahoo.com, yav_mas@hotmail.com

Absract

The paper describes the on-going work on creating the WordNet-type lexicon for Russian, so called RussNet. The project started 3 years ago, preliminary results will be available at www.phil.pu.ru. The existing database contains verbs, nouns, and adjectives, the number of senses amounting to 2500.

The Top Ontology of RussNet is under construction, it will be co-ordinated with that of EuroWN. RussNet has inherited EuroWN language-internal relations. Several types of derivational links are added to describe Cross-Part-Of-Speech relations as well as Inner-Part-Of-Speech ones. Adjective-to-noun and verb-to-noun relations of words in collocations are described in details.

An overview of methods used for construction of the Russian WordNet is presented, the procedure of sense definition generation is also discussed.

1. RussNet Structure

1.1.Vocabulary

For the RussNet structure we accepted the general approach, presenting only **Standard Russian** lexis, as opposed to various terminological subsets. The position doesn't prevent us from including those terms that were incorporated into the common language.

On the one hand this approach follows Russian lexicography tradition and on the other hand allows us to provide first and foremost **frequently-used current** vocabulary, that will be exploited by the majority of users. The main sources for such words are newspaper and magazine articles.

1.2. Inherited Features in RussNet

- RussNet is structured along the same lines as Princeton WN, EWN (Vossen, 1998, Miller et al, 1993) and other wordnets: words are grouped into synonym sets (**synsets**), each representing one underlying concept.
- Synsets in their turn are linked by means of various **Language Internal Relations** (LIR), such as hyponymy/hyperonymy, antonymy, meronymy/holonymy, entailment, causation, etc., hyponymy/hyperonymy being the most important one.
- RussNet consists of **4 interrelated files** for basic POS: nouns, verbs, adjectives and adverbs. So far we dealt only with 3 of them, but later we are going to add adverbs as well.
- Each of the 4 files contains a number of hyperonymy trees, with concepts of top levels constituting so called **Top Ontology**.
- Now, we are elaborating mainly internal structure of Russian wordnet and are not dealing with **Inter-Lingual-Index** (ILI).

2. Synset Formation

There are two different ways to define synonymy:

- in terms of substitution
- in terms of semantic similarity.

Although in EWN the weaker notion of synonymy is adopted: «two words are synonyms if there is a statement (class of statements) in which they can be interchanged without affecting truth value», we have to combine substitution method with that of semantic similarity. The reason for such a decision is as follows: in Russian there are many words which are not interchangeable in a context because of the syntactic, stylistic, expressive differences, but they are considered by native speakers as having similar meanings, denoting the same objects, entities, etc., e.g. aspect opposition for verbs.

There are two types of synonymy dictionaries for Russian:

- New Explanatory Dictionary of Russian Synonyms (Apresjan et al.) is following the substitution strategy. The first issue of this dictionary was published in 1999, but so far it includes 132 entries only.
- Dictionary of Russian Synonyms (Evgenjeva,1970) & Explanatory Dictionary of Russian Verbs (Babenko, 1999) are based on semantic similarity.

Unfortunately, conventional Russian lexical resources may be used only partially because they don't cover all the lexis, the words definitions provided are made according to inconsistent patterns, and they may even obscure real semantic relations between words. That's why we can't simply import the data from those resources into RussNet without correcting it by means of our own lexical research procedures.

We begin with the collection of word senses for particular semantic groups of Russian words such as emotional verbs, nouns denoting the social relations and so on. The words realising the hyperlexeme sense were picked out from the sample of fiction or newspaper texts. A mean sample size ranges from 200 to 400 thousand word occurrences, from which about 150 core words and 70 peripheral words with appropriate senses were usually chosen. Having examined the synonymic relation in such groups we saw that words with the most abstract sense were encountered with relatively higher frequency and they would have synonymic equivalents. The hyponyms of the group were rare and may have derivational synonyms, but quite a few synonyms with different roots. So the collected words may be considered to be dominant representatives for respective synsets. Afterwards, extending the sample size or using synonymic information given in a conventional dictionary, we may expand synonymic sets with extra members.

3. Problems and discussion

3.1. Derivation

The Russian vocabulary, in particular verbs and nouns, is characterised by the high degree of derivation motivation. For example, dealing with verbs of thinking in Russian and English, we can see that there is about dozen of verbs with different roots in English (*to think, to contemplate, to consider, to regard, to reflect, to muse, to ponder, to cogitate, to meditate, , to conceive, to imagine, to picture etc*), and only 3 such items in Russian (*думать, мыслить, мозговать*), with a number of affixed derivatives amounting to 30 resultant verbs. Thus the total number of lexemes in Russian may be twice as much as that in English, while the situation with roots may be quite the opposite (Mitrofanova, 1999). From the point of view of frequency this causes specific distribution of lexical items in texts: it is rather flat in English in comparison with Russian sharp peak of frequencies for a hyperonym of this group *думать (think)* see Table 1, Table 2.

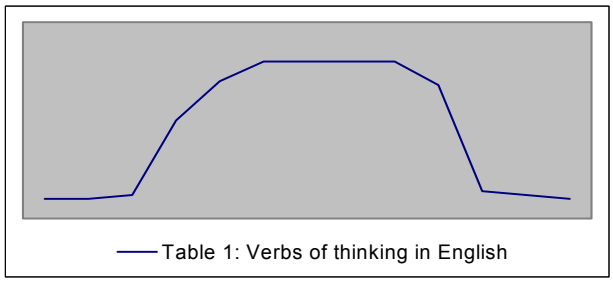

Table 1: Verbs of thinking in English

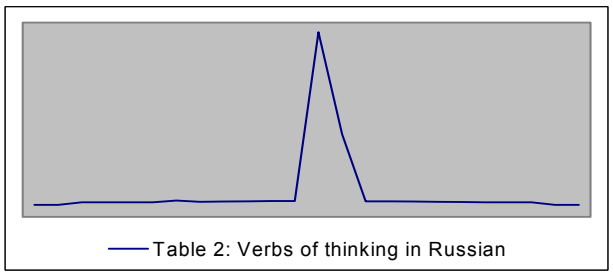

Table 2: Verbs of thinking in Russian

In many cases semantic relations between stem word and its derivatives couldn't be treated in terms of EWN Language Internal Relations (Vossen, 1998). They are more complicated: the main difficulty is that they are relations **between lexical items**, not synsets. Other reasons why we have to introduce new links are as follows:

- There are many almost **unlimited** derivational chains: verb denoting process => noun denoting the process => attribute denoting the relevance to the process => adverb denoting the changing quality and so on, e.g. *удивлять (to astonish, to surprise) - удивление (astonishment) - удивленный (surprised) - удивленно (surprisingly).*
- The important traits of these chains are, that derivatives may be used freely in **paraphrases**: the motivating item may substitute the motivated ones in syntactic transformations. For example, a Russian noun *проверка* (*a check*) is paraphrased as a denotation of the process expressed by Russian verbs *проверить, проверять, проверяться, проверяться (to check, to be checked)*. These links may be useful for syntactic analysis.
- **Lexical meaning** of derivatives is determined by that of the stem word.
- We would like to stress that verbal nouns inherit also the **syntactical** features of the motivating words. So if we describe the complex system of verb valences, they would be reproduced with little (and well known) changes by nouns denoting the same action or quality, on the one hand, and participants of action, on the other hand.

In those cases when it is possible we regard derivational relations in terms of LIR:

- **SYNONYMY -** relations between words which have the same root and different sets of affixes. They are not expressive and their senses differ so slightly that not every native speaker (researcher) is able to explain the distinction between them. Those words are also rarely interchangeable in the same context. *Семья – семейство (family), зло (malice) – злоба (malice, anger) – злость (malicious anger), бунтарь – бунтовщик (rebel, insurgent, mutineer, rioter), беда (misfortune, calamity) – бедствие (calamity, disaster).*
- **NEAR_SYNONYMY -** relations between
  - verb and abstract nouns, denoting processes of the same nature, e.g. *двигаться => движение (move => movement)*,
  - adjectives and abstract nouns, denoting characteristics and qualities, e.g. *красный => краснота (red => redness)*,
  - adjectives and nouns, e.g. гриб => грибной (fungus => relative to fungi)
  - verbs and adjectives, e.g. гнить => гнилой (rot => rotten).

In other cases we have to introduce a set of Derivational analogues of LIR, such as:

- **DERIVATIONAL_SYNONYMY** – relation between neutral words and their expressive derivatives. As those words differ from their stem word in style, they are not interchangeable in context, e. g. *старик (old man) => старикан, старикашка* (*impolite appeal to an old man), дом (house) – домик (house to which the speaker has positive emotions)*. Here we follow the idea, offered in Czech WordNet, of special attributes introduction. Thus *домик* will have X_EXPRESSES_ POSITIVE_EMOTION, while *старикашка* – X_EXPRESSES_IMPOLITE .
- **DERIVATIONAL_HYPONYMY** – verb-to-verb, noun-to-noun, adjective-to-adjective relations of following types. For verbs we may use
  - specific attributes X_HAS_INCHOATIVE or X_HAS_SPECIFIED_DURATION for actions restricted in time duration (inchoatives), e.g. *петь => запеть (to sing => to begin to sing), сидеть => посидеть (to sit => to sit for a while), сидеть => просидеть (to sit => to sit for a long time)*;
  - an attribute X_HAS_SPECIFIED_RECURRENCY for actions repeated only once or several times, e.g. *кричать => крикнуть, покрикивать (to shout => to shout out once, to shout not aloud many times);*
  - an attribute X_HAS_SPECIFIED_NUMBER for actions, having many objects involved, e.g. *думать - раздумывать (to think - to ponder about many things for a long time), резать - вырезать (to cut - to cut out some part from many things)*, and so on.

These special verbal derivatives interacting in a complex manner with an aspect category of verbs and having semi-grammatical nature. We still don't know in which manner to treat them, on the one hand, aspect pairs look like very

close synonyms, though on the other hand, they realise a very important semantic opposition, such as activity ⇔ action. We may introduce specific attributes, as follows: X_HAS_IMPERFECT, X_HAS_ PERFECT.

- For nouns and adjectives we may add attributes X_IS_SMALL and X_IS_BIG, and possibly several others, when the clear sense component is added by some affixes to the stem word meaning, and the resultant word couldn't be regarded as purely expressive variants; this why we should treat such pairs as *стол => столик (table => small table), дом => домишко (house => small house), пожар => пожарище (fire => big fire), громадный => громаднейший (huge => very huge)* as derivational hyperonym - hyponym.

We should note that the majority of these derivational variants doesn't belong to the core of Russian lexis because of their infrequency in texts. However, the highly inflected nature of Russian may turn any potential derivative into common and frequently used one, that's why all derivational regular models should be taken into account.
Moreover, we may find several cases when an expressive shade may disappear, then a word would change expressive synonym status for a synonym position. Another example of extending the sphere of usage for diminutives may be seen in the Russian spoken language (usually by women), when these words function as oral equivalents for their neutral motivating counterparts, so we may expect that in future they have a chance to become colourless synonyms.
Expressive synonyms and hyponyms may exist beyond the derivational scope, but in these cases they are rather few, irregular, and disputable, that's why it would be adequate to include them into the synset with a proper attribute.

- **DERIVATIONAL_ROLE_RELATIONS** are established to link a verb to its derivatives, designating action participants, such as ROLE_DERIVED_AGENT, ROLE_DERIVED_ OBJECT, ROLE_DERIVED_INSTRUMENT, ROLE_DERIVED_ LOCATION and so on, e.g. *сеять => сеятель, сеянец, сеялка (to sow => sower, seedling, seeding-machine*). The link in the opposite direction is a realisation of the semantic link INVOLVED_IN_ACTION. We are inclined to treat such cases as a specific derivational relation because the semantic link usually has wider scope, e.g. *принимать => приемник (receive => radio set = receiver)*, the object is involved in the first place into the situation *слушать (listen)*. This is usual for complex activity nomination, which as a rule is designated with regard to one action varying from one language to another, e.g. *шить => швея (to sew => seamstress)*. Above we have mentioned the inheritance of syntactic features, moreover, the collocation restrictions of stem verbs may be inherited by their derivatives.

3.2 Adjectives in RussNet

As there is no common solution for treatment of adjectives in EWN, we offer the following one.
We comply with the idea of GermaNet to make use of hyponymy relations wherever it is possible, but our German colleges determine hierarchical structure of adjectives according to semantic fields, while we regard adjectival hyperonymy in terms of their collocations with nouns. We received preliminary results which prove that on the level of adjectives grouping and nouns tree hyperlexeme, it is the **adjective** in Russian that **predicts** certain type of **nouns to collocate with** it, and not vise versa. For example, meaning of *долговязый (lanky)* involves the pointer to a human being, i.e. it can collocate with such nouns as *мальчик (a boy), человек (a man), папа (a father).*
We are prone to the opinion that **adjectival hyponymy trees** can be built according to their collocation with nouns from different levels of hyponymic tree. For example, lets take two adjectives, which express the similar semantic quality – denotation of *height*. In case when one adjective – *высокий (tall)*– may collocate with all nouns denoting "entity": objects, animals, humans and so on, while the other – *рослый (well-grown, srapping)* – collocates only with a certain part of the tree – human beings, the first one may be thought as hyponym for the second one. So checking the co-occurrence of adjectives with nouns, we are to produce hyponymic structure for groups of adjectives denoting the similar quality.

3.3. Verb Valencies

It is generally accepted that syntactic features of words, especially verbs, are determined by their semantic properties, that the meaning of a verb outlines the form and semantic features of words accompanying it.
The semantic and syntactic structure of verb arguments is called the **valencies frame**. Valencies may be thought in terms of morphological noun forms, which are obligatory or optional. This characteristic is vital for Russian syntax, as well as for that of other Slavonic languages (Pala, Sevecek, 1999).
Verbs have different valencies frames associated with dfferent meanings, cf.

- *Бить (посуду) [to crash]*
- *Бить (в барабан) [to bit into]*
- *Бить (врага) [to fight against]*

The minimal form of valency description implies the noun case specification, often it needs the indication of a preposition (or number of prepositions).
We may fix the **semantic** features of nouns as well, which a verb can take as arguments in a sentence. It means we want to use top-level concepts, to deal with **classes** of words, including verb-to-class relations in the synsets. In the example above, the argument of a verb in the first frame is a fragile object, in the second – musical instrument, more precisely – percussion, in the third – human beings, military units and so on. This references to the hyponymic tree structure of nouns would be very helpful for syntactic description as well, though sometimes this relation may be very comlicated.
The situation with valencies frames is not clear due to versatility of syntactic preferences of verbs included into a synset, while sometimes they behave uniformly. We'll use **a list of valencies frames** for a synset specifying which one fits the member of a synset. The set of frames is better than separate verb description, because in this case the paradigm influencing the native speaker is presented.
Moreover, it would be very useful to represent the inheritance of syntactic frames of a hyperonym by its hyponyms, e. g. *двигаться (to move) ==> идти (to walk):* hyperonym *двигаться* has valencies frames: (a) "starting

point – location", (b) "destination point – location", which are inherited by its hyponym *идти*.

4. Definition Generation

4.1. Subset Sense Definition

We still don't speak about definition generation procedure, but it's vital to have in mind guidelines for definition formulation because dictionary ones for a long time have been a target for an extensive criticism. In this respect we propose several key notes.

4.1.1. Hyponymic Definition

The definition of a synset incorporated into the hyponymic (or troponymic) tree should be constructed on the following pattern "the dominant **lexeme** of the **hyper** level **plus** a **distinguishing part** showing difference between co-hyponyms", e.g. *плыть (to swim)* has hyperlexeme: «to move in certain direction» + differentiation: «on the surface or in depth of water using special organs», *лететь (to fly)* has hyperlexeme: «to move in certain direction» + differentiation: «in the air using wings». In this case there is no Russian hyperlexeme denoting *moving in some direction*, though it's important to oppose this way of moving to the other one in various direction, with repetitions, to and fro.

It's clear that in case of a large number of co-hyponyms the problem may become practically insolvable because of a great number of necessary differential features, then it would be better to use other types of defining or artificial names (used in GermaNet) uniting several lexemes into a cluster.

4.1.2. Meronymic Definition

The definition of a synset incorporated into the meronymic relations may be based on either holonym, or meronym.

In the first case, a holonym is the referential part of the definition (similar to hyperlexeme), but a simple indication that something is a part of the holonym is not sufficient, so it is usually supplied with a special function (for artefacts) or construction peculiarties. For example, structure «part + construction characteristic + holonym + function» may be used: *крыша (roof)* = «the upper part of the building, covering it from precipitation».

In the second case, a limited number of meronyms may be used for generation of list-type definition, e.g. *фигура (chessman)*: «king, queen, castle, knight, bishop in chess opposed to pawns».

4.1.3. Derivational Definition

In those cases when a synset is associated with a purely derivational link we use a definition describing the additional sense of the derivational affixes, e.g. *столик* «a small table», *генеральша* «general's wife».

4.1.4. Semantic Pointer Definition

The simplest way of defining the quality is to show the synonyms expressing it, which are united in the synset, so in this case we have a rudimentary definition equal to an ordinary synset. This type of definition is frequent for adjectives and adverbs.

Antonymic definition is adequate in those cases when one member of the antonymic pair is marked showing the positive content while the other shows its absence, e.g. *глупый (foolish)* «not clever» <=> *умный (clever)* «having the intellect».

Causative definition is alike the derivational one so as it makes implicit the causative copula and the final state of transition, in Russian there is a specific affix with anti-causative meaning, e.g. *поднять (raise)*: *каузировать подняться (cause to rise)*. Usually in such a definition the artificial causative is used, which is the transliteration of English *cause*, because a Russian equivalent *заставить* means 'to enforce', that is not neutral at all.

Moreover, using semantic attributes, such as X_HAS_IMPERFECT, X_HAS_PERFECT, X_IS_SMALL, X_IS_BIG etc., incorporated into the WordNet structure, we may later elaborate a procedure for automatic definition generation.

4. Conclusions

To sum up we may say that RussNet presently covers the core of the Russian lexis (the resulting number of synsets is more than 2500). So it can be regarded as a reliable starting point for further extending and elaboration of the system, which will be carried out by addition of peripheral groups of words, emotionally coloured lexis and derivatives, in particular. This should enrich the content of the database. The introduction of new relations allows us to perform more adequate semantic analysis of the Russian language.

Development and Use of Thesaurus of Russian Language RuThes

Natalia V. Loukachevitch* and Boris V. Dobrov*

Research Computing Center of Moscow State University
339, Research Computing Center of Moscow State University,
Vorobyevy Gory, Moscow, 119899, Russia
{louk, dobroff}@mail.cir.ru

Abstract

In the paper we describe the main principles of developing Thesaurus of Russian Language RuThes, which is constructed specially as a tool for automatic text processing. The thesaurus contains more than 95 thousands words and multiword expressions. It has a specific system of conceptual relations, describing existential properties of concepts. Means of description and disambiguation of lexical ambiguity are discussed. The technology of development the bilingual resource based on RuThes is described. We also consider current stage of the thesaurus and describe the use of the Thesaurus in various applications of automatic text processing.

1. Introduction

Large volumes of electronic text collections require mighty tools for their processing. Texts in these collections include thousands of various words and syntactic constructions, they can have various sizes and styles. All these factors pose an important question what linguistic resources facilitating processing large collections of electronic documents could be.

The paper is devoted to description of main principles of development of the Thesaurus of Russian Language RuThes, which belongs to the same type of such linguistic resources as WordNet (Miller et al., 1990) and EuroWordNet (Climent et al., 1996).

This work arises from our experience in creation of domain-specific Thesaurus on Sociopolitical Life, which was constructed as a tool for automatic conceptual indexing in the large domain of social life (Loukachevitch et al., 1999). Development of Sociopolitical Thesaurus for automatic text processing of large text collections required use of two different traditions: the tradition of development of information-retrieval thesauri for manual indexing, which pay specific attention to terminology and representation of domain-specific relations (LIV, 1994; UNBIS, 1976; EUROVOC, 1995), and the tradition of development of linguistic resources with their attention to description of single words, lexical ambiguity, semantic relations.

The Sociopolitical thesaurus was used in such applications of automatic text processing as term disambiguation, automatic conceptual indexing, knowledge-based text categorization, automatic text summarization (Loukachevitch et al., 1999). The Sociopolitical thesaurus is an information retrieval tool in University Information System RUSSIA (Russian inter-University Social Sciences Information and Analytical Consortium; www.cir.ru/eng/).

The technique of text processing using Sociopolitical thesaurus is based on lexical cohesion property of coherent texts, that is, the thesaurus relations were used to find semantically related sets of terms in texts (Loukachevitch & Dobrov, 2000). For several years the results of the text processing were tested through manual analysis. We tried to understand how thesaurus relations work in the thematic structure of coherent texts. This activity led us to development of RuThes, a linguistic resource for automatic text processing of large Russian text collections.

Now thesaurus RuThes includes 95 thousand Russian words (nouns, verbs, adjectives), expressions and terms, 105 thousand senses, 42 thousand concepts (synsets). In contrast to European wordnets we began to describe Russian-English relations of RuThes after considerable part of RuThes had been already created.

2. General Structure of RuThes

RuThes is a hierarchical net of concepts. Every concept has a set of its textual expressions, a synonymic row (a synset in terminology of WordNet) and a set of relations with other concepts of the thesaurus. So its general structure is the same as the structure of WordNet and EuroWordNet.

RuThes consists of two main parts: general lexicon and Thesaurus on Sociopolitical life (Figure 1).

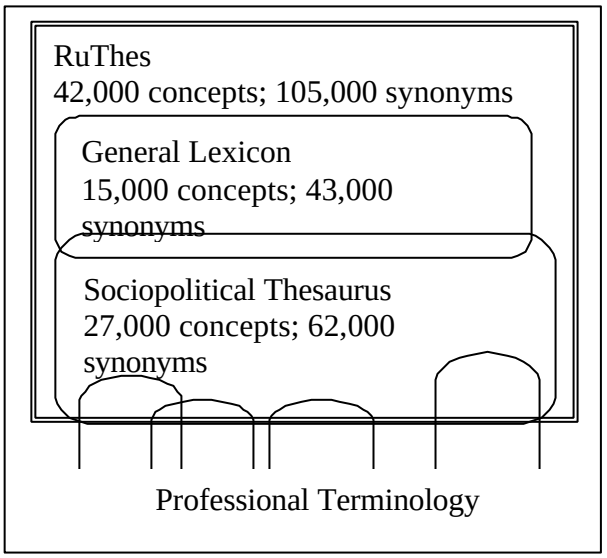

Figure 1. General Structure of RuThes

Thesaurus on sociopolitical life includes concepts which correspond to a domain of social life, these words and terms are usually thematically significant: *car, river, town, economy, computer, sports, serviceman* and many others. The domain of Sociopolitical Thesaurus is not domain of social research, but comprises situations and

problems of social life, which are discussed in official documents and newspapers. Sociopolitical thesaurus encompasses as words and expressions usually included in general explanation dictionaries and terminology of such domains as economy, law, defense and others. Besides Sociopolitical thesaurus includes the geographical subdomain describing 7000 geographical names.

General lexicon contains concepts, which can be met in texts of any domains, for example, *part, create, new*. In texts these words and expressions are less significant, they usually express relations and features of main entities discussed in texts. Besides general lexical contains concepts expressing human emotions, feelings, personal human relationships. General lexicon contains 15 thousand concepts (from 42 thousand in RuThes), 33 thousand words and language expressions (from 95 in RuThes).

The main goal of the division was as follows: this borderline separates very lexically ambiguous area from much less ambiguous, very relational area from much more thematically significant. The result of this division is that Sociopolitical thesaurus is used in various applications of automatic text processing for several years. General lexicon is now under development. Its numerous multiple senses are added and corrected. But Sociopolitical thesaurus and General lexicon are parts of the same system. Therefore if necessary, knowledge from General lexicon is used in computer applications together with Sociopolitical thesaurus.

3. Synsets in RuThes

3.1. Description of different parts of speech in RuThes

Elements of synsets in RuThes (below Thesaurus) are: single words (nouns, verbs, adjectives), noun groups, verb groups, adjective groups. We describe semantically equivalent words belonging to different parts of speech as elements of the same synset - our tradition from 1994.

Here and below we present examples in English to show how our decisions would look in English. So a synset looks like: *partake, participate, participation, participative, participatory, take part.*

Every synonym has its part of speech tag, and this information can be used in automatic text processing.

Incorporation of parts of speech makes description of relations more consistent. If we create three different concepts for different parts of speech and know about their semantic equivalence, we have to repeat similar relations for them. This leads to inconsistency in description of relations. For example, in WordNet 1.6. we can see that word *engagement* is in the same synset as *participation*, but there is no relation between *engage* and *participate*. However in Webster (1999) we can find the following example: *to engage in business or politics*, which means that the relation between verbs has to be described.

This incorporation also means that the hierarchy, the set of relations is the same for all parts of speech.

3.2. Multiword expressions in RuThes

We pay special attention to description of multiword expressions and terms as sources for lexical disambiguation and representation of situational and encyclopedic knowledge. A number of multiword expressions in the Thesaurus is 42 thousand (of 95 thousand).

We began development of Sociopolitical thesaurus using semi-automatic methods to find multiword terms in text collections of official documents and newspaper articles. Our procedure of terms acquisition consisted of two stages. At the first stage term-like expressions were automatically identified in the texts of the corpus. Rules defining term-like expressions included syntactical and lexical conditions. At the second stage our specialists had to look through the revealed expressions, choose terms from them and add new terms to the Thesaurus (Lukashevich, 1995). The procedure was working during four years, processed more than 200 Mb of texts and collected more than 200 thousand term-like expressions. It was stopped because it became difficult to find new useful terms, terminology coverage became very high.

From that experience we understood how important to add unambiguous multiword expressions containing ambiguous words to conceptual synonymic rows. They diminish percentage of ambiguous words in a text and help disambiguate neighbor expressions. Since we specially seek unambiguous multiword expressions in any sources we have: in glosses and examples of dictionaries, in text collections. For example, the following expressions could be added to synonymic rows of WordNet and are very useful in automatic text processing:

*Petition to god (*sense2 of noun *petition);*
transfer to private ownership (verb *privatize),*
*conductor of an orchestra (*sense1 of noun *conductor)*

As an example how a full synonymic row of multiword expressions could looks, let us see the synonymic row of Russian concept *ZDRAVOOHRANENIE* (*PUBLIC HEALTH*), which is similar to the following English list:

p*ublic health, community health, health care, health care sector, health care system, health field, health of population, health promotion, provision of health, public health field.*

So one can see how this list diminishes necessity to disambiguate such “difficult” words as *care, sector, field, system, public.*

A multiword expression can also initiate a new concept. There are several factors that can make possible creation of a new concept based on a multiword expression:

- A multiword expression presents an important and frequent enough subtype of a concept already described in the Thesaurus;
- A multiword expression is unambiguous and contains very ambiguous words;
- A multiword expression has conceptual relations that do not follow from its constituent parts;
- A multiword expression has relations with concepts of lower levels, based on single words, so a new concept additionally structures the thesaurus knowledge, can join separate conceptual substructures of the thesaurus net.

3.3. Name of concept

Every concept of the thesaurus has a unique name, which has to be clear and unambiguous for native speakers. Name of a concept can be

- one of unambiguous synonyms;
- a multiword term which is unambiguous and possible as one of textual expression corresponding to a concept;
- a pair of synonyms;
- a synonym with a fragment of the definition of a concept.

This name presents the whole synonymic row in different representations of results of text processing, for example, in structural summary of a text which is very convenient in cross-language information retrieval (Loukachevitch & Dobrov, 2000) or as explanation means for knowledge-based text categorization systems.

A concept usually does not have a full gloss but formulation of its name has to be enough to find a corresponding sense in explanation dictionaries if necessary.

4. Description of lexical ambiguity

In linguistic resources intended for automatic text processing there is a serious problem how detailed division of senses must be. The sources of the problem are as follows:

- it is difficult to disambiguate close meanings during automatic text processing in large domains;
- it is impossible to refine query with help of a user because a user must not understand and distinguish subtle linguistic distinctions;
- at last close meanings (even if we have divided and can disambiguate them) are often both relevant or not relevant to a query.

Therefore we have to understand, what types of ambiguous terms it is necessary to distinguish and represent as different concepts of the Thesaurus.

In a linguistic resource represented as a conceptual net the desire to reduce number of senses is in contradiction with other problem: if two senses have different sets of conceptual relations (especially different sets of links to lower levels of the conceptual net), then their clustering can lead to loss of descriptive clarity and new problems in efficiency of automatic text processing.

Therefore in RuThes we do not cluster senses that have different hyponyms and/or parts. If the difference between sets of conceptual relations consists only of hypernyms, sense clustering is possible.

For example, it is impossible to cluster concepts corresponding to the senses of word *building* as process and result as proposed in (Pustejovsky, 1995), because in the Thesaurus difference in conceptual relations between the concepts is significant. Compare fragments of lower levels corresponding to these concepts:

CONSTRUCTION OF BUILDINGS (build, building, building construction, construct, construction….)
RESIDENTIAL CONSTRUCTION (home construction, homebuilding, home building…)
...
COSTRUCTION EQUIPMENT(building equipment)
TOWER CRANE
BULLDOZER
EXCAVATION EQUIPMENT
...

BUILDING…
PUBLIC BUILDING
ADMINISTATIVE BUILDING
MUSEUM…
SCHOOL BUILDING…
...
RESIDENTIAL BUILDING
APARTMENT HOUSE
VILLA
...

The problem of description of close senses became less serious if it is possible to describe relations between corresponding concepts. The relations of RuThes allow us to connect various types of polysemic senses, and in automatic processing if it was not possible to distinguish a correct meaning, the most broad concept among all related senses is chosen in default way. In general, it is possible to have a special indicator, showing which concept can be chosen in default.

For example, we can introduce two concepts *SCHOOL (EDUCATIONAL ORGANIZATION)* and *SCHOOL BUILDING*, connect them with relation WHOLE-PART and include word *school* in synsets of both concepts. In automatic text processing if it is not proven that a school building is discussed, concept *SCHOOL (EDUCATIONAL ORGANIZATION)* is chosen. It means that there is no real difference between description of these polysemic senses as two concepts or a single concept. In RuThes choice of separated or clustered description of close polysemic senses depends on if sense concepts are central in the thesaurus net and require their own sets of lower relations or they are peripheral.

5. Relations in RuThes

Linguistic resources intended for automatic text processing usually include descriptions of semantic relations between their entries such as ‘part’, ‘agent’, ‘material’, ‘time’, ‘cause’, ‘result’, and others. At the same time when huge conceptual-based resources are developed, it is supposed that these resources have to be used in automatic text processing of large and heterogeneous text collections. However, at present text processing systems can not provide deep linguistic analysis of such texts. It means that a computer system can not check if described relations are valid in a current text. Therefore other, not semantic, characteristics of any relation become especially important, if a relation can change or disappear in a specific situation described in a text. These characteristics can be considered as existential characteristic of a relation.

Therefore if we describe that a tree is a part of a forest, but in fact a tree can grow in a lot of other places, the system can not rely on this description because in a specific text the relation can be not valid. It can lead to problems in efficiency of automatic text processing.

To test changeability of a relation between concepts *C1* and *C2* it is necessary to answer the following questions:

1) if every example of a concept *C1* has the relation with an example of a concept *C2* (and vice versa);
2) if an example of concept *C1* has the relation with *C2* (or its example) during all time of its existence, for example, concept *GARMENT* can be considered as *CONSUMER GOODS* (as described in WordNet 1.6), but when a specific person wears garment, it ceases to be goods;
3) if all properties of a concept *C1* are properties of concept *C2*, for example, concept *SHIPWRECK* loses very important properties of concept *SHIP*.
4) if existence of a concept *C1* is impossible without existence of concept *C2* or existence of an example of a concept *C1* is impossible without an example of concept *C2* (dependency relations (Guarino, 1998)), for example, existence of concept *BOILING* is impossible without existence of concept *LIQUID*.

At present description of relations in RuThes do not present semantic nature of relations distinct from hyponymy-hyperonymy relations and part-whole relations, but its existential properties. At the same time it gives additional very powerful possibility not to decide what a semantic name of a relation can be. It is very important for complex relations such as *CREDITOR – BANCRUPCY*: if the name of the relation is 'agent' or 'source' or both.

Current names of conceptual relations in RuThes were introduced in earlier version of Sociopolitical thesaurus and arise from names of relations in conventional information retrieval thesauri. There are three basic relations:

1) BT-NT relations (broader-narrower terms) is now used as equivalent to hyponym-hypernym relations;
2) WHOLE-PART relations for descriptions of conventional parts, properties and participants of situations;
3) RT (related term) relations for description of all other relations, which can be symmetrical and nonsymmetrical. Nonsymmetrical RT relation is denoted as RT1 – RT2 and serves for description of dependency relations.

Let us see fragments of description of concept *RIVER* to see usage of PART and RT relations

RIVER

PART	*RAPIDS OF A RIVER* (Russian 'bistrina')
PART	*WATERFALL* (Russian 'vodopad')
PART	*MOUTH OF A RIVER* (Russian 'ust'e')
RT1	*FRESHWATER* ('presnaya voda') /* concept *RIVER* does not exist without existence of concept *FRESHWATER* therefore there is a dependency relation denoted as RT1. At the same time a lot of concepts depend on existence of concept RIVER. So below reverse relation RT2 is used */
RT2	*CATCHMENT BASIN* (Russian 'bassein reki')
RT2	*HYDROELECTRIC PLANT* ('gidroelectrostancia')
RT2	*EMBANKMENT* ('nabereznaya')
RT2	*BOTTOMLAND* ('poima')
RT2	*RIVER TRANSPORT* ('rechnoi transport')
RT2	*SLUICE GATE* ('shljuz')

If for a BT or WHOLE relation there is an answer 'OFTEN' to one of questions 1-3, then a relation is marked with special modifiers.

If a relation can be considered as a default relation or there are only two main alternatives, we mark the relation with modifier V (variability)

If a relation exists during most time of existence of an example of a concept, we mark a relation with modifier A (aspect, point of view). The same modifier is used if a relation does not preserve all properties of an upper concept. For example:

PENSIONER

BT_V	*OLDER PERSON*
BT_V	*DISADVANTAGED PERSON*
$WHOLE_A$	*PENSION SYSTEM*

So we described that a pensioner is often an older person and a disadvantaged person. A pensioner is a role in pension system, which does not characterize it fully because of two first relations. In fact, a pensioner is also a social status. Therefore if a text mentions pensioners, it does not always mean that the text discusses some problems of pension system.

Every type of conceptual relations has its own set of properties such as transitivity and inheritance. Modifiers restrict transitivity of relations (Loukachevitch & Dobrov, 2002).

6. Lexical coverage of RuThes

Now thesaurus RuThes includes 95 thousand Russian words (nouns, verbs, adjectives), expressions and terms, 105 thousand senses, 42 thousand concepts (synsets). At present we have finished comparison of lexical units in RuThes and in a text collection of more than 600 thousand documents (Russian official documents and newspaper articles). Analysis of 100,000 most frequent lemmas of the collection (frequency > 25) showed that about 7 thousand lemmas are necessary to describe in RuThes. We plan to continue study of the text collection and to add new lexical units in RuThes for next 100 thousand lemmas (frequency > 10). We suppose that this stage will give us other 5-7 thousand words to include in RuThes.

The lexical analysis of the collection allows us to describe new words, not included in contemporary Russian dictionaries, and see new usage of words that are considered in the dictionaries as obsolete.

Other important stage of our current work is verification of sense representation for polysemic and homonymic words in RuThes. Beginning from very

frequent words we analyze senses of every lexeme described in various dictionaries of Russian language (Ozhegov & Shvedova, 1999; BTS, 1998) and decide if

a) all senses of a lexeme have to be represented;
b) there are obsolete senses;
c) different senses can be represented as a single concept;
d) a sense is only used within multiword expression.

So current stage of development of RuThes can be characterized as verification and correction.

7. RuThes and English linguistic resources

Development of cross lingual linguistic resources is a very important task. For Russians bilingual text processing of Russian to English and English to Russian is especially significant. We began development of RuThes from Sociopolitical thesaurus, which is an important searching tool in our information system. To provide bilingual retrieval in our information system we began to develop Russian-English Sociopolitical Thesaurus. It means that we could not connect RuThes and WordNet because of absence of significant in our technology concepts of the sociopolitical domain in WordNet. Besides we considered collection of multiword terms as very important for any language. The following list presents English terms included to English part of Sociopolitical Thesaurus recently and not included to WordNet: *wheelchair user, construction area, airline ticket, travel field, home building, civil rights activist, top manager, produce market, cargo shipper, stress disorder* and others (terms are extracted from newspapers).

Development of bilingual Sociopolitical thesaurus has the following main stages.

At first Russian terms were translated into English using traditional bilingual dictionaries (Apresyan & Mednikova, 2000; Multilex, 1996). We received 30 thousand terms in the English part of our Thesaurus. However these translation could not provide rich synonymic rows we needed and could not provide terms describing phenomena that are absent in Russia but are significant for other countries.

Therefore at the second stage we took well-known American and British dictionaries and thesauri: Webster dictionary (1999), Longman dictionary (1995), Collins (1990), WordNet (Miller et al., 1990), Thesaurus Roget's (1991), information retrieval thesauri Legislative Indexing Vocabulary (LIV, 1994), EUROVOC (1995), UNBIS (1976)). Our specialists analyzed these resources and manually extracted terms contained in these resources as vocabulary entries, parts of explanations, examples.

Therefore an English expression can have a mark, indicating its origin. For example, a concept *EQUALITY BETWEEN MEN AND WOMEN* has the following synonymic expressions:

equal rights for women (WordNet's gloss)
equal rights of men and women (EUROVOC)
*equality between sexes (*Multilex*)*
*equality between women and men (*texts - documents of Council of Europe)
gender equality (texts)
sex equality (texts*)*.

Text variants of related concept *SEX DESCRIMINATION* are as follows*:*

*Discriminations on the ground of sex (*texts)
*Gender descrimination (*LIV*)*
*Sex discrimination (*LIV*)*
*Sexism (*Webster, WordNet*)*

This stage is planned to take two years and be finished before 2003. Now the English part of Sociopolitical thesaurus comprises 48 thousand English terms.

Now we began the third stage of the development – revision and correction of collected material.

And the fourth stage is use of the bilingual resource in various applications of automatic text processing, which will lead to further improvement and enrichment of our linguistic resource.

It is important to stress that during analysis of dictionaries our specialists were approved to make Russian-English connections for any Russian words in RuThes (not only from Sociopolitical Thesaurus). Full volume of included English words and expressions is more 62 thousand entries, 67 thousand senses. So this work can be considered as a significant basis for connection to other English structural resources.

8. Use of RuThes in text processing applications

8.1. Use of Sociopolitical thesaurus

Thesaurus on sociopolitical life is used in automatic processing applications since 1996. The Thesaurus is a searching tool in University Information System RUSSIA (UIS RUSSIA, www.cir.ru/eng/), containing more than 600 thousand documents. The text collection of this information system includes such various types of documents as official documents of Russian Federation, legislative acts, international treaties, newspaper articles and statistical reports.

The Sociopolitical thesaurus is used as a linguistic resource in such information retrieval applications as automatic conceptual indexing, knowledge-based text categorization, automatic text summarization (Loukachevitch et. al., 1999). In these applications a thesaurus-based technique of construction of thematic representation of texts is used (Loukachevitch & Dobrov, 2000).

In (Loukachevitch & Dobrov, 2002) we describe an experiment which showed that use of this part of RuThes in information retrieval was much more efficient than retrieval based on vector model. Average precision of document retrieval with the Sociopolitical thesaurus (using its synonyms and hierarchy) was 1.4 times more than average precision of vector retrieval.

8.2. Use of RuThes in text categorization systems

RuThes is currently used as a linguistic resource for knowledge-based text categorization systems.

There are a lot of applications where machine-learning approaches (Joachims, 1998) to text categorization are impossible to use. There can be no sufficient training collection, or a system of categories can include hundreds of hierarchical categories. In these cases a knowledge-

based technique using RuThes can be appropriate (Loukachevitch, 1997). Knowledge described in RuThes substitutes information received from training examples in machine learning approaches.

In our text categorization technique the categories are manually described using Boolean expressions of a relatively small number of 'supporting' concepts. Boolean expressions including all necessary concepts of RuThes are generated on the basis of properties of the Thesaurus relations. The resulted Boolean expressions usually include much more disjunctive and conjunctive components, sometimes in hundreds times more. It became possible owing to detailed presentation of various aspects of described concepts and careful testing of the Thesaurus relations.

One of our last text categorization systems categorizes Russian legislative documents using the system of 1168 categories (3-4 levels of hierarchy), other text categorization system categorizes public opinion polls (almost 400 categories).

Description of categories in large hierarchical systems of categories usually requires large range of lexical knowledge from very specific terminology to very general words. For example, one of categories for categorization of public opinion polls was “Image of woman” and required detailed descriptions of human traits, the list of which was stored in RuThes.

9. Conclusion

In the paper we described main principles of developing Thesaurus of Russian Language RuThes, which is constructed specially as a tool for automatic text processing. The thesaurus contains a lot of multiword expressions, has a specific system of conceptual relations, describing existential properties of concepts, has specific means for lexical disambiguation. We describe current stage of the Thesaurus developing in comparison to 100,000 the most frequent lemmas of the text collection of University Information System RUSSIA, including more than 600 thousand documents. Now thesaurus RuThes is a basis for development the bilingual Russian-English resource for cross lingual text processing. Also we consider the use of the Thesaurus in various applications of automatic text processing.

Issues in Generating Text from Interlingua Representations

Stephan Busemann

DFKI GmbH
Stuhlsatzenhausweg 3

busemann@dfki.de

Abstract

Multi-lingual generation starts from non-linguistic content representations for generating texts in different languages that are equivalent in meaning. In contrast, cross-lingual generation is based on a language-neutral content representation which is the result of a linguistic analysis process. Non-linguistic representations do not reflect the structure of the text. Quite differently, language-neutral representations express functor-argument relationships and other semantic properties found by the underlying analysis process. These differences imply diverse generation tasks. In this contribution, we relate multi-lingual to cross-lingual generation and discuss emergent problems for the definition of an interlingua.

1. Introduction

In this contribution, we relate multi-lingual to cross-lingual generation and discuss emerging problems for the definition of an interlingua. Multi-lingual generation starts from non-linguistic content representations for generating texts in different languages that are equivalent in meaning. The generation of weather forecasts or environmental reports are typical examples. In contrast, cross-lingual generation is based on a language-neutral content representation which is the result of a linguistic analysis process. Generation for machine translation is a most prominent example.

Non-linguistic representations do not specify linguistic semantics nor do they reflect the structure of the text to be generated. In contrast, language-neutral representations express functor-argument relationships and other semantic properties found by the underlying analysis process. These differences imply diverse generation tasks.

However, there are also commonalities. In both cases, generation is the mapping of some semantic representation onto linguistic strings. We may assume a single generation process that uses different separately defined language-specific knowledge sources. In both cases, we may view the underlying representation as an interlingua, since it attempts to cross the language barrier by providing content descriptions independently of the target language.

An instance of each type of tasks has been implemented using the generation system TG/2 (Busemann, 1996), quickly overviewed in Section 2.. The usage of the same framework allows us to relate the tasks to each other (Section 3.) and to gain insights relevant to a coherent definition of interlinguas, generation tasks, and generation knowledge (Section 4.).

2. TG/2 in a Nutshell

TG/2 is a flexible production system that provides a generic interpreter to a set of user-defined condition-action rules representing the generation grammar. The generic task is to map an input structure onto a chain of terminal elements as prescribed by the rule set. The rules have a context-free categorial backbone used for standard top-down derivation, which is guided by the input representation. The rules specify conditions on input ("tests") determining their applicability and allow navigation within the input structure ("access functions").

The right-hand side of a rule can consist of any mixture of terminal elements (canned text) or other categories associated with an access function. The presence of canned text is useful if the input does not express explicitly everything that should be generated. With very detailed input, the terminal elements of the grammar will usually be words.

Given a category C and some (piece of) input structure I, production rules are applied through the standard three-step processing cycle:

1. Identify the applicable rules;
2. Select a rule on the basis of some (freely programmable) conflict resolution mechanism; and
3. Apply that rule.

A rule is applicable if its left-hand side category is C and its tests hold on I. A rule is applied by processing its right-hand side elements from left to right. Canned text is output right away, and non-terminal elements induce a new cycle with the new category and the return value of the access function. Processing terminates when all right-hand side elements have been realized successfully. In the case of a failure, processing backtracks to step 2. If no more rules are applicable, a global failure occurs. For details see (Busemann, 1996).

3. Relating Two Distinct Generation Tasks

TG/2 has been used in a variety of NLG tasks. We look at multi-lingual report generation and cross-lingual summarization. We then locate the tasks on a scale ranging from shallow to in-depth generation, and discuss advantages and drawbacks of these locations.

3.1. Task 1: Generating air quality reports from measurement data

Reports about air quality in a German-French border region (Busemann and Horacek, 1998) are currently

```
[(COOP THRESHOLD-PASSING)
 (LANGUAGE ENGLISH)
 (TIME [(PRED SEASON)
        (NAME [(SEASON WINTER)
               (YEAR 2001)])])
 (POLLUTANT SO2)
 (SITE "Saarbruecken-City")
 (SOURCE [(THRESHOLD-TYPE MIK-WERT)])
 (EXCEEDS [(STATUS YES) (TIMES 1)])]
```

Figure 1: A Non-Linguistic Input Expression for Report Generation: "In Winter 2001 at the measuring station at Saarbrücken-City, the MIK value for sulfur dioxide was exceeded once."

```
(defproduction site "S01"
  (:PRECOND
     (:CAT SITE-E
      :TEST ((always-true)))
   :ACTIONS
     (:TEMPLATE
        "at the measuring station at "
        (:RULE SITE-NAME-E (self)))))
```

Figure 2: Making Implicit Meaning Explicit: A TG/2 grammar rule. The rule is "unconditioned" and uses the current piece of input structure to access the site name.

produced in six languages (a web demo is available at `http://www.dfki.de/service/nlg-demo`). The reports are based on real measurement data taken from a database and on the user's parameters determining the type of the report (time series, average or maximum value description, threshold passing description). A report consists of up to six statements most of which are verbalized by TG/2. The initial text organization stage retrieves the relevant data, decides about the content of the statements and defines their order. For each statement to be verbalized by TG/2 it produces a domain-oriented non-linguistic intermediate feature structure serving as input to TG/2 (cf. Figure 1 for an example). Input expressions for TG/2 may specify e.g. the pollutant, the actual measurements, and their date and location. Moreover, further information is specified according to the user's choice of parameters. It should be noted that some input is just carried forward from the original system input (in Figure 1, this is `LANGUAGE, TIME, POLLUTANT, SITE, THRESHOLD-TYPE`), whereas other information originates from the DB query and text organization stage (`COOP` and `EXCEEDS` in Figure 1).

The text organization stage is entirely content-oriented, and the intermediate feature structures do not exhibit linguistic properties. The 'language' feature causes the selection of the rule set for the language requested. The determination of linguistic structure for each input expression is achieved by the TG/2 grammar rules. Since implicit information is associated with some parts of input expressions, canned text is used to make it explicit at the surface. An example in Figure 1 is the added notion of "at the measuring station at" in the case of `(SITE "Saarbrücken-City")`, which is verbalized through the rule in Figure 2.

The grammars comprise about 100-120 rules for each language and are specifically designed for this application. The development of a grammar for another language takes between one and three weeks depending on skills.

3.2. Task 2: Generating medical scientific text for summaries

This generation task occurred in the context of the cross-lingual text summarization system MUSI (Lenci et al., 2002). MUSI involves a combination of analysis and generation similar to machine translation. An interlingua approach was chosen to represent selected English and Italian medical scientific sentences in a language-neutral way. The sentences can be complex and quite long (50 words are no exception). Interlingua expressions were fed to sentence generation components producing the elements of a French or German summary.

The generation of German sentences (Busemann, 2002) starts from so-called IRep4 interlingua expressions. A sample IRep4 expression is shown in Figure 3. IRep4 expressions are hierarchical predicate-argument structures complemented by a rich variety of features and modifiers. The basic elements are atomic and predicative concepts, forming an ontology shared across the MUSI system. In particular, predicative frames are based on the SIMPLE formal specifications (Lenci et al., 2000). IRep4 expressions are composed of `PROP` and `ITEM` elements used to represent propositions and terms, respectively. Although IRep4 is in principle a semantic representation language, its expressions also keep track of some syntactic properties of the source language elements. For instance, number and determiner information is specified for NPs as well as categorial information for propositions (`CAT`). This information can be very useful in guiding text generators.

IRep4 is suitable for representing the semantics of very complex sentences, but at the same time, it leaves room for various degrees of specification. In fact, co-reference resolution, attachment ambiguities and the incorrect identification of arguments and modifiers are common sentence analysis problems that may lead to incomplete output. To cope with these problems, IRep4 has been designed to integrate possibly underspecified or fragmentary representations. This feature greatly enhances the robustness of the system and can guarantee a better interface with the text analysis component.

A direct interpretation of IRep4 by TG/2 would require choosing the lexemes and the syntactic realizations. This could have been achieved within the TG/2 grammar through complicated tests. These choices partly depend on each other, which would have caused massive backtracking. Moreover, testing the presence of a concept in IRep4 would have been triggered by rules expanding the syntactic category of the lexemes (part of speech), e.g. the rule `Noun` $\rightarrow$ `"acetylcholin"` would have been associated with a test whether the current concept was `C_acetylcholine`. As there would have been hundreds of these, concerns of processing efficiency were in order. Finally, a pre-existing grammar should be reused that was not previously adapted

```
PROP{ Value = P_ARG1_cause_ARG2;
      Time_Rep = [PRESENT, PRES_USUAL];
      Cat = V_SEN;
      Arg1 = PROP{ Value = P_antagonism_with_ARG1;
                   Cat = NP; Det = INDEF;
                   Arg1 = ITEM{ Value = C_acetylcholine;
                                Mod1 = [LOC, ITEM{
                                        Value = C_level;
                                        Det = DEF;
                                        Mod1 = [RESTR, ITEM{
                                                Value = C_sight;
                                                Number = PLUR; Det = DEF;
                                                Mod1 = [RESTR, C_muscarinic];
                                                Mod2 = [RESTR, ITEM{
                                                        Value = C_substance;
                                                        Number = PLUR;
                                                        Det = DEMONST1;}]; }]; }]; };
                   Mod1 = [RESTR, C_competitive]; };
      Arg2 = ITEM{ Value = C_effect;
                   Det = DEF; Number = PLUR; }; }
```

Figure 3: IRep4 Expression for "Die Wirkungen werden durch einen kompetitiven Antagonismus zu Acetylcholin auf dem Niveau der muskarinischen Bindungsstellen dieser Substanzen verursacht." [The effects are caused by a competitive antagonism with acetylcholine on the level of the muscarinic sights of these substances.].

to IRep4.

For these reasons it appeared more convenient to introduce an initial sentence planning stage. The resulting representation – see Figure 4 for an example corresponding to Figure 3 – forms the input to TG/2. It can be viewed as a syntactically enriched, language-specific paraphrase of the underlying IRep4 expression. It represents explicitly the linguistic structure of the sentence. The TG/2 grammar is responsible for word order and inflection. Very much like in a classical sentence realization system, no canned text parts are used. If a phrase like "at the measuring station at" had to be generated here, an underlying interlingual semantic expression would be mandatory.

A pre-existing TG/2 grammar for German syntax was reused and adapted to the needs of MUSI (Busemann, 2002; Lenci et al., 2002). Its final version comprises over 950 rules.

3.3. Shallow and in-depth generation

The notion of shallow generation, as opposed to in-depth generation, has been coined by (Busemann and Horacek, 1998) to describe a distinction corresponding to that of shallow and deep analysis. In language understanding deep analysis attempts to "understand" every part of the input, while shallow analysis tries to identify only parts of interest for a particular application, omitting others. In-depth generation is inherently knowledge-based and theoretically motivated, whereas shallow generation quite opportunistically models only the parts of interest for the application in hand. Often such models will turn out to be extremely shallow and simple, but in other cases much more detail is required. Thus, techniques such as those developed within TG/2 for varying modeling granularity according to the requirements posed by the application are a prerequisite for reusing NLG systems.

Obviously a shallow NLG system is, in general, based on representations that carry implicit meaning. We call this shallow input. Additional text has to be "invented" by the generator (in TG/2, this is usually achieved using canned text in the grammar).[1] This leads to domain-dependent, shallow grammars that cannot be reused easily for another task. The in-depth models assume a very fine-grained grammar describing all the linguistic distinctions covered by the interlingua. Such a grammar corresponds closely to familiar generic linguistic resources.

The report generation task described was solved by a typical shallow approach, whereas the MUSI generation task required an in-depth model.

The tension between shallow and in-depth generation has been discussed further in the literature. According to Reiter and Mellish, shallow techniques (which they call "intermediate") are appropriate as long as corresponding in-depth approaches are poorly understood, less efficient, or more costly to develop (Reiter and Mellish, 1993). Bateman and Henschel describe ways of compiling specialized grammars out of general resources (Bateman and Henschel, 1999). A platform for generating, storing and reusing representations is described in (Calder et al., 1999), showing that such reuse can be seen as a shallow methodology to text generation. A major conclusion seems that there is no dichotomy between both approaches, but that shallow systems can indeed be based on theoretically sound in-depth models.

In practice though, NLG tasks turn out to be highly diverse, and no NLG system could be reused for a new application off the shelf. The necessary effort for adaptation and extension of large existing in-depth resources such as KPML (Bateman, 1997) or FUF/Surge (Elhadad and Robin, 1996) is often considered high. In fact, the de-

[1] Of course, these texts are defined by the application, viz. the customer, as all other output.

The material for "on the level of the muscarinic sights of these substances" would appear under `DEEP-SUBJ.PP-ATR.LOCATIVE`, but has been omitted for reasons of space. The representation contains content word stems and names for syntactic structures (`SBP, NR` features). Determiners and prepositions are also provided.

velopment from scratch of a shallow grammar for a small NLG application on the basis of a simple framework like TG/2 can be more cost-effective.

Shallow and in-depth generation tasks can be related with help of TG/2. As the amount of domain-specific canned text in the TG/2 grammars correlates to the shallowness of the input, the generation tasks described can be located on a scale that ranges from shallow to in-depth domain and input models. There are trivial systems at one end that just produce canned text according to triggers (e.g. system error reports). A bit further on the scale we find template-style systems, like the air quality report generator, which use canned text to make knowledge implicit in the input explicit. In-depth realizers with sophisticated grammars that do not use domain-specific canned text at all are located at the other end of the scale, such as the MUSI generator.

Why are shallow and in-depth interlinguas both viable? One obvious reason lies in the origin of the interlingua representations. Shallow representations usually originate from non-linguistic processing, such as accessing a database or interpreting some user interaction, whereas in-depth representations generally have a linguistic origin, e.g. from an NL parsing component.

More interestingly, the type of domain and application determines the depth of modeling. Air quality reports form a small and closed domain. Implicit knowledge is easy to make explicit. A shallow model, being inherently simple, is perfectly adequate. A complex functor-argument representation would mean a dramatic overshot for this type of application. The same holds for many generation applications, such as reporting about stock exchange (Kukich, 1983) or weather forecasts (Boubeau et al., 1990). Medical scientific texts, on the other hand, form a very large domain, requiring broad-coverage linguistic knowledge. A shallow model would not even be able to capture the most frequent semantic relations. General means of expressing semantic relationships are mandatory.

What are the advantages and drawbacks of either approach? Shallow interlinguas allow for a straightforward multi-lingual generation. All linguistic processing can be concentrated in the module consuming the interlingua expression, e.g. TG/2. A drawback consists in domain-dependent grammars, which are hardly reusable for other applications. Still it is worthwhile, as the effort to create a grammar for another language is low.

With in-depth language-neutral representations, the issue of reusing existing linguistically motivated grammars arises, simply because of the tremendous effort for developing them from scratch. Technically an existing grammar may be reused if a well-defined interface is available. In TG/2, the interface to the input representations consists of the tests and access functions called from within the grammar rules. Depending on the different organization of information within input languages, this interface must be modified. If the same types of information required by the grammar can be produced by the new input language, the way is paved for a successful reuse. If the new input language offers different types of information, the adaptation problem described above arises.

4. On the Definition of Interlinguas

We now address issues on the semantics and pragmatics of interlinguas from a generation perspective by discussing three types of problems generators may encounter with in-depth interlinguas, using experiences with IRep4 as our source of examples.[2]

4.1. Extrinsic problems

In MUSI, a variety of problems with interlinguas known from machine translation were experienced, showing that this interlingua, as so many others, is not language-neutral in a strict sense. The problems were related to the fact that languages encode information differently and the interlingua cannot sufficiently abstract away from this. More precisely, although IRep4 does not contain elements specific to any of the four languages involved, the analysis results reflected some grouping and nesting of phrases and clauses of the source language.

[2] By critically reviewing IRep4, we necessarily omit mentioning many excellent features that made it very useful for the challenging task of representing scientific text.

For instance, Italian (and English) uses post-nominal adjectival clauses that correspond to a post-nominal relative clause or pre-nominal adjectival modifiers in German (cf. Figure 5a). German does not have the possibility to linearize or nest several adjectival or participial clauses after the head noun. Moreover, large phrases in pre-nominal position are difficult to understand since the head noun is uttered only afterwards.

In IRep4, these clauses are typically represented as restrictive modifiers (RESTR), accompanied, in the case of a predicative concept, by the source-language specification CAT = ADJP. The generator follows the heuristic strategy of assigning small adjectival phrases to the pre-nominal adjective position and large ones to the post-nominal relative clause position. In the latter case, the CAT specification will be ignored, as a full sentence with a copula must be generated. A further requirement consists of the need for one argument of the adjective to be realizable as the relative pronoun.

The result is not satisfactory, as it can lead to recursive center-embedding causing bad readability (cf. Figure 5b). The sentence in Figure 5c is stylistically much better; it has fewer closing brackets in a sequence, which means less deep embedding and improved readability. Linguistically, it shows two extrapositions, i.e. the innermost relative clause (not bracketed further) occupies the post-field[3] of the embedding one, which in turn occupies the post-field of the main clause. The stylistically preferred solution would be to realize the innermost clause as a prenominal AP, while extraposing the larger clause as a relative clause, as in Figure 5d.

Another striking example of language differences experienced with IRep4 is the use of determiners. English text does not use always definite articles when they are mandatory in German. For instance, "features of malnutrition" should be translated into "Merkmale der Mangelernährung" (definite article included), whereas "features of chronic malnutrition" corresponds to "Merkmale chronischer Mangelernährung" (no article).

IRep4 does, of course, not represent definite articles when there are no such determiners in the source-language text. The generator uses as a general rule that "naked" generalized possessives – i.e. the head of a RESTRictive modifier that corresponds to a noun and does not have a determiner or a modifier – are automatically accompanied by a definite article, covering the above examples.

English "Treatment consisted in..." should translate to "Die Behandlung bestand aus...", using a definite article. In these cases, a decision within the generator on whether or not to use a definite article would rely on lexical semantic information about both the source and target language lexemes.

The obvious solution to the extrinsic problems is to complement the level of interlingua with a set of transfer rules specific for every pair of source and target language. This complicates the situation, but would, in MUSI, have led to considerable stylistic improvements of the generated sentences.

For shallow models, this problem simply does not exist.

4.2. Intrinsic problems

IRep4 also has a few intrinsic properties that affected generation. Most prominently, it does not represent scope and thematic, or constituent, order information. The scope of negation would be important for the proper placement of the negation particle. Moreover, the scope of modifiers is not represented. With the current, inherently flat representation, i.e. multiple modifiers at the same level of embedding, generation cannot decide between e.g. "the following clinical case" and "the clinical following case". Modifiers should be nested to express this information.

Deciding about word order in generation is relevant to represent the argumentative structure in complex sentences and ensure coherence. The order of constituents in the source language text is not marked in IRep4, which may cause a deviating target-language order in German. This can lead to a lack of textual coherence, if e.g. a modifier that starts the sentence appears at the end. Consider "upon objective investigation, the woman's face was red and congested", which was translated into "das Gesicht der Frau war rot und geschwollen bei objektiver Untersuchung", generating the introductory PP at the end. A possible subsequent anaphoric reference would be less felicitous than in the original text. In the absence of a super-ordinated text planning stage, interlingua expressions should specify thematic order, or constituent order, in the source language text.

German generation assumes a standard word order for active voice, unless other information is given. The standard word order does not take into consideration the complexity, or the "weight", of a constituent. A heavy-weight subject preceding a short object in a transitive sentence is often considered bad style. Based on heuristics about a constituent's "weight", passive voice could have been chosen within the generator, causing the short constituent to precede the complex one, which generally leads to more fluent text (cf. the example in Figure 3). An interlingua should include hooks to provide this information. IRep4 might indirectly allow a good estimate by counting concepts, arguments and modifiers; further investigation is needed to identify a reliable formula.

For shallow interlinguas, intrinsic problems of this kind do not exist, as they are entirely dealt with in the grammar.

4.3. Pragmatic problems

In this section, we sketch some issues that can take a lot of effort to create a shared understanding among the researchers looking at interlingua expressions from different perspectives.

A grammatically correct input sentence is a legitimate input to a parser. Few systems can deal with incorrect sentences in an error-tolerant way. For generation, in-depth interlingua expressions should be correct in a similar sense. A formal specification of the interlingua is required to define its syntax and, very importantly, its semantics. Generation requirements should be formally specified as well and

[3] The post-field follows the infinite verb complex in a German declarative sentence. This position can be occupied by one constituent.

a) [[In the clinical case described,] [the symptoms] [were] [caused] [by ingestion [of anticolinergic substances [probably contained [in the leaves [of plants [consumed a few hours before]]]]]]].

b) [[In dem beschriebenen klinischen Fall] [wurden] [die Symptome] [durch [Verzehr [von anticholinergen Substanzen, [[die] [die Blätter [der Pflanze], [die vor ein paar Stunden genossen wurden,] möglicherweise enthielten,]]]]] [verursacht]].

In the described clinical case were the symptoms by ingestion of anticolinergic substances, that-were in-the leaves of-the plants, that-were a few hours before consumed, possibly contained.

c) [[In dem beschriebenen klinischen Fall] [wurden] [die Symptome] [durch Verzehr [von anticholinergen Substanzen]] [verursacht], [[die] [die Blätter [der Pflanze]] möglicherweise enthielten, [die vor ein paar Stunden genossen wurden]]].

d) [[In dem beschriebenen klinischen Fall] [wurden] [die Symptome] [durch Verzehr [von anticholinergen Substanzen]] [verursacht], [[die] [die [vor ein paar Stunden genossenen] Blätter [der Pflanze]] möglicherweise enthielten]].

Figure 5: Stylistic Variations in Translation. Brackets indicate some syntactic structure. a) English original sentence; b) Corresponding sentence in German with APs realized as relative clauses, with inter-linear translation; c) Extraposition of the relative clauses beyond the respective verbs; d) Realization of the innermost clause as a prenominal AP.

should be part of the "pragmatics" of the interlingua. For instance,

- the omission of information about tense, aspect, determination and number may mean that a default applies;
- a personal pronoun must either refer to an antecedent, or be accompanied by information about gender, person and number;
- an expression realized as a relative clause must contain exactly one constituent with a plain coreference specification; this constituent will become the relative pronoun;
- etc.

During the development of IRep4, this effort was not spent due to shortage of resources.[4] While from an analysis viewpoint, some decent output looks more or less satisfactory, it is the details that make generation feasible or cause its failure. Most importantly, the interpretation of interlingua expressions in NLG should be functional. Different surface representations corresponding to the same interlingua expression should be considered as equivalent in meaning. If this fundamental principle is not maintained, translation is not guaranteed to be meaning-preserving.

An interlingua can support this principle by making meaning representation explicit. IRep4 unfortunately has a fairly abstract representation for PP adjuncts and modifiers. The scheme is "`Mod = [<name>, <Irep4-expression>]`", where `<name>` is taken from a finite set of strings that more or less denote the semantics of the modifier. These names can be interpreted unambiguously by generation, but analysis may encounter difficulties in relating prepositions and head nouns to them, if only little lexical semantic knowledge is available. In Figure 3, the same name `RESTR` is realized differently, depending on the part of speech used for the embedded concept. If it is a noun, the semantics is that of a generalized possessive, which is realized in post-nominal position in German. If it is an adjective, a prenominal adjectival modifier is usually generated. Other uses of `RESTR` were mentioned above. If two or more meanings are connected to one name, it may appear psychologically difficult to refrain from using this name as a waste-basket.

Pragmatic problems exist for shallow models as well, as shallow input expressions are partly produced by external systems. In the air quality report generator, measuring values are received as input from a database. Time series are occasionally shortened by aggregating information ("from 9.00 to 11.00: 6,7 μg/m^3"). During the development, we have not been aware of the systematic omission of certain half hour values in the database, which occasionally leads to awkward results: "at 9.00: 6,7 μg/m^3; at 9.30: 0 μg/m^3; at 10.00: 6,7 μg/m^3; at 10.30: 0 μg/m^3; at 11.00: 6,7 μg/m^3". We easily could have implemented another aggregation rule that leads to output like "from 9.00 to 11.00: 6,7 μg/m^3, with every half hour value at 0".

5. Conclusion

In this contribution, we have related multi-lingual to cross-lingual generation and discussed emerging problems for the definition of an interlingua. This discussion was based on experience gained from implementing NLG components for a multi-lingual report generator and a cross-lingual summarization system within the same framework, TG/2. Shallow interlinguas originate from non-linguistic processing. They usually carry implicit meaning that must be made explicit in the generation process. For relatively small-coverage, closed domains, such as air quality reports, weather reports, or stock market reports, it is adequate to write specialized grammars using domain-specific canned text for this purpose. In-depth interlinguas usually originate from linguistic analysis, as in machine translation. The nature of the interlingua is closely tied to the sophistication of

[4] It is debatable though whether the resulting difficulties have been resolved with less effort.

the generation task in hand.

While well-modularized generation systems can be easily adapted to shallow interlinguas, an in-depth interlingua is much more complex to work with, as so many distinctions need to be addressed. In this paper we have identified some NLG requirements on in-depth interlinguas. From the experience with the MUSI application, we have learned that it is worthwhile to formally specify NLG requirements on the interlingua at the outset.

For a new application involving multi-lingual or cross-lingual generation, the interlingua should be chosen, adapted or designed according to the kind of linguistic processing involved and in view of the depth of modeling envisaged. On the shallow/in-depth scale, it should be as shallow as possible.

Abstract

This paper reports on the distinctive features of the Universal Networking Language (UNL). We claim that although UNL expressions are supposed to be unambiguous, UNL itself is able to convey vagueness and indeterminacy, as it allows for flexibility in enconverting. The use of UNL as a pivot language in interlingua-based MT systems is also addressed.

1. Introduction

Machine Translation (MT) is one of the most controversial subjects in the field of natural language processing. Researchers and developers are often at odds on issues concerning MT systems approaches, methods, strategies, scope, and their potentialities. Dissent has not hindered, however, the establishment of tacit protocols and core beliefs in the area. It has often been claimed that[1]: 1) fully automatic high-quality translation of arbitrary texts is not a realistic goal for the near future; 2) the need of some human intervention in pre-edition of the input text or in post-edition of the output text is mandatory; 3) source language should be rather a sublanguage, and the input text should be domain- and genre-bounded, so that the MT system could cope with natural language ambiguity; 4) the transfer approach is more feasible than the interlingual one, since the latter, albeit more robust and economic, is committed to the somewhat insurmountable task of designing a perfect (universal) language, comprising any other one; 5) common sense and general knowledge on both the source and the target cultures are as important as linguistic information, like in Knowledge-Based Machine Translation Systems (Nirenburg et al., 1992); 6) existing human translations can be used as a prime source of information for the production of new ones, similarly to the Example-Based Machine Translation Systems (Furuse and Iida, 1992); 7) existing MT systems are not appropriate to monolingual users, although they can be used to facilitate, speed up or reduce the costs of human translation, or to produce quick and cheap rough translations that may help the users to get a very broad idea of the general subject of the text.

[1] Most of these assumptions can be extracted from the Survey on the State of the Art in Human Language Technology (Cole et al., 1995). Of special interest are the articles concerning multilinguality by Martin Kay (8.1, 8.2) and Christian Boitet (8.3, 8.4).

Many authors obviously do not endorse all the listed statements, specially the fourth one. Hozumi Tanaka (1993), for example, argues in favor of the interlingua-based approach, and so do the research and development groups involved in interlingua-based systems, such as ULTRA (Farwell and Wilks, 1993), KANT (Mitamura et al., 1993), or PIVOT (Okumura et al., 1993). These works, however, rather confirm the very general observation that commercially available MT systems (e.g., SYSTRAN, VERBMOBIL, DUET (Sharp), ATLAS I (Fujitsu), LMT (IBM), METAL (Siemens)) are primarily transfer-based.

The most serious arguments against the interlingua approach concerns its alleged universality and excessive abstractness (Hutchins and Somers 1992). In order to cope with multilinguality, the interlingua should put aside language-dependent structures (such as the phonological, morphological, syntactical and lexical ones) and work at the logical level, which is supposed to be shared by human beings. Even at such uppermost level, however, there seems to be cultural differences. Eco (1994) reports, for instance, the case for Aymara, a South-American Indian language which would have three truth values, instead of the two "normal" ones. Furthermore, it has been said that, even if one comes to find this kind of perfect language, it would be so abstract that it would not be cost-effective, since the tools for departing from natural language and arriving at the logical representation would be excessively complex.

In what follows, we present some extra evidence towards the feasibility of interlingua-based MT. The Universal Networking Language (hereafter, UNL), developed by Uchida et al. (1999), brings some distinctive features that may lead to overcome some of the bottlenecks frequently associated to the interlingua approach. Although UNL was not designed as an interlingua, and MT is only one of the possible uses for UNL, it has been claimed that multilingual MT systems can use UNL as a pivot language. In this paper, some of the distinctive features of UNL are analyzed. We build

upon the experience in developing the Brazilian Portuguese (hereafter, BP) UNL Server, a bilingual MT system for translating Portuguese into UNL and vice-versa.

This paper is organized as follows. Section 2 provides a brief introduction to the UNL approach and some of its premises. In Section 3 we describe an experiment in which human subjects were asked to enconvert sentences from Portuguese into UNL. Section 4 brings the general results of the experiment. One of them is specially addressed in Section 5. Some issues arising from the results are presented in Section 6. Conclusions are stated in Section 7. The reader is supposed to have previous information on the UNL Project and knowledge on UNL Specification (at http://wwww.unl.ias.unu.edu) is considered mandatory.

2. The Universal Networking Language

The Universal Networking Language (UNL) is "an electronic language for computers to express and exchange every kind of information" (Uchida et. al., 1999, p. 13). According to the UNL authors, information conveyed by each natural language (NL) sentence can be represented as a hyper-graph whose nodes represent concepts and whose arcs represent relations between concepts. These concepts (called Universal Words or simply UWs) can also be annotated by attributes to provide further information on the circumstances under which they are used.

In this context, UNL is not different from the other formal languages devised to represent NL sentence meaning. Its structure is said to suffice to express any of the many possible meanings conveyed by any sentence written in any NL. This does not mean, however, that it is able to represent, at the same time, all the possible meanings conveyed by the very same NL sentence. Instead, UNL is able to represent each of them independently, and it is by no means able to provide a single structure coping with all of them. In this sense, there will never be a single UNL expression that completely suffices the meaning correspondence to a NL sentence. Or else: no UNL expression will be ever completely equivalent to a NL sentence, since the latter, but not the former, will allow for ambiguity.

In the following section, we report on results of a BP-UNL enconverting task that has been carried out by BP native speakers. In this experiment, we observe evidences that BP sentences must be disambiguated in order to be represented as UNL expressions.

3. The Experiment

In August 2001, we carried out an experiment on BP-UNL enconverting that involved 31 BP native speakers, all of them graduate and postgraduate students. Most of them (over 95%) were Computer Sciences students, aging 21 to 42 years old (90% of them were under 30 years old).

The experiment was split into training (steps 1-4) and test sessions (step 5), as follows: 1) a very general description of the UNL structure; 2) a general presentation of the definitions provided for five relation labels by the UNL Specification (1999), namely, 'agt' (agent), 'cag' (co-agent), 'obj' (affected thing), 'cob' (affected co-thing), and 'ptn' (partner); 3) an individual exercise on the use of the presented relation labels, in which subjects were asked to identify 50 different relations appearing in different BP sentences, indicating the corresponding UNL relation labels; 4) a public discussion on the exercise results; and 5) a final individual test in which subjects were asked again to identify 30 different relations appearing in different BP sentences, through their correspondence with the very same set of UNL relation labels. In Step 3 and 5, the subjects had also the option of pinpointing the impossibility of identifying either a relationship or its corresponding relation label, by choosing a "catch all" alternative (see option (a) in Figure 1). This exercise aimed at providing the means for the subjects to understand and explore BP-UNL enconverting, concerning the relation labels identification. This was then reinforced in Step 4, which was supervised by a UNL specialist. As it can be observed, these steps aimed at Step 5, the actual BP-UNL assignment, focusing on specific relation labels. In this step, some of the BP sentences presented to the subjects in Step 3 have been replicated.

Altogether, this experiment has taken 1 hour and 40 minutes, considering a 20-minute interval between the training and test sessions. Steps 1 and 2 have last 20 minutes, and so has Step 3 alone. Step 4, the longest one, has taken 40 minutes. Step 5, the actual test, has taken another 20 minutes. The interval between training and test aimed at allowing for the subjects settling on UNL specification, since test has been totally unsupervised. This also justifies our replication of some of the BP sentences used in training.

An English version of the task proposed in Step 3 is presented in Figure 1 below.

Considering the information presented in the first part of this experiment, identify the following:
1) If the relation depicted between the words signaled in each of the sentences below belongs to the five-relation set discussed previously; and
2) If so, which relation label would most suitably describe the involved relationship.

Use, for reference, the following code:
a) if NO label describes the relationship between the signaled words;
b) if the label AGT (agent) is the most suitable one;
c) if the label CAG (co-agent) is the most suitable one;
d) if the label COB (affected co-thing) is the most suitable one;
e) if the label OBJ (affected thing) is the most suitable one;
f) if the label PTN (partner) is the most suitable one.

Figure 1. Instructions for identifying and classifying relations.

The 30-sentence set used in the test session, along with its corresponding English translation, is shown in Figure 2.

	SENTENCES
1.	A crise quebrou o empresário >> ???(quebrou, crise) *The crisis broke the business man.* >> ???(broke, crisis)
2.	A crise quebrou o empresário >> ???(quebrou, empresário) *The crisis broke the business man.* >> ???(broke, business man)
3.	A farsa acabou. >> ???(acabou, farsa) *The farce is over.* >> ???(is over, farce)
4.	A neve caía lentamente. >> ???(caiu, neve) *Snow felt slowly.* >> ???(felt, snow)

5.	Alugam-se casas. >> ???(alugar, casa) *Houses are rented* (also: *Someone rents houses*) >> ???(are rented, houses)
6.	Choveu canivete ontem. >> ???(choveu, canivete) *It rained knives yesterday >> ???(rained, knives) (Brazilian Idiom)*
7.	João jogou o vaso com Maria contra Pedro. >> ???(jogou, Maria) *John threw the bowl with Mary against Peter.* >> ???(threw, Mary)
8.	João jogou o vaso com Maria contra Pedro. >> ???(jogou, Pedro) *John threw the bowl with Mary against Peter.* >> ???(threw, Peter)
9.	João lutou com Maria para vencer a doença. >> ???(lutou,Maria) *John fought with Mary to win the disease.* >> ???(fought, Mary)
10.	João não teve filhos com Maria. >> ???(ter, João) *John did not have children with Mary.* >> ???(have, John)
11.	Maria esqueceu o dia do aniversário da filha. >> ???(esquecer, dia) *Mary forgot her daughter's birthday.* >> ???(forgot, birthday)
12.	Maria foi despedida. >> ???(despedir, Maria) *Mary was fired.* >> ???(fire, Mary)
13.	Maria lembrou Pedro do horário. >> ???(lembrou, horário) *Mary remembered Peter about the schedule.* >> ???(remembered, schedule)
14.	Maria morreu com a falta de oxigênio.. >> ???(morreu, falta) *Mary died with the lack of oxygen.* >> ???(died, lack)
15.	Maria namorou Pedro. >> ???(namorou, Maria) *Mary flirted (with) Peter.* >> ???(flirted, Mary)
16.	Maria não foi ao cinema com a vizinha. >> ???(foi, vizinha) *Mary did not go to the cinema with her neighbor.* >> ???(go, neighbor)
17.	Maria não quis matar Pedro! >> ???(matar, Maria) *Mary did not intend to kill Peter.* >> ???(kill, Mary)
18.	Maria não se sentiu bem. >> ???(sentir, Maria)
	Mary did not feel well. >> ???(feel, Mary)
19.	Maria nunca conquistou Pedro. >> ???(conquistou, Pedro) *Mary never conquered Peter.* >> ???(conquered, Peter)
20.	Maria parece cansada. >> ???(parece, Maria) *Mary looks tired.* >> ???(looks, Mary)
21.	Maria se esqueceu de João. >> ???(esquecer, João) *Mary forgot John.* >> ??(forgot, John)
22.	Maria se matou. >> ???(matou, Maria) *Mary killed herself.* >> ???(kill, Mary)
23.	O filme deu origem a muitas controvérsias. >> ???(deu, filme) *The movie raised many controversies* >> ???(raised, movie)
24.	O frio congelou o pássaro. >> ???(congelar, frio) *The cold froze the bird.* >> ???(froze, cold)
25.	O medo da morte provoca insônia. >> ???(provoca, medo) *Fear of death causes insomnia.* >> ???(causes, fear)
26.	O pai com os filhos matou a mãe. >> ???(matou, filhos) *The father with the children killed the mother.* >> ???(killed, children)
27.	O pássaro congelou com o frio. >> ???(congelar, frio) *The bird froze (i.e., was frozen) with the cold.* >> ???(froze, cold)
28.	Os carros se chocaram na estrada. >> ???(chocaram, carros) *The cars crashed each other on the road.* >> ???(crashed, cars)
29.	Pedro se parece com a mãe. >> ???(parece, mãe) *Peter looks like his mother.* >> ???(looks, mother)
30.	Precisa-se de funcionários. >> ???(precisar, funcionários) *Employees are needed.* (also: *Someone needs employees*) >> ???(need, employees)

* Students were presented only to the original Brazilian Portuguese sentence. In the translation from Portuguese into English we tried to preserve the Portuguese syntactic structure as often as possible, even when the resulting English sentence sounds agrammatical.

Figure 2. Test corpus.

4. Results

The results of the experiment were the following:

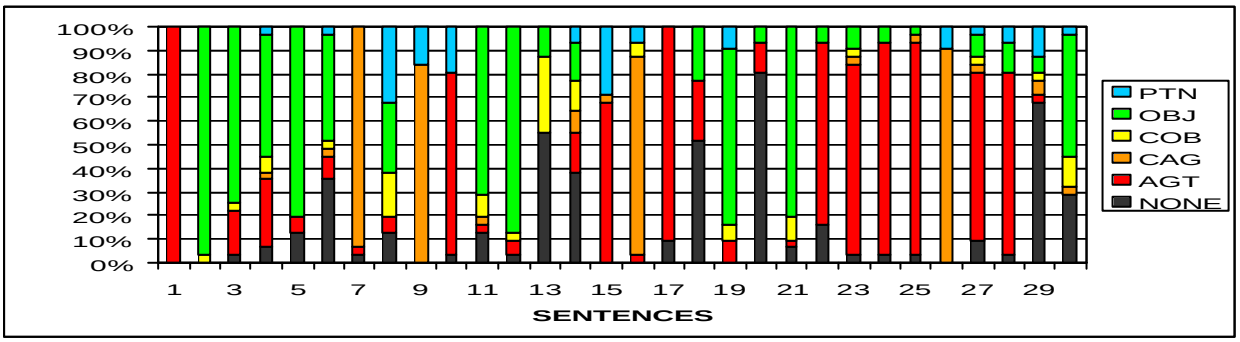

Figure 3. Distribution of BP-UNL enconvertings by subjects, with respect to the 5-relation labels set

Figure 4 below groups the results according to the agreement among enconverters.

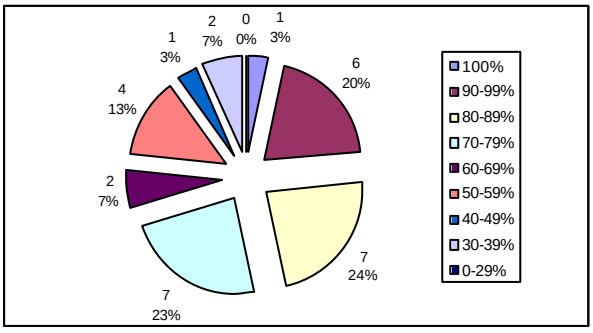

Figure 4. Agreement among enconverters.

A single relation (between "crise" (*crisis*) and "quebrou" (*to break*) in sentence 1: *"A crise quebrou o empresário" (= The crisis broke the business man*) led to an agreement of 100% among enconverters: they all used the 'agt' label in this case. There was an agreement between 90% to 99% on labeling relations in 6 sentences. Enconverters also agreed between 80% to 89% in assigning labels in 7 sentences. Other 7 sentences involved 70% to 79% agreement. In the remaining 9 sentences, agreement among enconverters was lower than 70%.

5. Case Study: Sentence 14

Sentence 14 ("Maria morreu com a falta de oxigênio." (literally: "Mary died with the lack of oxygen.") can be taken as a typical example of those involving considerable disagreement among enconverters. The relation between the verb "morreu" (to die) and the noun "falta" (lack) was encoded in varied ways, as follows: a) as an agent one (16%); b) as an object one (16%); c) as a co-object one (13%); d) as a co-agent one (10%); e) as a partner one (6%); and f) as none of the previous five relations (39%).

The unavoidable issue that follows from the above is why UNL labels were used in such apparently fuzzy way. Several reasons could be pinpointed here: a) the lack of expertise (or even of attention) of human enconverters', for they could not have had enough knowledge of language, or motivation, to carry on the experiment (although they are BP native speakers and seemed to be willingly helpful and interested in participating); b) the lack of clarity of the UNL Specification itself, even though there had been considerable discussion in the training session, for the problems posed by the enconverters to be tackled; c) the structure of the experiment itself, which was indeed too brief and too shallow to properly evaluate the human enconverters' performance; and, finally, d) the ambiguity of test sentences.

The analysis of the enconverters' choices certifies that disagreements are due to the latter point. Although it is unlikely for a BP speaker to say that 14 above, out of context, could have many different colliding meanings, the experiment has proved that apparently unambiguous sentences are unambiguous only apparently. Although eventually invisible, NL vagueness and indeterminacy would be pervasive in ordinary language,

Actually, none of the labels assigned to the relation between "morreu" (to die) and "falta" (lack) in sentence 14 could be considered wrong. The lack of oxygen could be understood in many distinct ways, such as:

a) an agent ("agt"), or the "initiator of the action" of "Mary dying" (or "killing Mary");

b) a co-agent ("cag"), or a "non-focused initiator of an implicit event that is done in parallel", in the sense it was not the lack of oxygen that killed Mary but either b.1) the situation (or the person) that has provoked the suppression of Mary's air supply or, in a more precise way, b.2) the reaction provoked (mainly in the brain) by the lack of oxygen;

c) an object ("obj") for the event described by "dying", since it is somehow "directly affected" by it, as the conclusion that the oxygen was lacking might be said to come directly from the fact that Mary died, otherwise no one would perceive that oxygen was lacking;

d) an affect co-thing ("cob"), or as being "directly affected by an implicit event done in parallel", if the observation that the oxygen was lacking were said not to come directly from the fact that Mary died, but from the fact that her lungs stopped working, which caused her to die;

e) a partner ("ptn"), for it could be somewhat "an indispensable non-focused initiator" of the action of "Mary dying", as if the main responsible for Mary's death was Mary herself (or someone else) that turned the oxygen suply off.

Besides such illustrations, many other relations can be said to hold between 'lack of oxygen' and 'die', namely, "met" (method), "man" (manner), "ins" (instrument), and "rsn" (reason), all easily applicable to such a case.

Such a variety proves that sentence 14 was indeed vague. The syntactic relation between the BP verb and its adjunct can convey many different semantic cases. Nevertheless, the UNL expression – whatever it may be – will have, in turn, a single interpretation, because relation labels are not supposed to overlap. The relations agt(die,lack), cag(die,lack), cob(die,lack), obj(die,lack), ptn(die,lack), although applicable to that very same NL sentence, are expected to label different (albeit related) phenomena. Indeed, to say agt(die,lack) is not the same as to say cag(die,lack) or ptn(die,lack). No intersection between these relations is envisaged in the UNL Specification, since they are meant to be exclusive[2].

This makes clear that the UNL specification forces filtering possible interpretations for NL sentences, in the sense a UNL expression must provide a completely unambiguous representation for the source sentence. As a matter of fact, although UNL is intended to be as expressive as any NL, UNL expressions cannot convey, at least at the relation level, NL vagueness and indeterminacy. Like any other formal language, UNL is committed to disambiguate NL sentences and, hence, to impoverish their semantic power.

Nevertheless, in no one of the above situations it is possible to say that a relation label is wrong, or that is completely inappropriate, although some of them may seem really unlikely to hold, depending on the context. The point is that the meaning of the sentence "Mary died with the lack of oxygen." is not encapsulated in the sentence itself but it is built out from the reading (and hence from the analysis) made by human enconverters. Since different enconverters have different underlying assumptions during their readings, the same BP phenomena can naturally imply different interpretations, which in turn lead to distinct UNL labeling. To conclude, it seems impossible to prevent subjectivity (or context-sensitiveness, or else, enconverter-sensitiveness) at that extent, no matter how univocal NL sentences seem to be.

6. Consequences

From the above it is possible to state that UNL should not seek for a straightforward correspondence between UNL expressions and NL sentences. It would be useless. As meaning is not encrypted in NL sentences but build through the analysis process, different enconverters will unavoidably propose different UNL expressions for the

[2] Accordingly, it is worthy to observe that the individuality of relations seems to be less strong when we consider other UNL relation labels set, e.g., that comprising "qua" (quantity), "nam" (name) and "pos" (possessor), which seems to be, to some extent and context, replaceable by "mod" (modification), implying that the latter can quite feasibly be at an uppermost level in a relation hierarchy. The same could be said of "met" (method) and "ins" (instrument), which seem to be under the scope of "man" (manner). Conversely, this does not mean that "mod" comprises any of "qua", "nam", or "pos", or that "man" embeds "met" and "ins". Instead, it does mean that both "mod" and "man" seem to share a comprehensive set of features with the relations that they replace. This is not the case of "agt", "cag", "cob", "obj", and "ptn", which seem to be in a more outstanding opposition.

very same NL sentence and many of these different expressions are legitimate.

Due to structure of UNL, UNL expressions cannot replicate NL sentence vagueness and indeterminacy. Enconverters are obliged therefore to choice a single interpretation among many different possible ones. This choice will be inevitably affected by the enconverters' context, which will be unreplicable itself by other enconverters. Once all these enconvertings will be valid, in the sense they are context-motivated, there will never be a one-to-one mapping between NL sentences and UNL expressions.

Accordingly, correctness, in UNL, instead of representing a (impossible) single possibility of enconverting, should rather be considered as fidelity to enconverters' intentions. UNL should clearly state that it would be up to the (human and machine) enconverter to decide what should the UNL representation be for a NL sentence. That is to say, the object of the UNL representation should be considered not exactly the meaning conveyed by the NL sentence but the *interpretation inferred by the enconverter from the use of that NL sentence in the enconverter's specific context*.

The fact that there could be more than a single (and adequate) UNL expression for the same NL sentence implies that UNL allows for flexibility in the enconverting process, although the UNL expression itself is not supposed to be flexible. It is up to the enconverter, and not the UNL specification itself, to decide which of the many possible interpretations is to be represented by a UNL expression. This is a significant UNL distinctive feature. Most formalisms do not allow for such variability and postulate that there should be a biunivocal relation between NL and its artificial representation. Otherwise, the formal representation would keep mirroring NL vagueness and indeterminacy, resulting useless.

The problem here is how to assure that enconverting flexibility will not prevent UNL from being a machine tractable language. As far as UNL expressions are dependent on the enconverter, there could be uncontrolled variations, which could blow out UNL into many different (and maybe mutually unintelligible) dialects.

This problem can be divided into two parts: 1) how to be sure that the UNL expression represents indeed what is intended by the enconverter; and 2) how to be able to generate, from such varied UNL expressions, NL grammatical sentences.

The first question is somewhat an educational problem. There are obviously misunderstandings and misuses of many relations. To say that it is up to the enconverter to decide which label should be used is not to say that the enconverter can do whatever he/she/it wants. The UNL Specification and other guidelines are to be followed. The relation "agt" must be applied to "a thing that initiates an action", and "ptn" should stand for "an indispensable non-focused initiator of an action". The relation "agt" cannot be used in a different sense: it would be wrong. Flexibility in encoding should not be mistaken for permissiveness. There are many correct UNL expressions for the same NL sentence, but there are also wrong UNL expressions.

The solution to such a problem cannot be, however, to state a rigid (a culture-, language-, context- and even enconverter-independent) relationship between a NL and UNL, otherwise UNL will not suffice to cope with inevitable varying enconvertings. The fact that meaning is build through the enconverting process and its main consequence, the fact that different enconverters will propose different expressions for the same NL sentence, should be both considered starting points, instead of something that one can or should avoid.

The best solution is, thus, to trust the enconverter (and maybe to certify enconverters), and to be conscious that, as in any other translation activity, there are good and bad translations, and bad translations do not prove that translating is not possible or that it does not work. Only time and enconverters' expertise can make UNL expressions better.

Nevertheless, to trust enconverters may imply making deconverting extremely difficult and costly. The more UNL allows flexibility in enconverting, the more costly will be UNL-NL deconverting, since the UNL expression may contain unexpected relations.

This is, however, a false problem. Deconverters are not committed to generate back the source sentence enconverted into UNL. Instead, they should be supposed to generate a NL sentence corresponding to the UNL expression. The original source sentence is definitely lost as it has been enconverted into UNL; only one of its possible interpretations (the one carried out by the enconverter) is preserved. Deconverters should take then UNL expression as the new source sentence, instead of using it just as an intermediate expression.

Furthermore, deconverting seems to be easier than enconverting, since much of the eventual meaning gaps may be inferred from the context by a human being (which is supposed to be the final user), instead of a machine. There is a very fragile break-even-point, from which generation results become excessively degraded, but the extent to which this happens will depend on the architecture of the UNL System.

7. Conclusion

The main conclusion to be extracted from the previous section seems to be a paradox: in multilingual MT Systems, in order to be a pivot language, UNL should not be treated as an interlingua, but as a source and a target language, at the same level as any other NL. Flexibility in enconverting brings UNL to be just like any other NL, in the sense it would allow UNL for coping with NL vagueness and indeterminacy, without sacrificing, however, the explicitness and clarity of UNL expressions, which would continue to be univocal and machine-tractable.

Acknowledgments

The authors acknowledge Mr. Tadao Takahashi, for his management of the Brazilian branch of the UNL Project, and to CNPq (Brazil) for the partial financial support. This work has also been partially supported by the UNU/IAS and the UNDL Foundation. The opinions expressed in the paper, however, do not necessarily represent the view of the UNL mentors.

Structural and lexical transfer from an UNL graph to an equivalent natural language dependency tree

Abstract

We describe the transfer of an UNL graph into a equivalent tree, allowing to build UNL deconverters using existing MT systems based on tree processing.

1. Introduction

In the Universal Networking Language, a text is represented as a graph where nodes, bearing "Universal Words" (UWs), are linked by directed arcs bearing semantic "Relations Labels". A particular node, the "entry node", is distinguished in the graph.

The structure of these UNL graphs makes them quite suited to be processed by various linguistic tools. In particular, the Deconversion (from a UNL graph into an equivalent Natural Language text) or the Enconversion (from a Natural Language text into a UNL graph) may be achieved not only using the specially devised Deco and Enco tools, but also using adapted existing classical MT systems. For instance, UNL to Russian, UNL to Chinese, UNL to French deconverters are being developed using transfer MT systems.

Most of the classical MT systems use tree representation and not graph representation. Therefore the first step in the deconversion based on such systems is a graph-to-tree transfer. The aim of this paper is to discuss such a transfer, and to present the method used in the UNL-to-French deconverter.

We will begin by an overall presentation of the UNL-to-French deconvertor based on the ARIANE-G5 generator of MT systems. We will then discuss in more detail the process of graph-to-tree transfer.

2. A UNL-to-French deconverter deriving from a classical transfer system

2.1. Ariane-G5, a generator of MT systems

ARIANE-G5 is a generator of MT systems, that is an integrated environment designed to facilitate the development of MT systems (Boitet, 1997). These MT systems are written by a linguist using specialized languages for linguistic programming. ARIANE is not devoted to a particular linguistic theory. The only strong constraint is that the structure representing the unit of translation (sentence or paragraph) must be a decorated tree.

Fig.1 shows an overview of a classical transfer MT system using the ARIANE environment. The processing is performed through the three classical steps : analysis, transfer and generation.

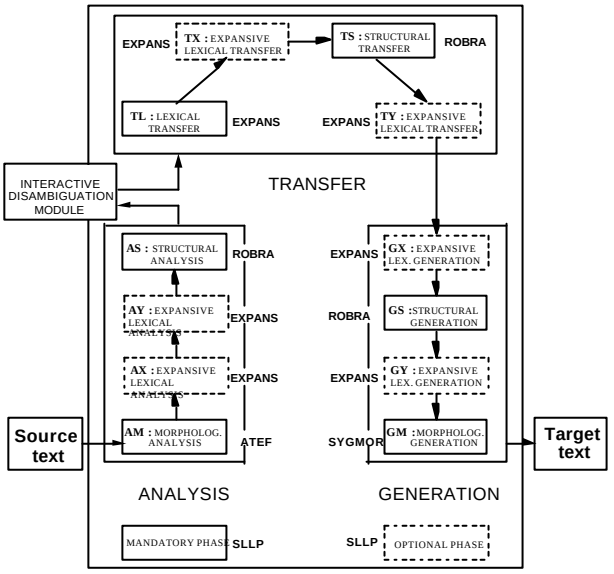

Figure.1 The Ariane-G5 environment as used for generating a transfer MT SYSTEM

2.2. Principle of the French Deconverter

Fig 2 shows an overview of the UNL-to-French deconverter using the ARIANE environment.

The first step is a graph-to-tree transfer, achieving both:

- the graph-to-tree structural transfer necessary for the ulterior Ariane processing
- a lexical "Universal Words" to French words lexical transfer.

The resulting tree is a classical "deep tree" ready for generation.

This first structural and lexical step will be discussed in detail below. The following classic generation step will not be discussed here.

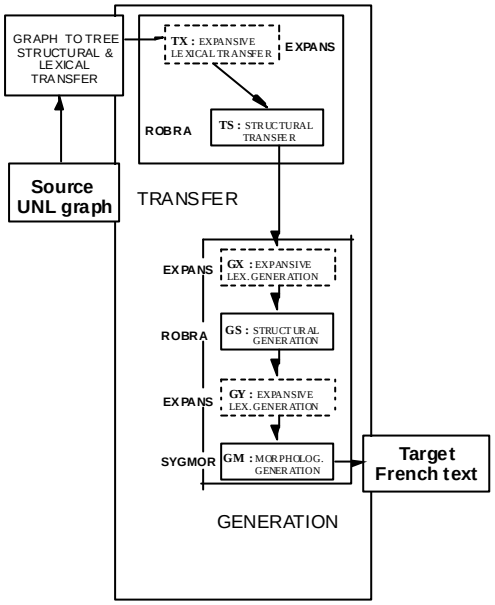

Figure 2 : The Ariane-G5 environment as used for generating a French deconverter.

3. UNL graph to NL tree structural transfer

The aim of the graph-to-tree structural transfer is to supply an output tree displaying all the structural information contained in the input UNL graph.

We will consider the following examples of tructural features encountered in a graph and needing some special coding in a tree are for instance:

- node having several mother nodes
- closed circuit
- hypergraph structure, that is graph containing nodes having themselves a graph structure (subgraphs, or "Compound Universal Words")

But before considering these examples, let's first illustrate the transfer on the simplest case, that is the transfer of a graph having in fact already a tree structure.

3.1. Graph with tree structure

In this simple case, the transfer is straightforward, as illustrated on figure 3.

This figure gives successively, from top to bottom:

- the meaning of the input graph as expressed in English
- the graph itself
- a sketch of its structure
- the structure of the equivalent tree as given by the structural transfer module (in this case the structure is the same as the structure of the graph)
- the decoration of the tree nodes.

The decoration of each node lists

- the Universal Word
- the semantic relation relative to its moither node (noted as a monovalued variable RSUNL)
- the attributes of the node (noted as a multivalued variable VARUNL)
- the id number (noted as the monovalued variable INST).

3.2. Graphs containing nodes with more than one mother node

In a tree, the root node has no mother node, and the other nodes have only one mother node. This is of course generally not the case for a graph, where all the nodes (including the entry one) may have several mother nodes.

Let's for instance consider the graph of fig. 4, where the entry node (« institute ») has a mother node (« establish ») the arc joining the first node to the second bearing the relation *obj*:

```
obj(establish(icl>found).@past,institute(ic
l>facilities).@present.@entry)
```

In order to get a tree, with a root node without mother node, the relation is inverted in the transfer module, and becomes

```
xxobj(institute(icl>facilities).@present.@e
ntry, establish(icl>found).@past)
```

where *xxobj* represents the inverse relation of the *obj* relation . The *obj* relation in the original graph expresses the fact that « institute » is the *obj* of establish, whereas the *xxobj* relation in the modofied graph expresses the fact that « establish » has « institute » as *obj*. Such an "inverted relation" is usally deconverted into French as a relative clause. The deconverted French text reads *"L'université des Nations Unie est un institut que l'Assemblée Générale des Nations Unies a fondé en 1975"."*

3.3. Graph containing a closed circuit

An equivalent tree structure of a graph containing a closed circuit may be obtained by opening the circuit, splitting one of its nodes as shown on fig.5 (the node "lecturer".splitted)

The new created node bears the same id number as the original one, indicating that it refers to the same object. In this example, this new node will be translated in French by the possessive "son", and the deconverter output reads *Le conférencier a lu son papier "*

3.4. Hypergraphs

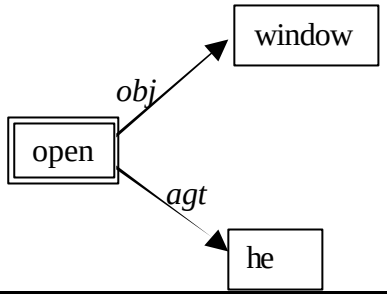
The processing of an hypergraph (graph containing subgraphs) is quite straightforward: the resulting tree is a tree containing subtrees.

English text: **He doesn't open the window.**

Graph :

```
agt(open(icl>do).@entry.@not,he)
obj(open(icl>do).@entry.@not,window.@def)
```

Graph structure:



Output tree:

```
                                          |-- 2:'WINDOW
                                          |
                                1:'OPEN' ---!-- 3:'HE'
```

Tree decoration:

```
1 'OPEN': VARUNL(ENTRY,NOT),INST(1)
    2 'WINDOW': VARUNL(DEF), RSUNL(OBJ),INST(1)
    3 'HE': RSUNL(AGT),INST(1)
```

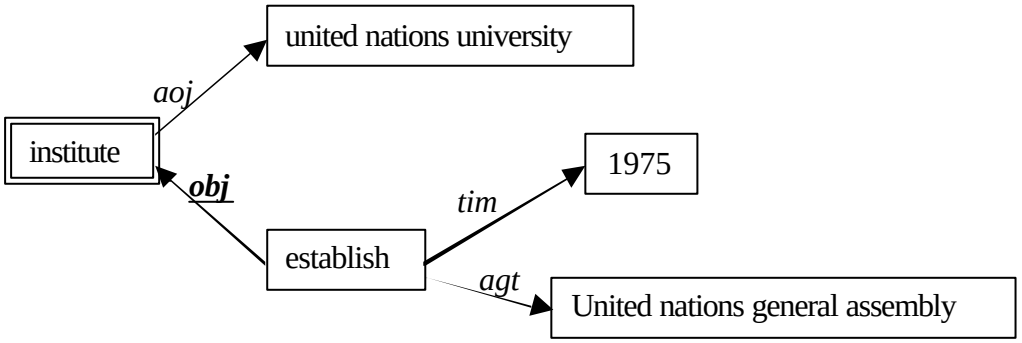
Fig 3. Structural transfer for a graph with tree structure..

English text: **The United Nations University is an institute which was founded by the United Nations General Assembly in 1975.**

Graph:

```
aoj(institute(icl>facilities).@present.@entry,united nations
university(icl>facilities))
obj(establish(icl>found).@past,institute(icl>facilities).@present.@entry)
agt(establish(icl>found).@past,united nations general
assembly(icl>organization))
tim(establish(icl>found).@past,1975)
```

Graph structure



Output tree

```
                        |-- 2:'UNITED NATION UNIVERSITY'
                        |                      |-- 4:'1975'
-- 1:'INSTITUTE' ------!-- 3:'ESTABLISH' -----!-- 5:'UNITED NATIONS GENERAL ASSEMBLY'
```

Tree decoration:

```
1 'INSTITUTE': VARUNL(PRESENT,ENTRY),INST(1)
    2 'UNITED NATIONS UNIVERSITY' RSUNL(AOJ),INST(1)
    3 'ESTABLISH': UL('<ESTABLISH>'), VARUNL(PAST), RSUNL(XXOBJ),INST(1)
      4 '1975':  RSUNL(TIM),CAT(CATCARD)
      5 UNITED NATIONS GENERAL ASSEMBLY': RSUNL(AGT),INST(1)
```

Figure 4 :Structural transfer of a graph whose entry node has a mother node

English text : **The lecturer read his paper.**

Graph :

```
agt(read(icl>do).@entry.@past,lecturer.@def)
obj(read(icl>do).@entry.@past,paper(icl>article))
pos(paper(icl>article),lecturer)
```

Graph structure:

Figure 5. Structural transfer for a graph containing a closed circuit.

4. UNL graph to NL tree lexical transfer

The structure of the UNL universal words makes in principle the lexical transfer a straightforward process.

A Universal Word like *mouse(icl>animal)* comprises indeed an headword "*mouse*" and a restriction "*icl>animal*" whose aim is to disambiguate the UW : distinction between *mouse(icl>animal)* and *mouse(icl>device)*.

But in practice incompletness or inadequacies of the dictionaries leads either to use a treatment of the unknown word or an interactive lexical transfer.

4.1. Treatment of the unknown word

The treatment of the unknown words (that is of Uws whose NL language equivalents are not available in the dictionaries) may be based on the restriction of the UW and/or on the semantic relations the UW participates to.

4.1.1. Treatment of the unknown word based on the UW restriction

Using the restriction of the UW, we perform a partial treatment of the unknown word: the UW is not translated (the headword appears in the deconverted sentence), but the sentence is as far as possible correctly build.

This is shown on figure 6 where the graph contains two UWs supposed unknown. Testing the restrictions of the unknown UWs `rake(icl>do)` and `rake(icl>thing)` indicates that the first one is a verbal concept, the second one a thing concept, which allowed a correct construction of the sentence.

*English text :***He rakes the leaves with the big rake.**

Graph :

```
agt(rake(icl>do).@entry,he)
obj(rake(icl>do).@entry,leaf(fld>botany).@def.@pl)
ins(rake(icl>do).@entry,rake(icl>thing))
mod(rake(icl>thing),big(mod<thing))
```

French output text : **Il <<rake>> les feuilles avec le? grand? <<rake>>.**

Fig 6 Treatment of the unknown word based on the UW restrictions

4.1.2. Treatment of the unknown word based on the semantic relations

The semantic relations may also be used to determine the nature of the unknown word, allowing thus to obtain the correct sentence structure.

Figure 6 shows the deconversion result for a (unrealistic) graph where two unknown UWs without restrictions are present : *rake:01* and *rake:02* (the two different ids :01 and :02 indicate that these UWs are associated to two different nodes).

The different natures of both UWs were determined by using the semantic relations: the first instance of the UW rake, being the origin of an *agt* relation, was considered as a verbal concept, while the second one, being the target of an *ins* relation, was considered as a nominal concept.

English text **He rakes the leaves with the big rake.**

Graph : `agt(rake:01.@entry,he)`
`obj(rake:01.@entry,leaf(fld>botany)`
`.@def.@pl)`
`ins(rake:01.@entry,rake:02)`
`mod(rake:02,big(mod<thing))`

French output text: **Il <<rake>> les feuilles avec le? grand? <<rake>>.**

Fig 6 Treatment of the unknown word based on the semantic relations.

4.2. Interactive lexical transfer

Our local deconverter may work in an interactive lexical mode. In this mode, for each UW in the graph, the French equivalent(s) present in the dictionaries are displayed for choice (figure 7).

`Meeting(icl>event)` `Click on one item below`

`Entering a new equivalent`
 	
`meeting(icl>event)`
`réunion`
`CAT(CATN),GNR(FEM)`
 	
`meeting(icl>event)`
`rencontre`
`CAT(CATN),GNR(FEM)`

Figure 7 : Interactive lexical transfer

If no satisfactory equivalent is present in the dictionaries, the user may enter the correct equivalent, which is stored in an auxiliary dictionary, and becomes immediately available.

This interactive mode makes use of the PARAX-UNL hypertextual multilingual database (Blanc 1999)

5. Argument transfer

By argument transfer, we mean the relation between a UNL semantic relation and the corresponding syntactic function in the target natural language. It is not a one to one relation.

We will show here on an example how testing the restriction of a predicate may help finding the syntactic function associated to a semantic relation.

In the UNL language, one distinguishes the verbal concepts *do*, *occur*, *be*. For instance, the graph of fig. 8 contains the UW « open(icl>do) », whereas the graph of fig. 9 below contains the UW « open(icl>occur) ».

Both UWs are translated into French by the same verb, « ouvrir » (or in English by the same verb « to open »). But it is clear that in the case of « open(icl>do) », the subject syntactic relation for the French (or the English) verb corresponds to the *agt* relation (figure 8), but to the *obj* relation in the case of the « open(icl>occur) » UW.

That means that in such a case the restriction had to be tested in order to find the subject of the sentence.

He doesn't open the window.

`agt(open(icl>do).@entry.@not,he)`
`obj(open(icl>do).@entry.@not,window`
`.@def)`

Il n'ouvre pas la fenêtre.

`dow.@def)`
`[/S]`

La fenêtre n'ouvre pas.

Figure 9 The obj relation of this graph corresponds to the syntactic subjet relation in French or English

6. Conclusion

Such a UNL graph to Natural Language tree transfer proved to be quite feasible, and allowed us to reuse an existing French generator.

Some Lexical Issues of UNL

Abstract.

The Universal Networking Language (UNL) developed by Dr. H. Uchida at the Institute for Advanced Studies of the United Nations University is a meaning representation language designed for multi-lingual communication in electronic networks, information retrieval, summarization and other applications. We discuss several features of this language relevant for correct meaning representation and multi-lingual generation and make some proposals aiming at increasing its efficiency.

1. UNL approach to the lexicon.

The Universal Networking Language (UNL) developed by Dr. H. Uchida at the Institute for Advanced Studies of the United Nations University is a meaning representation language designed for multi-lingual communication in electronic networks, information retrieval, summarization and other applications.

Formally, a UNL expression is an oriented hypergraph that corresponds to a natural language sentence in the amount of information conveyed. The arcs of the graph are interpreted as semantic relations of the types agent, object, time, reason, etc. The nodes of the graph can be simple or compound. Simple nodes are special units, the so-called Universal Words (UWs) which denote a concept or a set of concepts. A compound node (hypernode) consists of several simple or compound nodes connected by semantic relations.

In addition to propositional content ("who did what to whom"), UNL expressions are intended to capture pragmatic information such as focus, reference, speaker's attitudes and intentions, speech acts, and other types of information. This information is rendered by means of attributes attached to the nodes.

After 6 years of the UNL project development, it is possible to take stock of what has been achieved and what remains to be done. In this presentation, I am going to concentrate on one of the central problems with which any artificial language is faced if it is designed to represent meaning across different natural languages. It is a problem of the language vocabulary.

I would like to single out three distinctive features of the UNL dictionary organization.

1. **Flexibility.** There is no fixed set of semantic units. There is only a basic semantic vocabulary that serves as a building material for free construction of derivative lexical units with the help of semantic restrictions. This makes it possible to balance to some extent the non-isomorphism of lexical meanings in different languages.

2. **Bottom-up approach.** The UNL dictionary consisting of Universal Words is not constructed a priori, top-down. Since it should contain lexical meanings specific to different languages, it grows in an inductive way. It receives contributions from all working languages. Due to this, one can expect that linguistic and cultural specificity of different languages will be represented more fully and more adequately than it would be possible under the top-down approach.

3. **Knowledge base.** As the UNL dictionary comprises unique semantic complexes lexicalized in different natural languages, we are facing the task of bridging the gap between them. It is supposed to be done by means of the Knowledge Base – a network of UNL lexical units connected by different semantic relations. Special navigation routines will be developed that will help to find the closest analogue to a lexical meaning not represented in the given language.

There are, however, some circumstances that impede full realization of these features, at least at the moment. Inductive storing of UWs from different languages is a good idea, but this process should be well organized. If a specific UW that is not self-evident is introduced to the UNL dictionary, it should necessarily be supplied at least by an informal comment to make it understandable to other users. Lucidity and easy interpretability of UWs is a goal at which all the developers of the UNL dictionary should aim.

Below, I am going to discuss in more detail two problems that have not so far received sufficient attention in UNL: the argument frames and lexical collocations.

2. Argument frames.

The need to introduce the information on the arguments does not seem to require justification. Any meaning representation language should have an ability to draw a distinction between the argument and non-argument links of predicates. In the UNL expressions, semantic links between the UWs are represented by means of UNL semantic relations. UNL disposes of an inventory of relations which, according to the latest specification, contains 41 items. Here are some examples of the UNL relations:

agt – agent (*John runs*),
obj – object (*read a book, A tree grows*),
ben – beneficiary (*He did not do anything for her*),
cag – co-agent (*I live with him*),
cob – co-object (*He fell into the river with the car*),
aoj – a thing which is in a certain state or is ascribed a property (*I love Mary; my brother is a student*).
dur – duration (*He worked nine hours*),
fmt – a range between two things (*He worked from Monday till Sunday*),
gol – final state (*turn red*),

ins – instrument (*observe with the telescope*),
met – method or means (*separate by cutting*),
pos – possession (*John's mother*),
rsn – reason (*They quarrel because of money*).

It is well known that for correct generation it is essential to know the argument structure of the predicates and the way each argument is expressed in the sentence. The UNL dictionary does not contain explicit information on the argument structure. According to the UW manual, the restrictions which should be included in the UW definitions are not meant for this purpose. As the UNL relations roughly correspond to semantic roles, it is supposed that each argument can be reliably identified based on its semantic role. However, this is not the case. Numerous attempts to construct a set of semantic relations, made over the last decades, showed that only a part of the relations between the words can be unambiguously interpreted in terms of semantic roles. In many cases this interpretation is largely arbitrary. This could not be a problem for the purposes of generation, if it were possible to assign semantic roles in a consistent way. Unfortunately, in practice it is hardly possible, especially when it is done by different people trained in different frameworks and working in different countries. The UNL texts compiled by the UNL project participants from 14 countries over the last years abound in mismatches in the representation of the same or very similar phenomena. Not surprisingly, most of them concern the representation of argument relations. For example, the phrase *base on respect* was interpreted by one team by means of the locative relation (lpl) and by another team by means of the comparative relation (bas), *freedom for all* was described with the purpose relation (pur) and with the beneficiary relation (ben), *bottleneck for the flow of information* received two labels – purpose (pur) and object (obj). Very often, the interpretation of a phrase in the corpus was motivated by the surface form rather than by its meaning. A typical example is *relations among nations* which was described by means of the locative relation obviously under the influence of the literal meaning of *among*. However, nations are by no means the place where relations occur. Rather, nations are participants of the "relations" situation and therefore are more likely to be objects (obj).

Sometimes the motivation behind the use of certain relations may be difficult to understand (at least, this is the case for the author of this paper). For example, in one of the sentences of the corpus, the argument structure of the verb *prevent* was presented as follows:

(1) *Nothing* (obj) *prevents members* (ben) *from discussing* (gol) *this problem*.

In our opinion, these problems are rooted not so much in the erroneous use of relations as in the fundamental impossibility of a consistent interpretation of all argument relations in terms of a small number of semantic roles.

What could one do to avoid the mismatches?

First, one could renounce using semantic roles in cases in which they are not obvious and replace them by semantically uninterpreted relations (subject, first object, second object, etc.). In this case, sentence (1) will receive a more transparent representation:

(2) *Nothing* (subject) *prevents members* (1 object) *from discussing* (2 object) *this problem.*

Obviously, it will be in many cases easier for those who write UNL expressions to develop a common approach to deciding which argument is the first object and which is the second than a common approach to finding appropriate semantic roles for them.

Second, one could accept the proposal of the French team and assign special markers to the case relations when they attach arguments (for example, @A would correspond to the first argument, @B – to the second, etc.). In this case, sentence (1) would be represented as:

(3) *Nothing* (obj.@A) *prevents members* (ben.@B) *from discussing* (gol.@C) *this problem.*

This would certainly reduce the area of uncertainty, but not eliminate it completely. To be able to interpret representation (3), the deconverter should know in advance the argument frame of the UW *prevent*. Otherwise, the uniformity of interpretation will still not be ensured. The only way to eradicate any ground for discordance between different users of the UNL language is to LIST ALL THE ARGUMENT STRUCTURES IN THE UNL DICTIONARY.

To incorporate this proposal, one need not introduce to the dictionary format any new possibilities: the existing apparatus of restrictions is quite sufficient. The only – but very serious – problem is to acknowledge that the argument frame should be explicitly and systematically specified in the UWs. If this is done, then one could keep using semantic roles in all the cases. For example, the word *bottleneck* (in the meaning of an obstacle) can receive the information that its syntactic object (*for something*) has the semantic role "pur" (or any other role which seems appropriate to the lexicographer). If every predicate is supplied with this information in the UNL dictionary, the discordance of opinion between different UNL users will become their private concern and the uniform treatment of the UNL relations in the most controversial zone – that of the argument relations – will be fully assured.

It should be emphasized however that in a general case the marking of the argument frame in a UW is not sufficient either. In some cases the same relation can attach to a UW both an argument and a free adjunct. For example, emotional states (of the type *be afraid, be surprised, be angry,* etc.) have an argument denoting a cause of the state. In sentence (4)

(4) *She is afraid to go out alone at night*

going out alone at night is what makes her to be in the state of fear. Therefore, relation "rsn" between *afraid* and *go out alone at night* is appropriate. On the other hand, *afraid* can have a non-argument cause, as in (5):

(5) *She is afraid (to go out alone at night), because this area is not very safe.*

Even if UW "afraid" is assigned a cause as one of the arguments (afraid(rsn>*)), we should know whether or not a "rsn"-link in the UNL expression denotes this argument. A good solution would be to mark the argument relation by a special label, as proposed in (3). Then, (5) will be represented as (6):

(6) rsn.@A(afraid(rsn>*), go out)
rsn(afraid(rsn>*), safe)

3. Lexical collocations.

Lexical collocations pose a serious problem for any language designed for representing meaning. Here are some examples of collocations from English: *give a lecture, come to an agreement, make an impression, set a record, inflict a wound; reject an appeal, lift a blockade, break a code, override a veto; strong tea, weak tea, warm regards, crushing defeat; deeply absorbed, strictly accurate, closely acquainted, sound asleep; affect deeply, anchor firmly, appreciate sincerely.* For simplicity, I will only dwell below on verbal collocations.

One of the problems such collocations raise is as follows. Some of the members of these collocations do not have a full-fledged meaning of their own. For example, the verb *give* in the collocation *give a lecture* does not denote any particular action. Its meaning, or rather its function, is the same as that of *take* in the collocation *take action*, or that of *make* in *make an impression*. The verbs *give, take* and *make* in these collocations are practically completely devoid of any meaning. Still, they have a very definite function – that of a support verb. This function is exactly the same in all the three cases, and nevertheless the verbs are by no means interchangeable. One cannot say **take an impression, *give action* or **make a lecture.* Moreover, this function is not only performed by different verbs with respect to different nouns. Very often, similar nouns in different languages require different verbs. For example, in Russian a lecture is not given but read, an action is not taken but accomplished, an impression is not made but executed.

How should these phenomena be treated in UNL? In particular, what UWs should be used for support verbs? The current practice suggests that UWs should be constructed on the basis of the source languages. Each language center should produce UWs for the words of its language, without any regard to other languages or any general considerations. A UNL expression and the UWs it consists of are considered adequate if they allow generating a satisfactory text in the same language they originated from. To what extent is this approach applicable to lexical collocations?

To answer this question, we will consider a concrete example. Suppose we have to convert to UNL Russian sentences with the meaning (7), (8), (9) or (10):

(7) *They began the war.*

(8) *We began the battle.*

(9) *The army suffered heavy losses.*

(10) *He took a shower.*

The problem is that in these contexts Russian uses quite different verbs than English. In Russian, correct sentences would be:

(7a) *They undid (razvjazali) the war.*

(8a) *We tied up (zavjazali) the battle.*

(9a) *The army carried (ponesla) heavy losses.*

(10a) *He received (prinjal) a shower.*

If UWs for support verbs in sentences (7a) – (10a) are constructed on the basis of Russian, they would look as follows: "undo(obj>war)", "tie up(obj>battle)", "carry(obj>loss)", and "receive(obj>shower)". These UWs will allow the Russian deconverter to produce perfect Russian sentences (7a) - (10a). In this case, the condition for adequacy mentioned above is met. Still, I would not consider UNL expressions based on these UWs adequate. They are produced without any regard for anything except the needs of Russian deconversion and are not fit for other purposes. In particular, these UWs are incomprehensible for anybody except Russians and it is doubtful that any other deconverter will be able to produce acceptable results from them. UWs originating from English will probably look like "take(obj>shower)", "begin(obj>thing)", "suffer(obj>loss)". To generate English sentences (7) - (10) from the UNL expressions constructed on the basis of (7a) – (10a), one would need to somehow ensure the equivalence of UWs "carry(obj>loss)" and "suffer(obj>loss)" in the Knowledge Base. This does not seem to be a natural and easy thing to do. Therefore, UWs for support verbs should not be constructed based on the lexical items of the source language.

Another possibility would be to make use of the co-occurrence properties of English lexical items. UNL vocabulary employs English words as labels for UWs and their meanings – as building blocks for UNL concepts which can be to a certain extent modified by means of restrictions. If lexical labels and meanings of UWs have been borrowed from English, their combinatorial properties can also be determined by the properties of corresponding English words. In this case, UWs and UNL expressions for sentences (7a) – (10a) will be identical to those for (7) – (10).

The advantage of this solution is obvious: since knowledge of English is indispensable for all the developers of X-to-UNL dictionaries, they can be sure that UWs for support verbs they produce are understandable and predictable. This solution has also drawbacks.

First, the inventories of support verbs in different languages are different. Therefore, we will often be faced with gaps in the lexical system of English and find no equivalent for a verb we need. Second, support verbs are bad candidates for the status of UWs. They do not denote any concept. Different support verbs often do not differ in meaning but only in their co-occurrence properties. It seems unreasonable to have different UWs to represent *take* (in *take action*), *make* (in *make an impression*) and *give* (in *give a lecture*), since the difference between these words is not semantic but only combinatorial. This difference should not be preserved in a meaning representation language.

The best solution would be to abstract from asemantic lexical peculiarities of support verbs and adopt a language-independent representation of these phenomena. Theoretical semantics and lexicography have long ago suggested a principled approach to the whole area of lexical collocations. It is the well-known theory of lexical functions by I. Mel'čuk implemented in the Explanatory combinatorial dictionaries of Russian and French (Mel'čuk 1974; Mel'čuk & Zholkovsky 1984; Mel'čuk et al. 1984, 1988, 1992, 1999). Possible use of lexical functions in NLP is discussed in (Apresjan et al. (in print)). Briefly, the idea of lexical functions is as follows. For more details, the reader is referred to the works mentioned above.

A prototypical lexical function (LF) is a general semantic relation R obtaining between the argument lexeme X (the keyword) and some other lexeme Y which is the value of R with regard to X (by a lexeme in this context we mean a word in one of its lexical meanings or some other lexical unit, such as a set

expression). Sometimes Y is represented by a set of synonymous lexemes Y_1, Y_2, …, Y_n, all of them being the values of the given LF R with regard to X; e. g., MAGN (*desire*) = *strong / keen / intense / fervent / ardent / overwhelming*.

There are two types of LFs – paradigmatic (substitutes) and syntagmatic (collocates, or, in Mel'čuk's terms, parameters).

A substitute LF is a semantic relation R between X and Y such that Y may replace X in the given utterance without substantially changing its meaning, although some regular changes in the syntactic structure of the utterance may be required. Examples are such semantic relations as synonyms, antonyms, converse terms, various types of syntactic derivatives and the like.

A collocate LF is a semantic relation R between X and Y such that X and Y may form a syntactic collocation, with Y syntactically subordinating X or vice versa. R itself is a very general meaning which can be expressed by many different lexemes of the given language, the choice among them being determined not only by the nature of R, but also by the keyword with regard to which this general meaning is expressed. Typical examples of collocate LFs are such adjectival LFs as MAGN = 'a high degree of what is denoted by X', BON = 'good', VER = 'such as should be' and also support verbs of the OPER/FUNC family. Examples of the latter are OPER1 = 'to do, experience or have that which is denoted by keyword X (a support verb which takes the first argument of X as its grammatical subject and X itself as the principal complement)'; OPER2 = 'to undergo that which is denoted by keyword X (a support verb which takes the second argument of X as its grammatical subject and X itself as the principal complement)'; FUNC1 = 'to originate from (a support verb which takes X as its grammatical subject and the first argument of X as the principal complement)'; FUNC2 = 'to bear upon or concern (a support verb which takes X as its grammatical subject and the second argument of X as the principal complement)'.

If used in UNL, lexical functions will ensure a consistent, exhaustive and language-independent representation of support verbs and all other types of restricted lexical co-occurrence. For example, English and Russian support verbs we discussed above – *take* (*a decision, a shower*), *make* (*an impression*), *give* (*a lecture*), *suffer* (*losses*), *prinimat'* (*reshenie* 'decision', *dush* 'shower'), *proizvodit'* (*vpechatlenie* 'impression'), *chitat'* (*lekciju* 'lecture'), *nesti* (*poteri* 'losses') – are correlates of the same lexical function – OPER1.

Being abstract and completely language-independent, lexical functions are devoid of all the drawbacks discussed above and can serve as an optimal solution to the problem of representation of the lexical collocations in UNL.

LREC-02 First International Workshop on UNL, other Interlinguas and their Applications, 1 June 2002

Abstract

The UNL *language* of semantic graphs may be called as a "semantico-linguistic" interlingua. As a successor of the technically and commercially successful ATLAS-II and PIVOT interlinguas, its potential to support various kinds of text MT is certain, even if some improvements would be welcome, as always. It is also a strong candidate to be used in spoken dialogue translation systems when the utterances to be handled are not only task-oriented and of limited variety, but become more free and truly spontaneous. Finally, although it is not a true representation language such as KRL and its frame-based and logic-based successors, and although its associated "knowledge base" is not a true ontology, but rather a kind of immense thesaurus of (interlingual) sets of word senses, it seems particularly weel suited to the processing of multilingual information in natural language (information retrieval, abstracting, gisting, etc.).

The UNL *format* of multilingual documents aligned at the level of utterances is currenly embedded in html (call it UNL-html), and used by various tools such as the UNL viewer. By using a simple transformation, one obtains the UNL-xml format, and profit from all tools currently developed around XML. In this context, UNL may find another application in the localization of multilingual textual resources of software packages (messages, menu items, help files, and examples of use in multilingual dictionaries.)

Keywords: UNL, multilingual communication, cross-lingual information retrieval, localization

Introduction

UNL is the name of a project, of a meaning representation language, and of a format for "perfectly aligned" multilingual documents. There is some hefty controversy about the use of the UNL language as an "interlingua", be it for translation or for other applications such as cross-lingual information retrieval. On the other hand, there is almost no discussion on the UNL format, in its current form, embedded in HTML, or some directly derivable form, embedded in XML.

We argue that the UNL language is indeed a good interlingua for automated translation, ranging from fully automatic MT to interactive MT of several kinds through, we believe, spoken translation of non task-oriented dialogues. It is also more than that, due to the associated "knowledge base", and has a great potential in textual information processing applications.

We will first give our view of what the UNL language is, and then develop a "rationale" for using the UNL language UNL along the previous lines. We will then describe some interesting potential uses of the UNL format in an "XML-ized" form.

1. The UNL language

The UNL representation is made of "semantic graphs" where a graph expresses the meaning of some natural language utterance. Nodes contain lexical units and attributes, arcs bear semantic relations. Connex subgraphs may be defined as "scopes", so that a UNL graph may be a hypergraph.

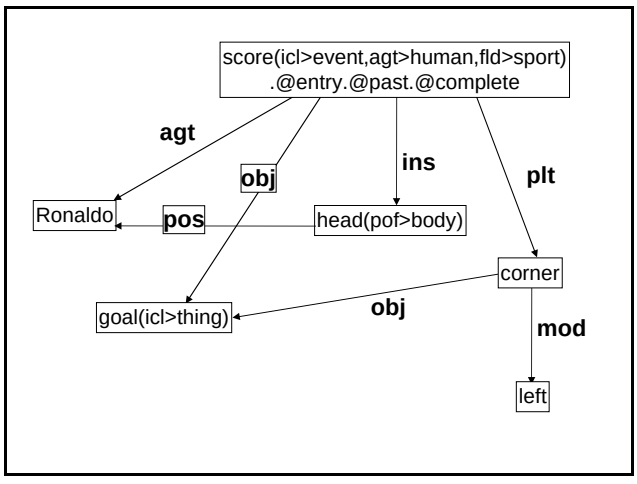

Fig. 1: a possible UNL graph for "Ronaldo has headed the ball into the left corner of the goal"

The lexical units, called Universal Words (in French, not "mot universel" but better "Unité de Vocabulaire Virtuel" or UVV or UW), represent word meanings, something less ambitious than concepts. Their denotations are built to be intuitively understood by developers knowing English, that is, by all developers in NLP. A UW is an English term or pseudo-term possibly completed by semantic restrictions.

A UW such as "process" represents all word meanings of that lemma, seen as citation form

(verb or noun here). The UW "process(icl>do, agt>person)" covers the verbal meanings of processing, working on, etc.

The attributes are the (semantic) number, genre, time, aspect, modality, etc.

The 40 or so semantic relations are traditional "deep cases" such as agent, (deep) object, location, goal, time, etc.

One way of looking at a UNL graph corresponding to an utterance U-L in language L is to say that it represents the abstract structure of an equivalent English utterance U-E as "seen from L", meaning that semantic attributes not necessarily expressed in L may be absent (e.g., aspect coming from French, determination or number coming from Japanese, etc.).

2. Some arguments for using the UNL language in various contexts

To show that using UNL is not only a workable but a good or perhaps the best idea at the moment, we can say that

- the "pivot" technique HAS BEEN not only experimented but deployed successfully (ATLAS, PIVOT, ULTRA, KANT).
- in particular, ATLAS-II (Fujitsu) is built on the basis of a pivot from which the UNL representation has evolved. The main designer of UNL, H. Uchida, was also the main designer of ATLAS-II.
- ATLAS-II has been recognized as the best EJ/JE MT system in Japan for over 10 years and has a very large coverage (586,000 words in English and Japanese).
- interlingual representations can not in principle be used (alone) to achieve the highest quality achievable by transfer systems, BUT they can give quite high quality as demonstrated by ATLAS-II.
- due to the precise nature of UNL, it is possible for human non-specialists to improve a UNL representation interactively, a posteriori, from any UNL-related language, and on demand (meaning partially — think of "lazy improvement").
- in many contexts other than translation, an interlingual, semantic-oriented representation like UNL is actually the best solution. For example, all applications related to information processing in multilingual contexts don't need a very precise representation of the FORM of the information, they need a precise ENOUGH representation of the INFORMATION CONTENT of the information.
- applications such as information retrieval and abstracting have already been prototyped successfully with UNL. It is far easier to generate SQL or SQL-like queries and answers from a UNL form than from text in many languages.

3. Applications of the UNL format

The UNL *format* of multilingual documents aligned at the level of utterances is currenly embedded in html (call it UNL-html). A sentence is represented between the [S] and [/S] tags. Its original text is contained between {org:el} (English, here) and {/org}, its UNL graph between {unl} and {/unl}, each French version between {fr} and {/fr}, and analogously for other languages. Atrtibutes such as version, date, location, author, etc. may appear in the tags. Here is a slightly simplified example of a file in UNL-html format.

```
<HTML><HEAD><TITLE>
Example 1  El/UNL
</TITLE></HEAD><BODY>
[D:dn=Mar Example 1, on= UNL French, mid=First.Author@here.com]
[P]
[S:1]
{org:el}I ran in the park yesterday.{/org}
{unl}
agt(run(icl>do).@entry.@past,i(icl>person))
plc(run(icl>do).@entry.@past,park(icl>place).@def)
tim(run(icl>do).@entry.@past,yesterday)
{/unl}
{cn dtime=20020130-2030, deco=man}
我昨天在公園裡跑步 {/cn}
{de dtime=20020130-2035, deco=man}
Ich lief gestern im Park. {/de}
{es dtime=20020130-2031, deco=UNL-SP}
Yo corri ayer en el parque.{/es}
{fr dtime=20020131-0805, deco=UNL-FR}
J'ai couru dans le parc hier. {/fr}[/S]
[S:2]
{org:el}My dog barked at me.{/org}
{unl}
agt(bark(icl>do).@entry.@past,dog(icl>animal))
gol(bark(icl>do).@entry.@past,i(icl>person))
pos(dog(icl>animal),i(icl>person))
{/unl}{de dtime=20020130-2036, deco=man}
Mein Hund bellte zu mir.{/de}
{fr dtime=20020131-0806, deco=UNL-FR}
Mon chien aboya pour moi. [/S] [/P][/D]
</BODY></HTML>
```

The French versions have been produced automatically while the German and Chinese versions have been translated manually.

The output of the UNL viewer for French is:

```
<HTML><HEAD><TITLE>
Example 1  El/UNL
</TITLE></HEAD><BODY>
J'ai couru dans le parc hier.
Mon chien aboya pour moi.
</BODY></HTML>
```

and will probably be displayed by a browser as:

Example 1 El/UNL

J'ai couru dans le parc hier. Mon chien aboya pour moi.

and similarly for all other languages.

The UNL viewer produces on demand as many html files as languages selected and sends them to any available browser.

The UNL-html format predates XML, hence the special tags like [S] and {unl}, but it is easy to derive from it an XML format and to transform the documents into an equivalent "UNL-xml" format. Then, using DOM and javaScript, it is possible to produce various views, including that of a classical viewer, a bilingual or multilingual editable presentation, and a revision interface where not only the text but the UNL graph and possibly other structures may be directly manipulated.

Let us take an example from an experiment performed for the "Forum Barcelona 2004" on documents in Spanish, Italian, Russian, French and Hindi. Hindi and Russian are not shown, but Japanese has been added by hand. The XML form is simplified.

Correct sentences are produced by the deconverters from correct and complete UNL graphs.

Suppose for the sake of illustration that some UNL graph has been produced from a Chinese version, and does not contain definiteness and aspectual information. All results may be wrong wrt articles, and some wrt aspect.

```
<unl:S num="1">
<unl:org lg="cn">在博覽會之後，城市 將獲得一片海岸域 </unl:org>
<unl:unl>
<unl:arc> agt(retrieve(icl>do).@entry.@future, city) </unl:arc>
<unl:arc> tim(retrieve(icl>do).@entry.@future, after) </unl:arc>
<unl:arc> obj(after, Forum) </unl:arc>
<unl:arc> obj(retrieve(icl>do).@entry.@future, zone(icl>place).@indef) </unl:arc>
<unl:arc> mod(zone(icl>place).@indef, coastal) </unl:arc> </unl:unl>
<unl:cn> 在博覽會之後，城市 將獲得一片海岸域 </unl:cn>
<unl:el> After a Forum, a city will retrieve a coastal zone.</unl:el>
<unl:es> Ciudad recobrará una zona de costal después Foro. </unl:es>
<unl:fr> Une cité retrouvera une zone côtière après un forum. </unl:fr>
<unl:it> Città ricuperarà une zona costiera dopo Forum. </unl:it>
<unl:jp> フォーラムの後で, 都市は沿岸水域を取り出す。 </unl:jp>
</unl:S>
```

The idea of "coedition" is applicable if there is a UNL graph associated with a segment one wants to modify. The goal is to share the revisions across languages, by reflecting them on the UNL graph, e.g.

- add ".@def" on the nodes containing "city", "Forum".
- replace "retrieve" by "recover" and add ".@complete" on the node containing it.

It is not possible in principle to deduce the modification on the graph from a modification on the text. For example, replacing "un" ("a") by "le" ("the") does not entail that the following noun is determined (.@def), because it can also be generic ("il aime la montagne" = "he likes mountains"). Hence, the technique envisaged is that:

- revision is not done by modifying directly the text, but by using a menu system,
- the menu items have a "language side" and a hidden "UNL side",
- when a menu item is chosen, only the graph is transformed, and the action to be done on the text is stored and shown next to its focus in the "To Do" zone,
- at any time, the new graph may be sent to the L0 deconverter and the result shown. If is is satisfactory, that shows that errors were due to the graph and not to the deconverter, and the graph may be sent to deconverters in other languages. Versions in some other languages known by the user may be displayed, so that improvement sharing is visible and encouraging.

New versions will be added with appropriate tags and attributes in the original multilingual document in UNL-xml format, or in a DBMS, so that nothing is ever lost, and cooperative working on a document is feasible. UNL may find another application in the localization of multilingual textual resources of software packages (messages, menu items, help files, and examples of use in multilingual dictionaries.)

Apart of the "coedition", there are many other portential applications of UNL, such as:

- crosslingual information retrieval, on which we are currently working,
- abstracting & gisting, which has been prototyped at NecTec and in India,
- localization of software packages: messages in multiple languages could be created from UNL graphs produced from a graphical interface or by enconversion, and then sent to appropriate deconverters.

For this last point, we have found how to represent messages including variables (such as integers, file names etc.), but not yet how to handle messages including morphological or even lexical variants (as "4 goda / 5 let" for "4 years / 5 years" in Russian).

Conclusion

The UNL language is an artificial interlingua, embeddable in html or xml formats for multilingual document representation and processing. Because of its both abstract and linguistic nature, the UNL language offers many more interesting potential applications than other types of interlingua such as task and/or domain specific interlingua.

The history of MT shows that UNL will also be usable in the context of high-quality MT,

quality being obtained through typology specialization and/or interactive improvement, a priori (interactive disambiguation after all-path robust analysis) and/or a posteriori by coedition of the text in any language and the corresponding UNL graph.

A Platform for Experimenting UNL (Universal Networking Language)

Wang-Ju TSAI

GETA, CLIPS-IMAG
BP53, F-38041 Grenoble cedex 09 France
Wang-Ju.Tsai@imag.fr

Abstract

We introduce in this article an integrated environment, which provides the initiation, information, validation, experimentation, and research on UNL. This platform is based on a web site, which means any user can have access to it from anywhere. Also we propose an XML form of UNL document as the base of future implementation of UNL on the Internet.

1 Introduction

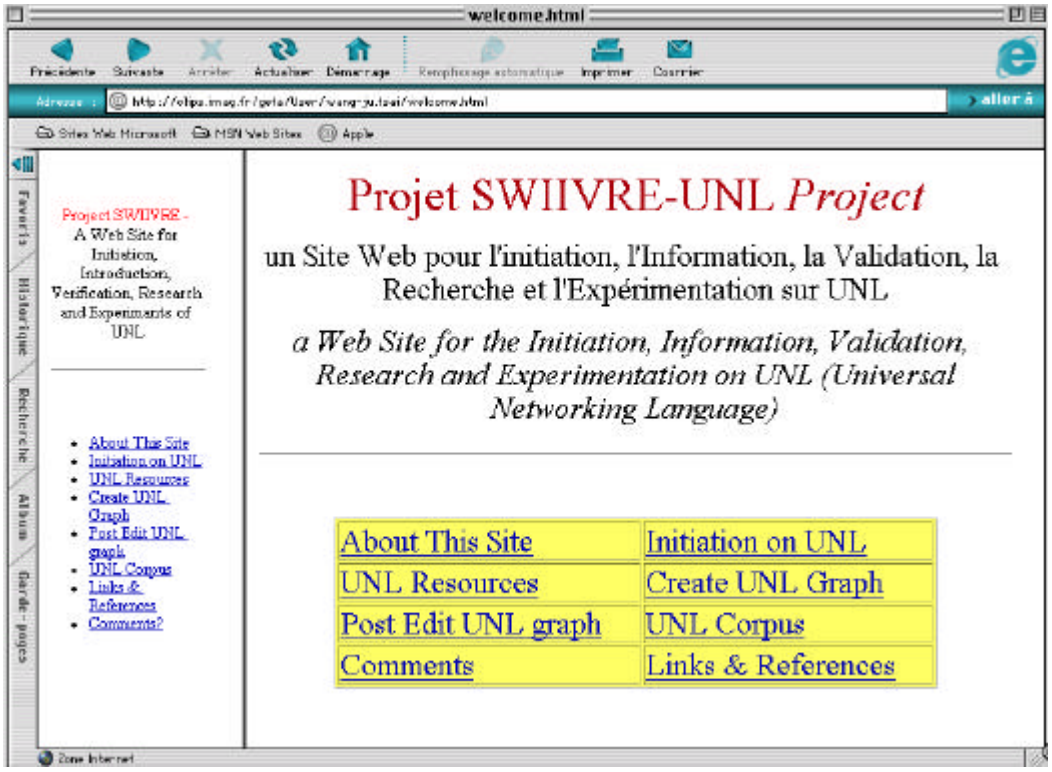
Since proposed 5 years ago, UNL project has attracted 16 international teams to join and is regarded as a very promising semantic Interlingua for knowledge representation on the Internet. The articles and applications of UNL have been found in many domain, such as: machine translation, information retrieval, multilingual document generation, ..etc. Now we can find on the Internet not only the web sites of UNL language centres but also some discussions. The applications to facilitate the usage of UNL have been produced as well. Now we see the need to create a platform to integrate these applications also to introduce UNL to new ordinary users. We create this platform on a web site SWIIVRE (http://www-clips.imag.fr/geta/User/wang-ju.tsai/welcome.html), which has several goals: for the initiation, information, verification, research, and experimentation of UNL. And since this platform is based on a web site, any user from anywhere can have access to it.

2 Introduction of the site SWIIVRE

In Appendix (I) we list all the resources accessible for UNL society members from internet. We can find out that most of the LC's connect vertically to UNL Centre but the horizontal connection among LC's is not enough, which means any user who wants to try the multilingualism of UNL will feel frustrated, since he will need to spend a lot of time try out every LC to know what service he can get.

The main purpose of this site is rather to integrate the current UNL applications and complete the services of Language Centres', when the function is available on a Language Centre, we simply provide the link to it, we also produce some applications to integrate or provide new functions, which all serve to facilitate the usage of UNL. Also we collect the useful information and publications on UNL, the web site is updated regularly. Lastly, by collecting the useful information and recording the related data, this site finally can serve as an evaluation of the performance of UNL community.

Here we show the welcome page of this site:



The following is the introduction to each link on the welcome page:

2.1 About This Site:

This page provides the introduction, why and how this site exists, the site log and current status of this site, also the new projects to come on this site, lastly all the recent activities of UNL community. When clicked, a news flesh will also show the most recent UNL activities and the new updates on this site. In the future, we think we will at least UNL-ise this page to demonstrate the multilingualism of UNL.

2.2 Initiation on UNL:

This page is to help users to take a first step in UNL, understand how UNL works. We first provide a copy of most recent UNL specifications, for the moment only Spanish Centre has prepared a "multilingual interactive page" can serve as the tutorial and give examples to each UNL relations, thus we put a link to this page. When UNL becomes more well known, there will be more and more tutorials for beginners in the future. Or we might finally create an graphical interface for user to manipulate and show the spirit of UNL. We would also like to introduce the XML-UNL document here. We put an example of XML-UNL document here and with the help of XSLT, we can create the same effect like UNL browser, then the users can choose to read the document in the language they wish. We will explain later in the article why we want to XML-ise a UNL document.

2.3 UNL Resources:

This page provides all the UNL<->NL deconverters / enconverters, dictionaries that are accessible on the Internet. Some deconverters accept the deconversion of one single UW (Universal Word), in this case they can serve as the UNL-NL dictionaries. We can simply add some scripts in our site to help users to access these deconverters as if they are accessing dictionaries. In the future, the status report of each server will be added; we hope we can provide "UNL daily bulletin" to report the updates and status of each server. Currently only French server report can be seen. To complete the services, we developed a "multilingual simultaneous deconverter" (Preedarat 2001), which can handle several deconversions at one time. Users can click on the language versions they want as output, the program will contact these servers at once, thus they don't need to do the deconversions one by one, and they can experience the automatic multilingual generation.

2.4 Create UNL Graph:

Since ordinary users are not able to write UNL graph without being trained, to help users create UNL graph will be an important function to develop. In this page we collect the links to accessible UNL editors, including editor for professional writers or for beginners. We have put a link to our "Basic UNL graph editor" (Preedarat 2001), which is implemented by

using a similar XML-UNL format and XSL transformation. The users can manipulate the UNL graph represented in tree-like structure, and save the result in XML format. We also put a link to the "interactive multilingual page" of Spanish Language Centre, here users can manipulate the UNL graph by the options provided, actually users can already generate many sentences based on these examples.

2.5 Post Edit UNL Graph:

This function is still under development. Our idea is to provide the users the possibility to correct the UNL document after it is deconverted. It provides ordinary users with the ability to correct the faults in the UNL graph and improve the quality of graph.

2.6 UNL corpus:

We collect all the UNL corpora here, and also we are currently working on designing a data base to store these corpora thus to facilitate the further exploitation or calculation. We can finally design an interface to allow users to upload the corpora in different forms, or produce the forms they desire. In appendix (II) is the first statistics we made on the corpus FB2004.

2.7 Comments:

To sends your comments to us.

2.8 Links & References:

We collect all the links to UNL Centre, Language Centres, articles, papers, discussion of UNL, and users can trigger the search engines here to find more information about UNL when they want.

3.XML-UNL document

The applications compatible to XML have been increasing a lot and XML can replace HTML as the next norm of a web-based document. And from an XML form, we can further produce other form, exchange or integrate the existing data easily. It would thus be reasonable to XML-ise the UNL document. We would like to propose here an XML form of UNL document as in Appendix (III). We created this DTD according to the UNL specification Version 3 Edition 1 (20/02/2002). Based on this DTD, we can create the UNL document in XML form, with an XSL Transformation we can produce the same effect as an UNL browser. Further more, we can easily expand this DTD to enable the XML-UNL document to register all the modifications and corrections on a UNL document, this can be very useful in our post-edition project.

Appendix (I)

4 Conclusion

We have made the first step in the integration of all the UNL components under a website. Next step is to streamline the procedures between current functions and to include more services.

Appendix (II) Some Statistics about FB2004 Corpus

Corpus Name : FB2004
Original Language : English
Other available versions : French, Spanish, Italian, Russian, Hindi, UNL
No. of Sentences : 122
No. of Words : 2799
No. of Relations in UNL: 1519

Part I. The relation count

Relaion	**Outside scope**	**In scope**	**TOTAL**	**Relation**	**Outside Scope**	**In scope**	**TOTAL**
AGT	**66**	**10**	**76**	SEQ	0	0	0
AOJ	**64**	**37**	**101**	FMT	5	0	5
OBJ	**225**	**89**	**314**	FRM	6	3	9
AND	**63**	**120**	**183**	PLF	0	0	0
OR	26	3	29	SRC	2	0	2
BAS	2	2	4	GOL	17	7	24
CAG	0	0	0	PLT	1	0	1
CAO	0	0	0	TO	5	1	6
COB	1	1	2	INS	0	0	0
PTN	4	1	5	**MAN**	**49**	**17**	**66**
BEN	7	5	12	MET	10	3	13
PUR	28	1	29	PER	0	0	0
CNT	22	6	28	QUA	12	5	17
MOD	**263**	**186**	**439**	PLC	17	3	20
NAM	21	15	36	SCN	13	5	18
POF	5	2	7	TMF	2	0	2
POS	17	8	25	TMT	0	1	1
CON	2	0	2	VIA	1	0	1
RSN	1	0	1	DUR	5	4	9
COO	4	2	6	TIM	20	5	25

Total no. of relations							**1519**

Remarks:
a.)The 6 most frequently used relations are marked in bold type. The result is not surprising, since these relations have either an important or a broad usage. MAN and AGT's usage are frequent though straight forward. Besides its own static verb and copula usage, AOJ also shares part of adjective-noun relation, otherwise the frequency of MOD will be even higher.
b.)AND relation appears much more frequently within a scope, which is not surprising, since scope is used to represent the union of the similar things or ideas, and AND relation links these UW's in te scope.
c.)Some other relations' usage is not very braod, so they didn't appear.

Part II. Attribute count

(1)Time Attribute
.@past 40 / **.@present 114** / **.@future 187**
(2)Aspect Attribute
.@complete 20 / .@progress 13 / .@state 16 / else 0
(3)Reference Attribute
.@generic 9 / **.@def 659** / .@indef 79 / .@not 2 / .@ordinal 8
(4)Focus Attribute
.@entry 530 / .@topic 48 / .@title 21 / else 0
(5)Attitude Attribute
.@exclamation 1 / else 0
(6)Viewpoint Attribute
.@ability 7 / .@obligation 7 / .@possibility 8 / .@should 2 / .@unexpected-consequence 2 / else 0
(7)Convention Attribute
.@pl 558 / elso 0

Remarks:
a)The original text langue is English, so the frequency of .@pl, .@def, .@indef and time attributes are among the highest. If the original language is one of those isolated languages, such as Thai, Vietnamese, Chinese, which don't provide so much information about definitiveness or time, it might be difficult to use or to decide these attributes. It's not because that the graph authors or enconverters are bad, it's simply because they can't find these informations from the text when encoding.

UCL – UNIVERSAL COMMUNICATION LANGUAGE

Carlos A. Estombelo Montesco
Dilvan de Abreu Moreira
Universidade de São Paulo, Instituto de Ciências Matemáticas e de Computação
Av. do Trabalhador São-Carlense, 400 - Centro - Cx. Postal 668 São Carlos - SP - Brazil CEP 13560-970
{cestombe, dilvan}@icmc.sc.usp.br

Abstract

For successful cooperation to occur between agents they have to be able to communicate among themselves. To enable this communication an Agent Communication Language (ACL) is required. Messages coded in an ACL should adequately express their meaning from a semantic point of view. The Universal Communication Language (UCL) can fulfill the role of an ACL and, at the same time, be convertible to and from a natural language. UCL design is concerned with the description of message structures, their underlining semantic context and the support for protocols for agent interaction. The key point about UCL is that the language can be used not only for communication among software agents but among humans too. This is possible because UCL is derived from the Universal Network Language (UNL), a language created to allow communication among people using different languages. UCL was defined using the Extended Markup Language (XML) to make it easier to integrate into the Internet. In addition, an enconverter-deconverter software prototype was written to serve as a tool for testing and experimenting with the language specifications.

INTRODUCTION

The technology of software agents can be an interesting tool for the creation of new models for complex software systems. In the project of software agents, many of the traditional techniques of artificial intelligence can be mixed with techniques from the field of distributed computer systems, theories about negotiation and theories about working teams (Dignum, 2000). Software agents are basically designed to cooperate (either with others or with humans) in a seemingly intelligent way. But for cooperation to occur a communication language is necessary.

What does it mean to be able to communicate with someone? Simplifying it, useful communication requires shared knowledge. While this includes knowledge of language, words and syntactic structures, meaningful communication is even more focused on knowledge about a problem to be solved. To interact with a florist you need some knowledge of flowers.

The widespread use of the Word Wide Web (WWW) and the growing Internet facilities has sparked enormous interest in improving the way people communicate using computers. To date, communication among software agents and humans has been done under limited conditions: communication is reduced to basic information exchange, ignoring the richness and flexibility implied by human language.

However to deal with any human language would be very difficult. To solve this problem, communication systems can use an Agent Communication Language (ACL) based in a simplified form of human language, which could be converted from and to a natural language.

OBJECTIVES

The main objective of this work is the specification of a new ACL, called UCL - Universal Communication Language, that focus on the specification of the semantic model and structure of the messages it represents. It also adds support for message transmission over the Internet and can be translated into or generated from natural language (English or other languages).

UCL is derived from the Universal Network Language (UNL) (Ushida et al., 1999) and implemented using the language XML (Extensible Markup Language) (Connolly, 2000). XML is a W3C (World Wide Web Consortium) standard language, like HTML, this means an easy integration with the Internet.

Another goal of this paper is to show a working UCL enconverter-deconverter prototype using the tool Thought Treasure and its associated ontology.

COMMUNICATION AMONG AGENTS

In the communication process among agents, it is indispensable an appropriate understanding of what will be communicated through the exchange of messages. A good representation of the knowledge domain, shared by the agents, can collaborate for a better understanding of the context where a message exchange takes place. As a consequence, it is important to explore concept classifications and their hierarchical structures for knowledge domain representation. The concepts in the knowledge domain have to be shared by the agents exchanging messages and be reusable in more than one context.

The specification of an ACL has to deal with the description of the message structure, his semantic model and the interaction protocols (Mamadou, 2000):

- The message format defines the communicative acts primitives and the parameters of the message (as sender, receiver, etc.). The message content describes facts, actions, or objects in a content language (KIF, Prolog, etc).

- The semantic model of an ACL should allow for messages with a concise meaning and no ambiguity.

- The interaction protocols are projected to facilitate the communication among agents. Protocols are optional, but, in case they are used, the communication among agents should be consistent with the chosen protocol.

ONTOLOGIES FOR COMMUNICATION

'Ontology' is a term used to refer to the common sense of some domain of interest. The ontology can be used as a uniform framework to solve communication problems.

An ontology necessarily links or includes some type of "general vision" regarding a certain domain. This "general vision" is frequently conceived as a group of concepts (for example: entities, attributes, processes), their definitions and their interrelations. That is called a conceptualization.

A conceptualization can be concretely implemented, for example, in a software component, or it can be abstract, being the implied concepts of a person. The use adopted in this work is that ontology is an explicit idea, or a representation (of some part) of a conceptualization.

An explicit ontology can take a variety of forms, but necessarily they will include a vocabulary of terms and some specification of their meanings (for example: definitions).

The level of formality for a vocabulary varies considerably. This variation can be shown in the following four points of view:

- Highly informal: expressed freely in natural language.
- Semi-informal: expressed in a restricted form and structure in natural language. Larger clarity for ambiguity reduction.
- Semi-formal: expressed in an artificial language defined formally.
- Strictly formal: defined meticulously with formal semantics, theorems and proofs.

A shared ontology is necessary for communication between two agents. Unfortunately UNL does not have a public available ontology. For this reason, the ontology embedded in the tool Thought Treasure was used to implement the enconverter-deconverter prototype.

THE TOOL *THOUGHT TREASURE* (TT)

This is a powerful tool for processing natural language, developed by Erik T. Mueller (1998). It is capable of interpreting natural language, as well as extending its ontology-based knowledge base. TT has a compiler for natural language that allows it to extract information of sentences.

TT has a database with 25,000 concepts organized in a hierarchical way. For example, Evian is a flat-water type, which is a drinking-water type, which is a food type and so on.

Each concept has one or more word translations what forms a total of 55,000 words and sentences of the English and French language. For instance, as it is observed in the Figure 1, the association with the concept *food* in the English language are the words *food* and *foodstuffs* and in French *aliment* and *nourriture* (among others).

In addition, *ThoughtTreasure* has approximately 50,000 assertions related to concepts such as: a *green-pea* is a *seed-vegetable*, a *green-pea* is *green*, the *grean-pea* is part of *pod-of-peas*, and *pod-of-peas* is found usually at a store of foodstuffs.

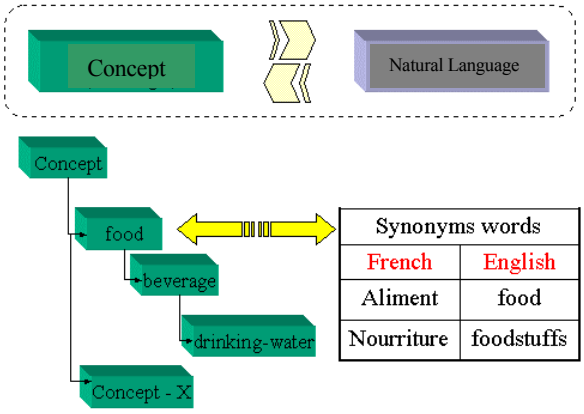

Figure 1: Association of the ontology with a natural language

UCL - UNIVERSAL COMMUNICATION LANGUAGE

The language UCL represents information in the same way UNL does, but using syntax based in XML. XML is a meta-language, a simplified form of SGML, which developers can use to create new languages based in tag elements. The new tags, created to represent the new language elements, can be described in a special file called DTD (Document Type Definition). UNL is a formal language for representing the meaning of natural language sentences and exchange information over a network. Information that is written in a native natural language is "enconverted" into UNL and stored in a server. This information can be "deconverted" into other languages to be read by each native reader. Thus, UNL can play the role of an interface between different human languages to exchange information.

UNL represents information expressed in sentences as a set of relations between meanings, expressed by words, and a

syntactic structure that makes up the sentence. The vocabulary of UNL consist of:

- Universal Words (UWs), to represent word meaning.
- Relation Labels, to represent relationships between UWs
- Attribute Labels, to express further definitions or additional information for the UWs that appear in a sentence.

In UNL, the information about a sentence includes its meaning, tense and aspect information (how the speaker grasp the event), intention of utterance, speaker's feeling or judgment upon contents, and sentence structure. In the language, the meaning of a sentence is represented by the description of the relationships between UWs and its structure is described by attaching attribute labels to these UWs.

UCL GOALS

The language UCL is to be used for high-level communication among agents through the exchange of messages. Some characteristics that guided the definition of the language were:

- To aid the communication involving agents giving importance to the semantics of the message;
- To be easy to use;
- To facilitate its integration into the Internet environment writing it in XML (*Extensible Markup Language*)

The language UCL represents the information in sentences (that can form messages) that involves a syntactic structure with a group of concepts, relationships and attributes similar to UNL:

- Universal Words (UW),
- Relationship labels,
- Attribute labels.

To define a language based in XML a specific DTD file is used. This DTD is essentially a grammar of free context, like the extended BNF form (*Backus Naur Form*) used to describe computer languages (Grosof & Labrou, 1999).

As in UNL, a Universal Word (UW) is the minimum unit that represents a concept, which denotes a specific meaning in a message. When a concept needs to be defined in more detail Relationship Labels and Attribute Labels are used. In addition, UCL uses a shared ontology, from the tool ThoughtTreasure, to add meaning to the UWs. All agents participating in a communication process should share this ontology.

In a UCL sentence, each defined UW has an identifier label (id) that is used to identify a particular concept inside a sentence. A sequence of alphanumeric characters forms this labels. The label `head` corresponds to the place where the name of the concept will be defined. The concepts used are always related to the ontology being used (ThoughtTreasure ontology). It is at this point that a sentence in UCL is connected with the ontology for a specify knowledge domain.

In UCL messages possess a certain meaning involving concepts. This composition of concepts is represented by groups of binary relationships, which allow different relationships involving the concepts. The relationship labels used come from UNL. Figure 2 shows an English sentence and its translation to UCL.

- *UNL is a common language that would be used for network communications.*

Figure 2 Definition a sentence in UCL

IMPLEMENTING AN ENCONVERTER-DECONVERTER

UCL is defined in the meta-language XML, to work with it a XML parser should be used. As the enconverter-deconverter is written in the language Java, the Java API for XML Processing (JAXP) Version 1.1 from Sun, was used (other Java XML parsers could have been used).

As said before, UCL uses the ontology available on the ThoughtTreasure (TT) tool (written in C). This tool includes program libraries to manipulate concepts of the ontology, to do consultations on the net of concepts, and to analyze their hierarchy. An instance of TT can run as a server in a network and communicate with a Java program running in another process. A Java communication API is supplied with TT to handle the low level details of this communication.

The enconverter-deconverter prototype uses the Java communication API to contact a running instance of TT and use its functionality. Those include natural language treatment, ontology queries, etc. A high level Java interface was written to communicate with the TT server (through the API) and implement the high level functions needed by the prototype. This interface is called *UclLanguage*.

Figure 3 presents a diagram with the sequence of events that happens when the prototype makes use of the interface *UclLanguage* to generate UCL messages.

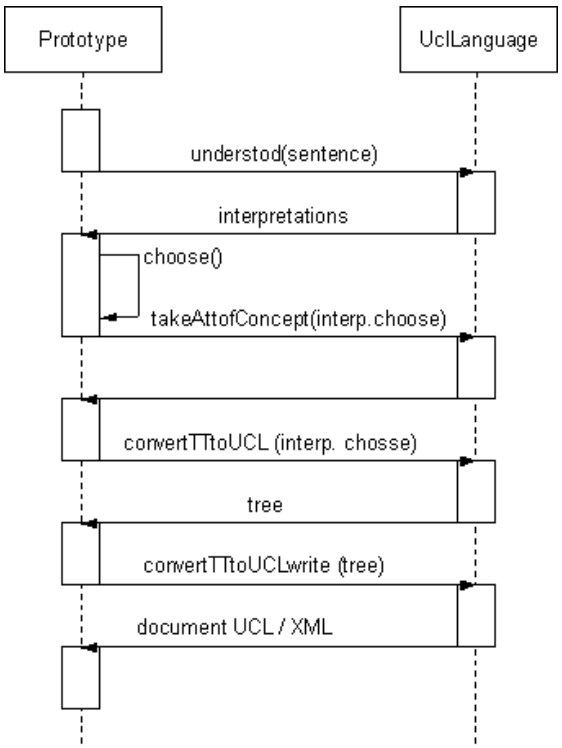

Figure 3: Diagram with the sequence of events during enconvertion.

The process begins when a user enters a natural language sentence into the prototype. The prototype calls the method *understood* of the interface *UclLanguage*. The natural language sentence is interpreted (using TT) and some possible semantic interpretations are returned. The user chooses the most appropriate interpretation. The chosen interpretation is converted to TT's format (method *takeAttofConcept*) and then to UCL format (method *convertTTtoUCLwrite*). The UCL format can be shown on the screen or saved in a file.

The reverse process, transform a UCL message in natural language is easier. The prototype uses the method *deconvertUCLtoTT* to convert the UCL message in a list of TT concepts. Then it uses the method *deconverterTTtoLN* to transform this list of concepts in a natural language sentence, which represents the original UCL message.

Example : Monkey eats bananas

```
======= Input Natural Language ==========
Example: Monkey eats bananas.

============ Choose Option ==============
<0>An ape eats a banana.

Option: 0
============ Message UCL  ===============
<?xml version="1.0" encoding="UTF-8"?>

<sentence>
  <uw id="uw2" head="present-indicative">
    <icl direction="to">
      <uw head="present-tense" />
    </icl>
    <focus attribute="entry" />
  </uw>
  <uw id="uw4" head="eat">
    <icl direction="to">
      <uw head="ingest" />
    </icl>
  </uw>
  <uw id="uw5" head="ape">
    <icl direction="to">
      <uw head="mammal" />
    </icl>
  </uw>
  <uw id="uw7" head="banane">
    <icl direction="to">
      <uw head="fruit-tropical" />
    </icl>
  </uw>
  <relation id="uw1" label="icl" id1="uw2" id2="uw6" />
  <relation id="uw6" label="icl" id1="uw3" id2="uw7" />
  <relation id="uw3" label="agt" id1="uw4" id2="uw5" />
</sentence>

======== Deconverter Message UCL  ===========
=>Debug : [present-indicative [eat ape banane ]]

English: An ape eats a banana.
French : Un singe croque la banane.
```

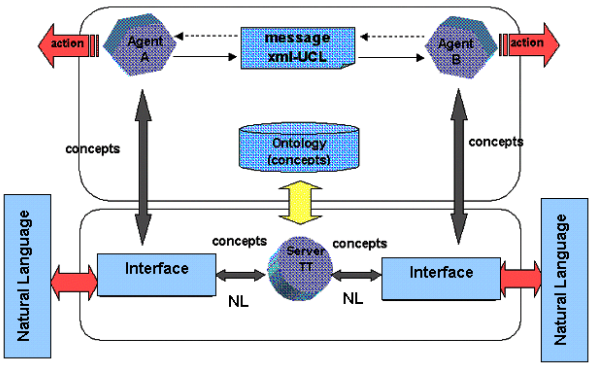

Figure 4: Architecture of a system that uses the language UCL

Figure 4 illustrates the use of UCL (using one TT server) in the communication process between two software agents.

CONCLUSIONS

The definition of the Universal Communication Language (UCL) includes all theoretical concepts of the Universal Networking Language (UNL). This was done to preserve the representative power of this language. The Web community currently regards XML as an important step toward semantic integration. Developing the language UCL using XML yielded some important benefits. The most important is the reuse of existing tools for creating, transforming, and parsing UCL documents.

The UCL enconverter-deconverter prototype shows the need for a shared ontology for the implementation of a successful enconverter-deconverter. UCL was developed to be used as a rich Agent Communication Language (ACL), which would make it easier for humans to communicate with and program software agents (using multiple natural languages). But UCL can be used in the same role as UNL.

The prototype also points out the need for an open shared ontology for UNL. UNL relation and attributes labels have some ontological knowledge already embedded in them. This makes impossible to map all possible UNL (and consequently UCL) constructs into ThoughtTreasure ontology based representation. The prototype can not be expanded into a full featured UCL enconverter-deconverter. For the time being this prototype is good enough to help the development of a prototype UCL interpreter for software agents.

The full power of the approaching of using UCL as an ACL and programming tool for software agents will only be realized, when an open shared ontology for UNL and enconverters-deconverters for many natural languages (using this shared ontology), are available. One will be able to program a software agent using his own native language and share this program with many other people, which will see and interact with the program in their own native languages.

Finally, UCL is still a proposal, but we hope that others in the Web community will help to shape its final format.

ACKNOWLEDGEMENTS

The authors would like to thanks the CNPq – National Council for Research in Brazil for the financial support for this work.

Abstract

The UNL, either as language or as a system, is not well known due to several reasons. At this moment, UNL is not only the name of a language for computers aiming at supporting multililingual services in Internet. It is also a system, with a defined architecture and a wide panorama of applications and possibilities to support business, institutional and educational applications, all of them going beyond the linguistic barriers. Nobody doubts about the possibilities of this type of system. However, this system today supported by an organization based on a Foundation (placed in Geneva and created only to support this UN initiative) needs the collaboration and financial help of all kind of sources (UN is not financing the initiative at this moment). This is a hard task. Perhaps the more significant case about the impossibility to reach financial support for this initiative and also about the different research and application issues has been the high number of project proposals made for different Call for Proposals of the EC in the area of Econtent and IST, as well. All of them have been rejected, thus creating a wall for the development of the systems of the European languages, that are actually the more advanced within the UNL Consortium. This paper will try to analyze the different evaluations made for the various proposals in order to clear up the real state of this system and also the reasons of the low level of knowledge about this important initiative. Our goal then is to examine the opinions of the EC evaluators giving in the paper the adequate answers to them even by the side of the UNL Consortium too. Dissemination policies and internal organization of the UNL will be clarified for a better analysis in the immediate future.

1. The New Organization for the UNL Program

The Universal Networking Language (UNL in the following) arises by the initiative from the Institute of Advanced Studies (UNU/IAS), of the United Nations University in 1996. The mission of the UNL Programme (UNDL, 2002a) is to develop and promote a multilingual communication platform for Internet, with the purpose of enabling all peoples to share information and knowledge in their native language. The IAS first selected a group of institutions from fifteen countries that were in charge of developing the modules for each corresponding language. The milestones and partial results are revised in yearly meetings. In Brussels, 1999 it was presented more than a project. It was presented an Organization for the future. But the most important fact is perhaps that, after three years of development work of the participating teams, the UNL Language specifications were made public. That is, anyone can develop, potentially, for public or commercial use, components and systems integrable with the UNL system.

The current organization of the UNL Programme (UNLP) has been put on the hands of the recently created UNDL Foundation (UNDL, 2002b), a non-profit international organization created to continue the research and development initiated by the UNU/IAS in Information Technologies, in particular, in the field of interlingua communication, UNL and its applications in all areas of human knowledge and activities. The UNDL deploys the UNL facilities to assist all peoples in bridging the digital and cultural divide, in accordance with the principles and objectives of the United Nations and its Members States.

The new organization of the UNL Programme has a network of persons and institutions under the direction and sponsorship of the UNDL Foundation. The UNLP network consists of the UNL Center, the Language Centers (LC) of each language and other elements as UNL National Units, Permanent Committees and ad-hoc working groups.

The UNL Center has the overall responsibility (UNDL, 2002c) for promoting and coordinating the UNLP. In this organizational structure the LC are considered as an expansion of the UNL Center for a given language and is responsible for the research, development and maintenance of the UNL System in that language. For all these tasks, each LC must, as opposed to the past, procure the necessary financial means for the support of the LC and UNLP operations (article VII.4.e, UNLP Statute). In this paper we explain the efforts addressed by European LC, in the last years trying to get funding from the European Commission (EU) Research Programmes.

2. History of the proposals presented

European LCs have been involved in the last years in the preparation of a lot of proposals in different EU Programmes including UNL as technological base. All of them failed. We think that there are no only specific reasons to reject every proposal. This total coincidence may can be explained additionally by global reasons related to the perception and knowledge of the UNL technology by the EC evaluators as the political and technical actions of the UNL Organization.

Globally speaking, we have collected information of 8 project proposals to the EC programmes with the UNL technology as basis; all of them rejected. However, we are going to focus in this analysis over the last 5 proposals because two reasons: they are the last ones, and we, this research Group as support of the Spanish LC, has had a very active participation in them. The three other proposals were made by consortiums coordinated by companies. In all cases the application of the UNL technology fit very well with the system proposed. These proposals were named HEREIN-ML, and AQUITRA with applications for the International Office of Water. Both proposals were thought for the multilingual support of the

European Heritage Project (www.european-heritage.net). Today the European languages are covering part of the multilingual support with the UNL technology with a high degree of precarity and with direct investment in resources from the Spanish government and the Spanish Language Centre, using resources of free collaborators. However in these proposals the UNL was not accepted at all as alternative for the multilingual support.

The 5 proposals considered (see table 1), in chronological order, will be described through the summary of goals and the action lines of the Programme in which the proposal has been developed.

Date	Identifier	Programme
July 00	QANET 3312	Econtent Preparatory actions
October 00	QANET IST2000-28568	RTD Proposal, IST
January 01	LINGWEB 30130	RTD Proposal, IST
July 01	EU-UNL: 22045	Econtent Programme. Demonstration Project
November 01	MULTIDOC: 34702	RTD Proposal. IST

Table 1: A view of the proposals presented

QANET-3312(econtent): Quality Assurance Procedures for an Internet Multilingual System

Summary of goals: This proposal aimed to make a selection of resources for testing and measures of coverage together with the definition of a common lexicon of general purpose, to address the definition and construction of tools to verify and maintain their resources, to test the cross lingual tools and resources, and to generate the Quality Manuals according to ISO9001 and validation procedures to support the implantation of the Quality System in the UNL Programme.

Action lines of the RTD Programme:

Action Line 3 This proposal fits with this action because this action line mentions explicitly the problems derived from linguistic diversity and from the services to be supplied with an effective infrastructure in order to sooth the consequences of the growing number of languages in Europe and the increase of institutional and commercial relations.

QANET (RTD) IST2000-28568: Quality Assurance System for Internet Multilingual Applications

Summary of goals: This proposal aimed to define the Quality System of the UNL Program of the United Nations to overcome the linguistic barriers in Internet. The definition of the Quality System required the generation of resources (lexicon corpora addressed to this task) and methods

to evaluate the future existing systems integrated with to the UNL system. For that two industrial applications would have been developed. One UNL editor based on existing analysers (demonstrating so the integrability of this approach and the capability to reuse existing systems) and also a target language Generator completely developed from the current public specifications of the UNL language that has real intention to be exploited after the project.

Action lines of the RTD Programme:

Action Line 3.3.3 (2000 WorkProgramme). Multilingual communication services and appliances.

This proposal fits with this key action. It is addressed concretely to services and appliances independently of the language of the user. The core of the system (the UNL System) has been developed to the wider multilingual capabilities system built until this moment. In fact, UNL forms the way to access from any language and generate any other language in the world.

LINGWEB (IST2000-30130): Multilingual Web-site Deployment based on an Interlingua Technology.

Summary of goals: We aimed to deploy the UNL technology that up to that moment we had had several basic components to create the UNL network addressed to support the multilinguism in Internet. Concretely we aimed to obtain a complete implantation of multilingual services in the user web-site based on UNL technology. The user would be the Organisation Barcelona2004. Besides, we would define the materials and contents to support international training courses including the testing and adaptation of the tools involved in the maintenance of the system and the UNL coding like part of the Technology Transfer process. These tools should be adapted for any other uses out of the Language Centers environment.

Action lines of the RTD Programme:

Action Line 3.3.4 (2000WorkProgramme). Trials in multilingual e-service and ecommerce. The proposal is conceived as a Trial. Technology users are at the same time suppliers of the contents to offer an information service in a highly multilingual environment. What underlies the concern of this proposal is the effective evaluation of a new and open technology in a real environment, and to define accurately Technology Transference tasks. EU-UNL was presented as a Demonstration project to prove the economic viability of the service on a specific field.

EU-UNL: European Use of UNL

Summary of goals: EU-UNL focuses in the implementation of the UNL technology for multilingual dissemination of contents on the field of the quality of water and on the field of tourism. The project includes the user corporate web implementation of a multilingual document generation system and definition of procedures for technology transfer, planning and implementation of measures and cost evaluation, as well as the complete set of materials to assure the necessary support for internal training in the organizations. EU-UNL constitutes just a case-study for the viability of the implementation of this technology that can be extended to different languages and different fields.

Action Line of the econtent Programme: Action 2. Enhancing content production in a multilingual and multicultural environment. The overall goal in this action is to investigate and experiment with new strategies, partnerships and solutions for designing e-content products and services that can accommodate local languages and cultural conventions. EU-UNL aimed to demonstrate the capabilities of the UNL technology for multilingual dissemination of e-contents as well as for introducing a new paradigm of creation and management of multilingual web-sites.

MULTIDOC-IST-34702: A system for multilingual document dissemination

Summary of goals: The goal of this proposal was the development and integration of the components for a multilingual dissemination system in the Web using the public and open UNL. This technology constituted the base of the multilingual support for the proposed application. Initially we planned to demonstrate it in a workplace/business scenario, but were equally applicable in a personal dissemination scenario. For providing multilingual functionalities to Internet publishers UNL would be embedded into their current documents. We would also provide the tools needed for processing the new multilingual documents.

Action lines of the RTD Programme:

Action Line III.3.1 (2001WorkProgramme). The Multidoc directly addresses most of the concrete objectives listed under action line III.3.1, such as the advance towards a fuller realisation of the multilingual Internet for personal development and informational purposes, wider availability and more effective production and use of multilingual information, Multilanguage design, authoring and publishing of online (web) multimedia documents, or multilingual generation.

3. The evaluation of the proposals

We aim in this section to reflect the view of the proposers and the EC evaluators for each proposal described. Before, the evaluation criteria and the process followed in the IST Programme are explained.

3.1. Evaluation criteria for the IST Programme

A number of evaluation criteria are common to all the programmes of the fifth framework programmes. Independent experts examine each eligible proposal against these criteria. The specific programme decisions provide further details of these criteria and may also provide for additional evaluation criteria that apply only to the particular programme(s) concerned. Any particular interpretations of the criteria to be used for evaluation and any weights and thresholds to be applied to the criteria are set out in the programme-specific annexes to this document and referred to in calls and all relevant supporting documentation.

For the detailed examination of proposals against the criteria set out in the rules for participation, the experts will generally provide marks and comments. In addition, the experts are asked to examine certain evaluation criteria by answering a set of questions relevant to the specifications referred to in the call. The following questions are addressed at an appropriate moment in the evaluation:

- Does the proposal address the parts of the work programme, including policy issues, open for the particular call? If the proposal is only partially in line with the call, does it have sufficient merit to be considered in its entirety or partially?
- Have relevant ethical issues been adequately taken into account in the preparation of the proposal; is the proposed research compliant with fundamental ethical principles, if relevant? Is the research proposed in line with Community policies, if relevant; have appropriate safeguards/impact assessment regarding Community policies (e.g. environment) been taken into account, where necessary?
- Does the proposal follow the requirements for presentation (notably requirements for anonymity)?

In the case of negative answers to these questions, the experts are required to provide comments to justify their answers. On the basis of the experts' remarks, the Commission reserves the right not to continue with the evaluation of any proposal which is found not to fulfill one or more of the above requirements. In clear-cut cases (for example, a proposal which addresses a research task which is not open in the particular call), a proposal may be ruled out of scope or contrary to clearly stated policy requirements at the moment that the eligibility checks are carried out.

All eligible proposals that conform to the requirements of the call are examined for their quality and relevance by the Commission assisted by external experts. Experts examine proposals and provide marks for the criteria set out below (which are drawn from the decisions on the framework programmes and the "rules for participation" decisions and grouped into five main blocks). In addition, they also provide an overall mark for each block of criteria (unless a proposal fails any thresholds – see below). Experts are required to provide comments to accompany each of their marks in a form suitable for providing feedback to the proposers. These comments must be consistent with any marks awarded.

The blocks of criteria to be applied by all programmes are as follows (EC, 2001):

Scientific/Technological quality and innovation

- The quality of the research proposed and its contribution to addressing the key scientific and technological issues for achieving the objectives of the programme and/or key action;
- The originality, degree of innovation and progress beyond the state of the art, taking into account the level of risk associated with the project;
- The adequacy of the chosen approach, methodology and work plan for achieving the scientific and technological objectives.

Community added value and contribution to EU policies

- The European dimension of the problem. The extent to which the project would contribute to solving problems at the European level and that the expected impact of carrying out the work at European level would be greater than the sum of the impacts of national projects;
- The European added value of the consortium - the need to establish a critical mass in human and financial terms and the combination of complementary expertise and resources available Europe-wide in different organisations;
- The project's contribution to the implementation or the evolution of one or more EU policies (including "horizontal" policies, such as towards SMEs, etc.) or addressing problems connected with standardisation and regulation.

Contribution to Community social objectives

- The contribution of the project to improving the quality of life and health and safety (including working conditions);

- The contribution of the project to improving employment prospects and the use and development of skills in Europe;
- The contribution of the project to preserving and/or enhancing the environment and the minimum use/conservation of natural resources.

Economic development and S&T prospects

- The possible contribution to growth, in particular the usefulness and range of applications and quality of the exploitation plans, including the credibility of the partners to carry out the exploitation activities for the RTD results arising from the proposed project and/or the wider economic impact of the project;
- The strategic impact of the proposed project and its potential to improve competitiveness and the development of applications markets for the partners and the users of the RTD results;
- The contribution to European technological progress and in particular the dissemination strategies for the expected results, choice of target groups, etc.

Resources, Partnership and Management

- The quality of the management and project approach proposed, in particular the appropriateness, clarity, consistency, efficiency and completeness of the proposed tasks, the scheduling arrangements (with milestones) and the management structure. In addition, the tools to be used for monitoring project progress, including the quality of specified indicators of impact and performance, and ensuring good communication within the project consortium;
- The quality of the partnership and involvement of users and/or other actors in the field when appropriate; in particular, the scientific/technical competence and expertise and the roles and functions within the consortium and the complementarity of the partners;
- The appropriateness of the resources - the manpower effort for each partner and task, the quality and/or level and/or type of manpower allocated, durables, consumables, travel and any other resources to be used. In addition, the resources not reflected in the budget (e.g. facilities to carry out the research and the expertise of key personnel). For this criterion, comments may be given rather than marks.

When examining proposals, experts will only apply these criteria, supplemented by any programme-specific criteria contained in the programme decision. These criteria as they apply to the particular programme may be described in greater detail in the programme-specific annex and the work programme. Experts are not be allowed to apply criteria which deviate from those set out and the programme-specific annex.

3.2. The Evaluation of the UNL Proposals

3.2.1. Evaluation Results of QANET (econtent)

The opinion of the EC Experts.

This proposal caused a good impression because, in opinion of the evaluators, showed a well documented overview of the subject, an extensive workplan, the consortium consisted of outstanding relevant experience, with a proposal well structured. However, it presented an R&D approach rather than a feasibility demonstration of econtent, as was required by the present call. For this reason the proposal fell outside the scope of the econtent call. The evaluators recommended the submission of the proposal to a more suitable EU programme.

The opinion of the EU-UNL Consortium.

We accepted the opinion of the expert evaluators.

Actions taken by the UNL partners.

We considered the evaluation of the proposal in an optimistic way. For this reason we decided to remake the proposal to be adapted to the next call of R&D IST Programme incorporating at least a company and a user (new QANET proposal).

3.2.2. Evaluation Results of QANET (RTD)

The opinion of the EC Experts.

This proposal failed to reach the threshold score on two of the criteria.

- *Scientific/technological quality and innovation.* In opinion of the EC experts the proposal did not provide a convincing integration of both aspects, quality assurance in multilingual applications and developing resources for the UNL platform. The detailed study of the state of the art in Machine Translation and NLP systems evaluation had several omissions and did not bring forward clear conclusions.
- *Economic development and S&T prospects*. A commercial partner was willing to take up the exploitation of the project results, but these were highly conditional on the success of the UNL approach. The viability of which was questionable. Likewise, the potential for commercial exploitation of Quality Assurance methodologies for Human Language Technologies is not demonstrated, and would have required a much deeper market analysis than provided in the proposal.

The opinion of the QAnet Consortium.

We proposed to develop a series of resources (corpuses and controlled dictionaries) to be produced during the project as the base of the testing of the UNL Quality System as well as to any other NLP. For this the results are not completely conditional on the success of the UNL approach. The conclusions derived from the state of the art, maybe not enough described, are that we need to produce instantiated quality models for human language technology applications (purpose of this project).

Actions taken by the UNL partners.

We decided to carry on presenting a new proposal.

3.2.3. Evaluation Results of LINGWEB

The opinion of the EC Experts.

This proposal was judged ineligible. The reasons were because:

(1) *Non-existence of technology*. Multilingual website creation technology based on UNL does not exist while it should be a prerequisite for a trial project;

(2) *Excessive resources for development*. A high level of development and integration of new components consumes more than a half of resources;
(3) *Non-study of benefits*. The benefit of the approach chosen even in terms of productivity enhancement or the impact on the management of the lifecycle of multilingual documents is not at all addressed;
(4) *Market study insufficient*. The market perspectives are not convincing despite the intention of the coordinating partner to spin-off the results.

However, as the evaluators said in their report, the idea of using UNL as an interlingua for multilingual website creation is attractive and could be reconsidered in the framework of future generation multilingual web activities.

The opinion of the EU-UNL Consortium.

In this occasion, we felt very surprised by the way of the rejection of this proposal (ineligible) and the reasons that explained this decision. We answer to every one of the arguments previously described:

(1) *Non-existence of technology*. The UNL technology was officially presented in UNL annual meetings at Brussels and Geneva previously to this proposal with attendance of representatives of the EC.
(2) *Excessive resources for development.* There is not any new component in this proposal. According to the requirements of the Call for this proposal we proposed the adaptation of resources and components already existing. For this task we planned 6 man month of the total 75 mm. The rest of the tasks are assigned to produce methodologies.
(3) *Non-study of benefits.* There is a whole workpackage (wp5) that addresses specifically the definition of metrics and methods for evaluating the technical and business performances and its associated costs.
(4) *Market study insufficient.* This is more subjective argument. We proposed several exploitation strategies based on the creation of new Language Centers, the promotion for the creation of new companies from the results obtained of some Business Plan made by the coordinator of the proposal, the expansion of the use of the UNL technology without costs to institutions, segmentation of the market uses, professional training for individuals that are working in the field of translation, the creation of a commercial version of the system at low price for individuals, forming associations for the developing of specific components and/or joint exploitation of specific contents with commercial interest, and by last, through the expansion of number of languages as priority.

In summary, we did not understand and we did not agree with this qualification of proposal "ineligible". What kind of political attitude of the Programme responsible were taken?

Actions taken by the UNL partners.

We collected the last comment of the evaluators concerning to the idea of using UNL as interlingua for multilingual website as an attractive idea and, in spite of the strong hit we received, we kept on our efforts promoting a new proposal in the econtent Programme (EU-UNL proposal).

3.2.4. Evaluation Results of EU-UNL

The opinion of the EC Experts.

This proposal was considered as an interesting approach to the development of an interlingua for the automatic translation of text. However, UNL, in opinion of the experts was not sufficiently established and proven. It bears too many risks and should probably addressed under an R&D Programme. They had serious concerns about UNL, hand-encoding and its long term viability. The overall score was 2 (fair). In brief, the evaluators appreciate good technical knowledge in consortium, and they think that based on this partnership this could be a good research project.

The opinion of the EU-UNL Consortium.

The purpose of the project is to prove the cost-effective feasibility of the integration of a well-proven translation system to a content provider deployment strategy. This would provide a big amount of information in several languages that would serve as base of the knowledge needed. By this reason, one of the main objectives of the proposal included a Methodology for the implementation of the multilingual UNL system, including the testing phase. Effectively, the basic components of the UNL system have been already developed in the latest years. Now, they need to be tested in an integrated way and in real environments to fine-tune the interrelation of every language components such as was planned in the proposal.

Actions taken by the UNL partners.

We followed the recommendations of the evaluators and we promoted a new proposal in a RTD Programme (Multidoc proposal).

3.2.5. Evaluation Results of MULTIDOC

The opinion of the EC Experts.

This proposal only failed to reach the threshold score on one of the criteria.

Scientific/technological quality and innovation. In opinion of the EC experts the innovative value is low as this approach to the translation is not new. The scientific value of the proposal rests on the merits of the technology, UNL, that is being applied. But for these experts UNL is not a well-proven translation system since it is not backed up by solid independent evidence. Thus, this proposal fails to adduce any reference in the literature in support of UNL. By other side, according to their opinions, the proposal does not contain any suggestion how the enormous linguistic complexities of the encoding process can be taken one stage beyond machine aided / validated human effort which renders the approach economically unviable on any scale.

The overall conclusion is that the project intends to employ a technology of insufficiently proven feasibility and questionably economic viability.

The opinion of the Multidoc Consortium.

We propose to use the UNL technology for representing the informal contents of web pages following the XML-compliance of document mark-up languages. It

is true that is not innovative. The innovative aspect in this project is the design and implementation of a multilingual dissemination system that covers all the steps of the publication chain: encoding of contents, generation of multilingual count parts and delivery of language specific versions to readers. The user site and the sites of the technology providers engage in a communication process involving standardized UNL-enriched documents using Internet-based communication software components.

As regards the complexity of the encoding process, in this moment several partners of the consortium have prototyped tools addressing this need.

Actions taken by the UNL partners.

We decided to take a period of reflection. We have taken a lot of man-month dedicated to the elaboration of proposals for the IST Programme without success. This is not a problem of a proposal but the perception of the UNL technology by the EC responsible.

3.2.6. Comparative Analysis of Evaluation Results

We have gathered the scores provided by the evaluators for previous proposals (see table 2). Each column corresponds to the scores obtained by each criterion, with the following meaning:

- Criterion 1: Scientific/technological quality and innovation
- Criterion 2: Community added value and contribution of EC policies
- Criterion 3: Contribution to Community social objectives
- Criterion 4: Economic development and S&T prospects
- Criterion 5: Resources, partnership and management

Proposal	Score Crit.1/3	Score Crit.2/2	Score Crit.3/0	Score Crit.4/3	Score Crit.5/2
QANET	Non numerical score. Global score = 0 (rejected)				
QANET	2	3	2	2	2
LINGWEB	Ineligible				
EU-UNL	Non numerical score. Global score = 2 (fair)				
MULTIDOC	2	3	3	3	2

Table 2: A view of the proposals evaluation

We have included in the table, together with the identifier of criterion, the threshold score required by the EC. An analysis of these results for the previous evaluations shows that the main obstacle for the approval of the proposals refers to the use of the UNL as technology (criterion of the technological quality and innovation). Evaluators do not find attractive and feasible the inclusion of this technology. However, in these proposals, the other criteria are in general well considered, issues such as the adequacy for the problem that address and its contribution to community social objectives, the fitness to the EC policies or a consortium balanced.

4. Conclusions

The initiatives described in this paper show at least two issues by the side of the European UNL LC (proposers). Firstly, proposers have shown a persistent interest to involve the EC in the success and diffusion of a technology for Multilinguality derived from the United Nations. Second, proposers have dedicated lot of resources trying to follow the recommendations of evaluators. Specifically, the Spanish Language Center was the coordinator of the first three proposals and was an active contributor to the rest. We have commented the last five proposals, but there are another three presented with the same results: HEREIN-ML (Towards a methodology for making textual information about European heritage multilingual by using UNL as metadata), AQUITRA and COACH (Company Organization for Automation Customer Help Integrated into ebusiness).

The diagnosis has been done but there are no clear causes. We can speculate with some of them.

- From the viewpoint of the EC evaluators, UNL technology is not feasible maybe because the lack of successful experiments and by the scarce presence of UNL in scientific areas of the sector.
- From the viewpoint of the proposers, we regret the absence or extension of more explanations or advices for the future, maybe at the political and strategic level in order to avoid apparent contradictions in the specific evaluations obtained.

The only view of all this information placed together is speaking by itself. All the proposers have long and intense European projects experience during the last ten years at least. On the other hand, it is not understandable why the interest of the EC in this global initiative of the UN is so low or inexistent. Europe must not be out of this initiative and some of the technical evaluations seem to be made in the best case by persons with a low level of knowledge about this initiative. The reader of this paper can extract conclusions by him/herself according the proposals, and the persistent and sometimes contradictory evaluations of all of them.

ABSTRACT

Arabic language has unique characteristics that greatly affect its automation. Arabic language exhibits a very complex but very regular morphological structure. Different proposed morphological analysis techniques for the Arabic language are based on heavy computational processes and/or the existence of large amount of associated information. Researchers in the field of Arabic computational linguistics faced with some basic technical difficulties including lack of propre evaluation and testing frameworks. Because of that, researchers in their works provided general description for approaches with almost no effectiveness or efficiency measures.

This work proposed an initiative for a framework to be used for testing and evaluating Arabic morphological and stemming techniques. A new Arabic stemmer is proposed where the generated data set were used to construct, test and evaluate the stemmer.

INTRODUCTION

Stemming and morphological analysis techniques are computational processes that analyze natural words by considering their internal structures. Stemming techniques usually deal with languages with simple morphological systems while morphological techniques are widely used in languages with complex morphological systems. Stemming and morphological analysis techniques can be viewed as clustering mechanisms and usually help in resolving the lexical ambiguity. The main objective of the stemming algorithms and one objective of morphological analysis techniques is to remove all possible affixes and thus reduce the word to its stem. Both processes are very useful in many natural language applications such as information retrieval, text classification and categorization, text compression, data encryption, vowelization and spelling aids and automatic translation (Lovins, 1968; Dawson, 1974).

Semitic languages require more complicated systems for processing their morphology. Arabic language, for example, consists of a very complex but very rich and regular morphological structure. English has a simple morphology compared to other languages. European languages involve more complex morphology than does English (Savoy, 1999).

In Arabic, a root is a single morpheme that provides the basic meaning of an Arabic word. Arabic root is the word's origin before any transformation process. A stem, on the other hand is a morpheme or a set of concatenated morphemes that refers to some central idea while a word is the single isolated lexeme that represents certain meaning.

An affix is a morpheme that can be added before, after or inserted inside a root or a stem as a prefix, suffix or infix respectively to derive new words or meaning. Arabic prefixes are derived from small set of letters and articles, while suffixes are derived from small set of letters, articles and pronouns. Removal of prefixes in Arabic is not harmful process most of the time because, as oppose to English, the process does not reverse the meaning of the word.

A pattern is a model used to study the internal structure of Arabic words. It consists of the three basic Arabic pattern letters that corresponds to the first, second and third letter of the Arabic trilateral root respectively. For the quadrilateral roots, the third letter is duplicated to represent the fourth root letter. In addition, zero or more augmented letters or one or more short vowels are inserted to expand the pattern.

Computational Arabic morphology drew the attention during the last two decades. This, consequently, has led to the emerging of some morphological analysis techniques. Arabic morphological analysis techniques can be categorized into table lookup, linguistic and combinatorial approaches (Ali, 1988; EL-Affendi, 1991; Al-Fedaghi & Al-Anzi, 1989). Some researchers suggested analyzing Arabic words to reach their roots (Ali, 1988) while others suggested analyzing them to their

stems only (Alsuwaynea, 1995; Al-Atram, 1990). Analyzing words to their roots is preferred in linguistic processing-based applications while analyzing words to their stems is more useful in some other applications such as information retrieval-based systems. A simplified system for generating/analyzing Arabic words is shown in Figure 1.

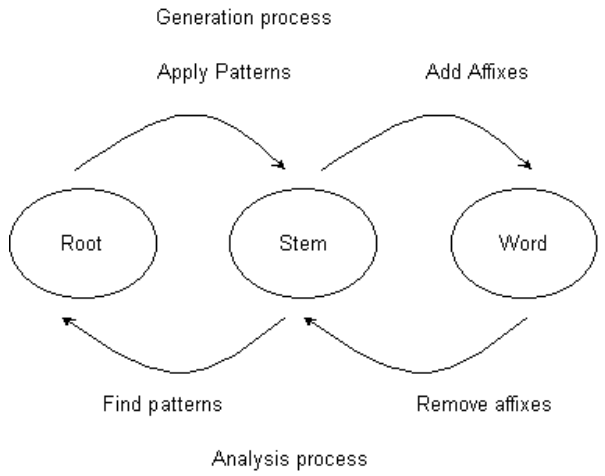

Figure 1. Arabic system for generating/analyzing words

Researchers in the field of Arabic computational linguistics faced with some basic technical difficulties including lack of propre evaluation and testing frameworks. Because of that, researchers in their works provided general description for approaches with almost no effectiveness or efficiency measures.

This work proposed an initiative for a framework to be used for testing and evaluating Arabic morphological and stemming techniques.

ARABIC DATA SET

The framework is based on a data set initially used to design and evaluate a proposed Arabic stemmer. The data set is a collection of about 23,000 Arabic words extracted from 100 short Arabic articles collected randomly from the internet. Extracted words were normalized by removing vowels and then stored in a binary file in the same order as the original natural text. Since word order was preserved, it is very easy to deduce the contextual meaning of any word by listing few words before and after the current word.

Structure of the word record is shown in Figure 2. Each word in the data set was manually investigated to produce morphological components including stem and affixes. In this work, the stem is defined as a singular, masculine and past tense Arabic word without affixes. To guarantee an adequate level of accuracy, an Arabic linguist has been consulted during this stage.

Figure 2. Data structure used in storing words.

If expanded, this data set can be used for other linguistic studies and researches such as morphological analysis techniques, affixation compatibility and different frequency analysis.

Usually, gathered natural text used in modern Arabic is full of spelling errors and spelling variations. Errors corrected partially during the manual processing stage and then completed semi-automatically. Table 1. Lists some examples of errors and spelling variations.

Following is some statistical characteristics of the data set. Figure 3. shows the length distribution of words. Most of the words with length of two letters and some of those with length of three letters are stop words. Furthermore, most of words with the highest lengths are foreign words. Figures 4 and 5 show frequency distribution for word and stem respectively. Figures show normal distribution over the collection.

Spelling mistake	Arabic terminology	Example
Using different spelling variations of foreign words	تهجئة الكلمات الأجنبية	انترنت و انترنيت
Compound nouns. With and without space between parts.	الأسماء المركبة	عبد الرحمن و عبدالرحمن
Confusing between Arabic letters	ه and ة ا and أ ى and ي	هرة – هره استنجار – أنباء علي – على

Table 1. Spelling errors and variations

Table 2. and Table 3. give the frequency of prefixes and suffixes. Such statistics are very useful in different computational and linguistic studies.

يا	68	ك	9	تنا	3	اها	1
نا	61	ني	8	اتنا	3	اتكم	1

Table 3. Suffix List Derived from data set

PATTERN-BASED ARABIC STEMMER

In this section, a new approach that utilizes the apparent symmetry of generated natural Arabic words is introduced. In this approach, a unique regular expression-based rule is generated for group of similar Arabic words. Rules are used to describe the internal morphological structure of Arabic words and guide the decomposition process of a given word to its basic units i.e. stem, prefix and suffix. A very simple rule parser was developed to perform the analysis to process and extract word morphological components.

Created rules are written from right to left to match script writing direction of Arabic language. Rule pattern may contain up to three distinct parts. The first and last parts describe affixation properties of the word while the middle part controls the stem extraction process. Pairs of angle brackets surround affixation parts. Absence of prefix or suffix in the rule patterns is sometimes denoted by empty angle brackets. This is necessary in order to distinguish them from an angle-bracketed part of the stem.

The complexity of rules varies from very simple passive ones to very complicated rules that deal with complex morphological behaviors. Set of passive rules is created to handle words already in stem forms, isolated articles, proper names and foreign words.

A rule will be fired if it has the same length as the length of the inspected word. A match is achieved if and only if a fired rule produces the correct prefix, stem and suffix. A given word should fire at least one rule and match only one rule.

EXPERIMENTATION

Created data set has been used in the design and implementation stages of the stemmer. The first part of the experiment was designed to study rule growth in a natural text. In this part each word passed to the parser for analysis. The parser has access to list of accumulated rules. The parser tries to fire rules in sequence. On match, the word structure will be updated with number of fired rules, the id of matched rule and its sequence. On mismatch, a new rule should be created and appended to the rule list.

Figure 6 shows the growth of rules. It shows very rapid growth at lower number of words and a tendency to

be stabilized as more words introduced. Figure 7 depicts number of generated rules for every thousand words. It clearly shows that number of generated rules decreases as number of words increases.

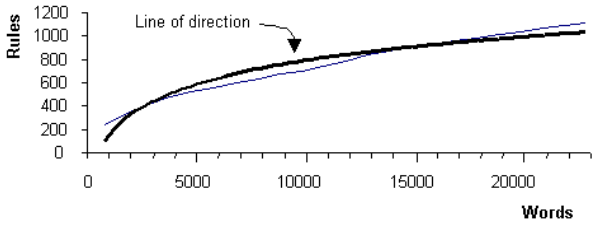

Figure 6. Rules growth per 1000 words

Figure 8 shows the length distribution of words and created rules for the test collection. It can be deduced that majority of rules were generated by words of length 5, 6, and 7 letters. This is a normal phenomenon because words of such lengths are more likely to have diverse kind of affixes. Existence of affixes, consequently, produces more rules. For words with shorter lengths, number of introduced rules were low due to the fact that shorter words are most likely to be particles or words already in stem forms. Fewer rules were introduced for words with longer lengths because most words are either proper names or foreign words. Such type of words is less likely to have affixes.

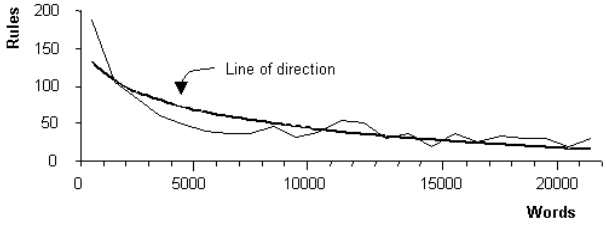

Figure 7. Number of rules generated per 1000 words.

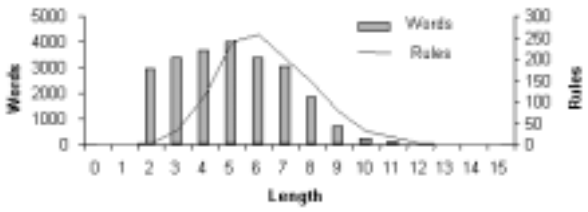

Figure 8. Distribution of rule and word lengths

The order of rule firing plays an important role in the efficiency of the analyzer. For a given word, it is desirable to fire less number of rules and to maintain firing order in such a way that first fired rule is the matched one. Figures 9 and 10 show the relationship between matched and total firings per rule. Having different rule orders will produce different plots. In order to achieve optimized performance the curve of Figure 9. should follow the horizontal line or the scattered points in Figure 10. aligned with the diagonal line. Although it is impractical to achieve such optimum state, it is possible to have certain rule ordering that produces the best performance for such rule set.

Figure 11. indicates that average fired rules is in-line with the conclusion derived from Figure 8. For optimized analyzer, it is desirable to keep average fired rule for each word length class as low as possible. Also, for optimization, it is needed to keep the sequence of the matched rule at the top of firing sequence.

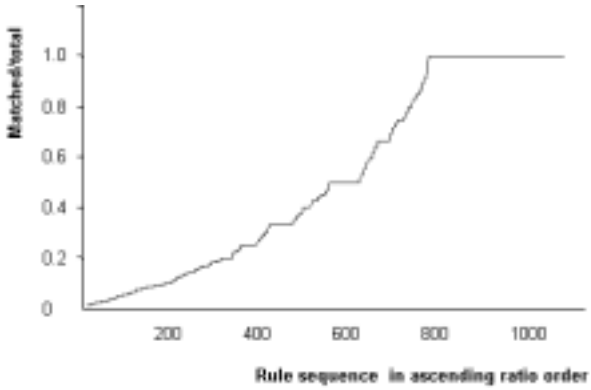

Figure 9. Relation between matched and total firing.

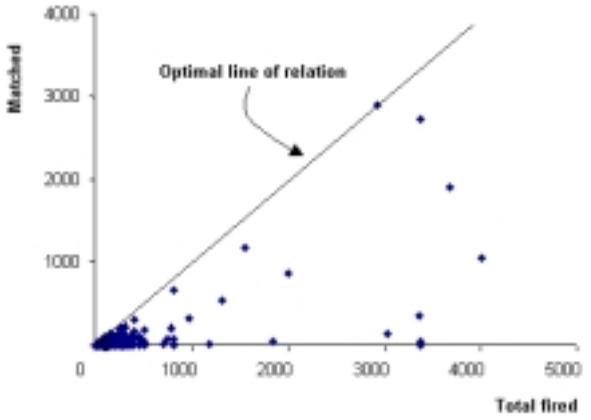

Figure 10. Match vs. total per rule matched and total firing.

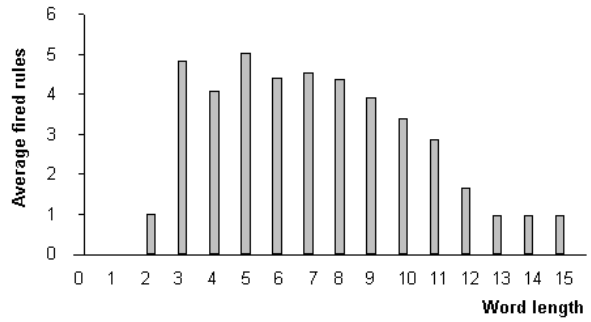

Figure 11. Average fired rules vs. word length.

CONCLUSION

Known Arabic morphological analysis techniques suffer from few problems including the need for testing and evaluating frameworks. This paper proposed an initiative for a framework to be used for testing and evaluating Arabic morphological and stemming techniques. The framework is based on a data set initially used to design and evaluate a proposed Arabic stemmer. The data set is used to construct, test and evaluate the stemmer.

This data set can be used for other linguistic studies and researches such as morphological analysis techniques, affixation compatibility and different frequency analysis.

Abstract

This paper describes an ongoing research project on English-to-Arabic Interlingua-based machine translation. Section 1 gives a description of the system that generates Arabic sentences from Interlingua representations (IRs). In section 2, we show how basic sentential components are mapped. In this context, we address some of the differences between English and Arabic such as agreement in number which cannot be transferred exactly from the IR of an English sentence. Results and an example translation are provided in section 3. In this context, we address the issue of word order variation in Arabic.

1. The Architecture of the Arabic Generation System

An Interlingual approach to machine translation (MT) has a number of advantages over other approaches, such as the 'transfer' model. In an Interlingua-based architecture, source text analysis and target text generation are divided into separate components. A language-independent intermediate representation (or Interlingua) mediates between these two components. The decoupling of the analysis and generation phases allows the system to handle multiple-language output and avoids the reconfiguration of the system for each new language.

In the KANT Interlingua-based MT system (Nyberg, and Mitamura, 1992), each sentence is first conveyed into tokens. The KANT analyzer uses a lexicon, a morphological analyzer, source language grammar and semantic information in order to parse the tokenized sentence into a feature structure (FS), a list of feature-value pairs that reflects the syntactic structure of the source language (i.e., English). The interpreter then uses mapping rules to convert the FS into an IR. An IR is a tree-structured representation that abstracts away many of the syntactic details of both source and target language, while conveying the meaning of the source language. In section 3 below, we provide an example of a source language FS, the IR produced from this FS and the target language FS produced from the IR.

Generation of the target language sentence begins with the IR. The system which generates Arabic sentences from IRs consists of 4 subsystems: the mapping system, the sentence generation system, the sentence/morphology generation interface and the morphological generation system, as shown in Figure 1 below.

First, the generation mapping rules convert the IR into an FS that reflects the syntactic structure of the target language. The FS is a list of feature-value pairs that reflects the syntactic structure of the target language. Target language lexicon entries are FSs. They are retrieved during mapping and added to the sentence FS under construction. The Genkit grammar analyzer and generator (Tomita and Nyberg, 1988) processes the input FS and generates a preliminary target sentence string, calling MORPHE when it encounters lexical symbols in the generation grammar.[1] This string is optionally run through the CODA post-processing system to produce the final target sentence.

1.1. The Mapping System

The mapping system produces FSs for Arabic from IRs, using a set of mapping rules and a mapping lexicon. The mapper recursively traverses the Interlingua, stopping at each level to examine slots and their fillers (features, concepts and nested Interlinguas). Testing a hierarchy of rule declarations, the mapper performs a structure-building operation called mapping. The goal and result of mapping is a target-language FS whose contents reflect the contents of the Interlingua, expressed in terms of the syntactic and lexical properties of the target language. The mapping process involves three main stages:

- Selecting lexical items for each Interlingua concept;
- Mapping the semantic roles for each Interlingua concept (slots in the Interlingua frame) to grammatical functions (slots in the FS);
- Mapping semantic features for each Interlingua concept to the appropriate syntactic features in the FS.

The mapper's knowledge is represented as mapping rules that are stored in a mapping hierarchy. The use of a hierarchy allows one to write specific rules for specific concept/lexeme pairs and general ruleswhich are inherited.

[1] The morphology/generation interface consists of a lisp program that defines some functions that are used to call the morphological generator from the sentence generator.

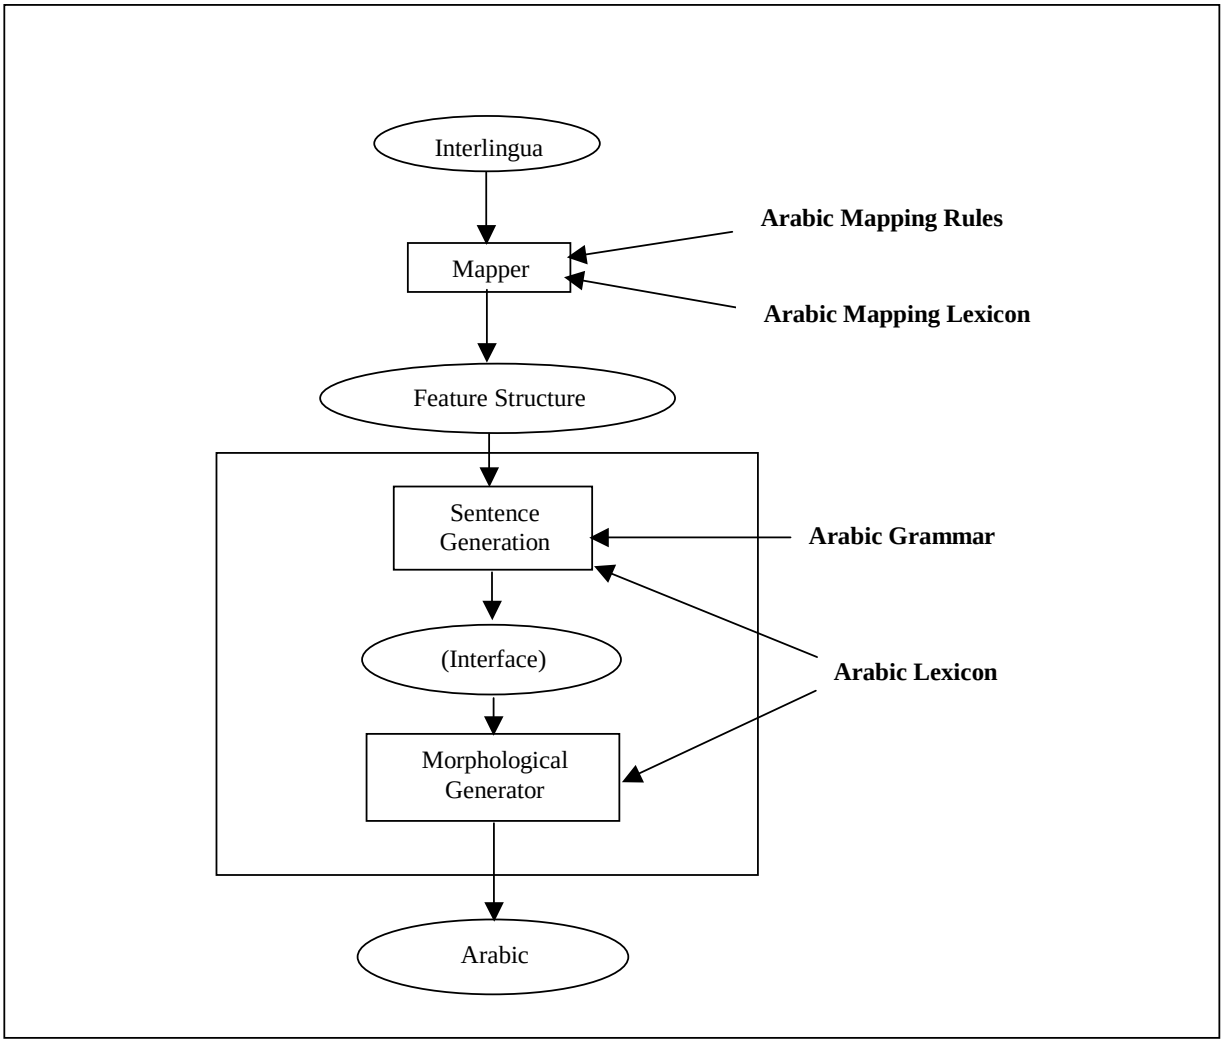

Figure 1. The Architecture of the Arabic Generation System

1.1.1. Concept Encoding Information

Each node in the mapping hierarchy has a name, a list of concepts, and a list of mapping rules to be executed. In addition, it has links connecting to one or more parent nodes. The examples in (1) below show how the concepts *shine* and *house* are encoded:

```
(1)
a. (node ?A-shine
        :parents (VERB)
        :encodes (*A-shine)
        :rules ((:lex "ta?allaq")))

b. (node ?O-house
        :parents (NOUN)
        :encodes (*O-house)
        :rules ((:lex "manzil")))
```

The node names *A-shine and *O-house are arbitrary symbols used to distinguish the nodes. They denote lexical interlingua concepts that would be associated with the lexical entries for the verb 'to shine' and the noun 'house' in the English lexicon. The :parents field specifies the part of speech that these nodes inherit from in the mapping hierarchy. The :encodes field and the :rules field specify which Interlingua concept this node will realize and the mapping rules associated with this node, respectively. ?A-shine and ?O-house denote the names of the lexical nodes used to determine the corresponding Arabic translation.

1.1.2. The Syntactic Lexicon

The syntactic lexicon consists of two parts: templates and entries. The templates specify the default contents of various types of lexical FSs. (2) below illustrates an Arabic syntactic template:

```
(2)  (soft-template conj ((cat conj)))
```

The entries associate each lexeme with a template class and specify the unique features for that particular lexeme, as is illustrated by the following example:

```
(3)  (conj "wa" ((ROOT "wa")))
```

1.1.3. The Mapping Rules

A mapping rule is a set of slots and values that specify operations involved in building an FS from an Interlingua. The lexical nodes in (1a-b) above illustrate a :lex mapping rule, which retrieves a translation from the target language lexicon. Mapping rules may also contain other directives

(e.g. such :map, :test, :add, :force-add, :consume, etc.) for performing other operations on the IR and FS.

For the sake of concreteness, consider the following mapping rule from (Soudi, 1999, pg. 13):

```
(4)  (:test (:sem (number plural)
            :syn (:not (human +)))
     :force-add ((agr ((gender f) (number sg)))))
```

The mapping rule above consists of a set of slots and values associated with the noun mapping hierarchy node. The :test slot specifies a set of conditions that must be passed for the rule to be applied. The :syn subslot specifies a negated condition on the FS, namely the feature (:not (human +), that must be met. The :sem subslot specifies a condition on the IR, namely the FVP (number plural). The slot :force-add indicates that the FS under construction should have feminine as its gender value and singular as its number value. This slot actually overrides information in the IR: the value of the number feature in the IR, namely plural, is overridden here by the singular. The mapping rule above applies to the sound plural feminine in Arabic (i.e., the *-At* class). By way of example, in the IR for the French noun *les animaux* 'animals', we would have, inter alia, the feature-value pairs (number plural) and (gender masculine). This information should be overridden for the corresponding Arabic noun 'Hayawanaat' – which is (human -) – by the feature-value pairs (number singular) and (gender feminine). Note that the information specified by the :force-add slot in the example above relates to subject-verb agreement. Thus, the sound plural noun *Hayawanaat* is plural but has 'singulative' agreement with verbs.

1.2. The Generation Grammar

To generate Arabic sentences, we have used Genkit (Generation Kit) (Tomita and Nyberg, 1988), a system that compiles a grammar written in a formalism called Pseudo-Unification Grammar into a sentence generation program. The generator follows a top-down, depth-first strategy for applying rules during generation.

The following example shows a unification-based grammar rule for generating sentences. The rule consists of a context-free phrase structure rule and a list of pseudo equations.

```
(5)  (<S> ==> (<NP> <VP>)
          (((x1 agr) = (x2 agr))
           (x1 == (x0 subj))
           (x1 case) = nom)
           (x2 = x0)))
```

The non-terminals in the phrase structure part of the rule are referenced in the constraint equations as $x_0 \ldots x_n$, where x_0 is the non-terminal in the left-hand side (here, <S>) and x_n is the *n-th* non-terminal in the right hand side. In these equations, x_1 represents <NP> and x_2 represents *<VP>*. The rule in (5) is for sentences with an *<NP>* and a *<VP>* that agree in number, person and gender. The equation ((x1 agr) = (xs agr)) indicates that the *<NP>*'s agr feature has a value that unifies with the value of the *<VP>*'s agr feature.

2. Arabic Noun and Verb Mappings

The generation of properly inflected Arabic verbs and nouns is a concern of both the mapper and the generator for a partial integration of the Arabic Morphology system into the KANT system). For example, the generation of correct agreement between nouns and their modifiers or other parts of the sentence may be performed either during mapping or during generation. Different cases must be considered:

(a) **Subject-Verb/Verb-Subject Agreement:** In Arabic, agreement in number between subject and verb depends on the nature of the subject of the sentence and word order. On a VS order, verbs do not agree in number with a plural subject. Agreement is always singular. Verbs, however, agree with their subjects in person and gender, as is illustrated by the following rule for generating a VS order sentence (from Soudi, 1999, pg. 16)):

```
(6)  (<s> ==> (<vp> <np>)
          (((x1 agr) = (x0 subj agr))
           ((x1 agr number) <= 'sg)
           (x2 == (x0 subj))
           ((x2 case) = nom)
           (x1 = x0)))
```

(b) **Intrinsic Number:** In most cases, the number feature for a noun is determined by the input sentence, reflected in the IR, and mapped directly from the IR into the FS by the mapper. Some nouns, however, may have agreement constraints already present in the lexicon. While lexical entries for nouns are usually assumed to be singular, certain nouns may be intrinsically plural in terms of agreement. For example, the noun *naAs* 'people', would contain the agreement information (number pl) in the lexicon, and the mapper should not override it with information that may be present in the Interlingua (for example, if the source language were Italian or Spanish, in which the word is a singular collective noun).

(c) **Number-Noun Agreement:** Number-noun agreement is governed by a set of complex rules. With the number 'one', agreement is as expected, but there may be a reversal of word order (e.g. *kitaabun waaHidun* 'one book' (nominative)). The number 'two' is expressed by the dual of the noun. Numbers 'three' through 'ten' require the noun to be plural and the gender of the number to be the opposite of the gender of the singular noun. For example: *xams* 'five' (masculine) *sanawaat* (plural of *sanat* 'year', feminine) but *xamsatu* 'five' (feminine) *kutub* (plural of *kitaab* 'book', masculine). Up to ten (plural of paucity), numbers and nouns agree in case, which is determined by the syntactic construction they appear in. Numbers above ten (plural of multiplicity) require a singular noun in the indefinite accusative. Agreement decisions can be made in the generator with the help of a callout function, but are most easily handled using the mapper.

3. An Example Translation and Results

To demonstrate the function of the components described in section 1, we will use the example sentence below:

(7) Jakarta and Bangkok are shining the most.

In the current system, the mapper takes as input the IR in (8), which is generated by the KANT analyzer and interpreter, and produces the FS for Arabic (9), using a set of mapping rules and a mapping lexicon (Soudi, 1999, pg. 20):

(8) **The Interlingua**

```
(*A-SHINE
  (FORM FINITE)
  (TENSE PRESENT)
  (MOOD DECLARATIVE)
  (PUNCTUATION PERIOD)
  (PROGRESSIVE +)
  (IMPERSONAL -)
  (ARGUMENT-CLASS AGENT)
  (MANNER
  (*M-THE-MOST
    (POSITION POSTVERBAL)
    (UNIT -)
    (DEGREE POSITIVE)))
    (AGENT
      (*G-COORDINATION
        (PERSON THIRD)
        (IMPLIED-REFERENCE +)
        (CONJUNCTION  (*CONJ-AND))
        (CONJUNCTS
          (:MULTIPLE
            (*PN-JAKARTA
              (UNIT -)
              (PERSON THIRD)
              (NUMBER SINGULAR)
              (REFERENCE NO-REFERENCE))
            (*PROP-BANGKOK
              (UNIT -)
              (PERSON THIRD)
              (NUMBER SINGULAR)
              (REFERENCE NO-REFERENCE)))))))
```

(9) **The FS**

```
((ADV ((CAT ADV) (ROOT "?ak#ar")))
 (form 4)
 (CAT V)
 (ROOT "ta?allaq")
 (VOICE ACT)
 (TENSE IMPERF)
 (MOOD INDIC)
 (SUBJ
   ((ELEMENT
      (*MULTIPLE*
          ((AGR ((GENDER F) (PERSON 3) (NUMBER SG)))
           (CAT N) (ROOT "jakarTaa"))
          ((AGR ((GENDER F) (PERSON 3) (NUMBER SG)))
           (CAT N) (ROOT "baankuuk"))))
     (CONJ ((CAT CONJ) (ROOT "wa")))))
 (PUNCTUATION ((ROOT PERIOD))))
```

Most of the linguistic features used in the KANT Interlingua and FS (e.g., punctuation, form, tense, argument class, number, person) should be self-evident. Some other features are artifacts of KANT's evolution as a technical text system. The IMPLIED-REFERENCE feature is used for nouns, such as the proper noun in the example above. G-COORDINATION contains all conjuncts that are coordinated and the conjunction that is used.[2]

The resulting FS serves as input to the Arabic morphological and sentence generator, producing Arabic surface forms:

(10) baAnkuwk wa jakaroTaA tata^alGaqaAni ^ako#ar

A major problem with the current implementation of the system relates to the word order variation in Arabic. Arabic is basically a VSO language, in which constituents can change order according to the constraints of text flow or discourse. The grammatical roles of constituents are identified by explicit morphological case markings. However, the KANT analyzer does not mark constituents as topic or focus. That is, this information is not provided in the IR. For example, there is no information structure for the system to decide whether to generate a VS order (12a) or an SV order (12b) from an IR for the English sentence in (11):

(11) Zayd ate the apple.

(12)

a. ?akala zayd-un t-tuffaaHat-a.
   ate Zayd-nom the-apple-acc

b. zayd-un ?akala t-tuffaaHata
   Zayd-nom ate the-apple.

Currently, the system produces all sentences in the S(=topic)V order.

While there are challenges to be worked out where the source language and target language differ greatly in their morphology and syntax, an Interlingua approach allows for a flexible integration of software modules for languages that differ in their realization of the same unit of meaning. Indeed, most of the morphological and syntactic differences between the source language and the target language can be handled by either the mapper or the generation grammar.

The system is still under construction. It has been tested on 29 different structures and has produced good results.

4. Conclusion

In this paper, we have described an ongoing research project on English-to-Arabic Interlingua-based machine translation. After giving a description of the system that generates Arabic sentences from IRs, we have shown how basic sentential components are mapped. In this context, we have addressed some of the differences between English and Arabic, such as agreement in number which cannot be transferred exactly from the IR of an English sentence. We have also provided an example translation and results.

[2] To promote representational consistency, the same structure is (*G-COORDINATION) is used if there is no explicit conjunction. In this case, the feature CONJUNCTION will have the value NULL.

Arabic Document Topic Analysis

Thorsten Brants, Francine Chen, Ayman Farahat

Palo Alto Research Center (PARC)
3333 Coyote Hill Rd, Palo Alto, CA 94304, USA
{brants,fchen,farahat}@parc.com

Abstract

We adopt algorithms for document topic analysis, consisting of segmentation and topic identification, to Arabic. By doing so, we outline the requirements for Arabic language resources that facilitate building, training, and fine-tuning systems that perform these tasks. Our segmentation and topic identification algorithm is based on Probabilistic Latent Semantic Analysis. First results for segmenting Arabic texts are reported.

1. Introduction

Document topic analysis is the task of assigning one or more topics to a document, characterizing the sub-topics discussed in the document, and identifying boundaries between segments discussing the different sub-topics. Most of the work in text retrieval has been on identifying and ranking the most relevant documents, although there is also work on passage retrieval. Topic analysis has applications in enabling retrieval at a finer grain than at the document level, but at a broader level than a passage.

One step in document topic analysis is topic-based segmentation. This task has been addressed by several authors. All methods calculate the similarity between the text before and after a hypothetical segment boundary and assume a segment boundary if the similarity value is small. Hearst (Hearst, 1997) describes TextTiling. She uses a sliding window and computes similarities between adjacent blocks based on their term frequency vectors. Li and Yamanishi (Li and Yamanishi, 2000a; Li and Yamanishi, 2000b) present a structured Finite Mixture Model, which they refer to as a stochastic topic model (STM). Choi et al. (Choi, 2000; Choi et al., 2001) present a model based on Latent Semantic Indexing (LSI) and divisive clustering. We have developed a segmentation method that uses the Probabilistic Latent Semantic Analysis (PLSA) model (Hofmann, 1999) for smoothing the term frequency vectors in a way that better models synonomous terms.

Topic-based segmentation is different from finding story boundaries in the TDT program. There, segmentation is not necessarily topic based, but also can (and commonly does) utilize a large variety of cue phrases which are usually absent in topic-based segmentation.

Figure 1 shows an example topic analysis for a part of an article that appeared in the El Hayat newspaper (the complete article is too long to be printed as an example). Our segmentation algorithm identified two segments, which are represented as non-underlined as underlined text. The first segment is about Israeli military operations in the West Bank, the second segment is about international efforts to defuse the tension. The next steps in topic analysis are topic identification and keyword or key phrase generation. Possible keywords are given to the right of the text (first segment: Israel, occpupy, Palestine; second segment: withdraw, stop, international).

2. Training for Arabic Document Topic Analysis

In this section, we outline the resources that are currently available for performing Arabic document topic analysis, and the resources we ideally would like to have.

2.1. Morphology

Algorithms for English document topic analysis usually depend on a morphological analyzer that associates each full-form of a word with its base form or stem. This significantly decreases the number of distinct word forms in a text by uniquely mapping a full form to some base form.

Stemming Arabic is much more difficult than stemming English. Reduction to roots can be done uniquely in the majority of cases but this would yield a very coarse grained model because words with only remotely connected meanings often share the same root. Reduction to stems (i.e., a root and a pattern) is done by the analyzer presented in (Beesley, 1996), but the output at this level is very ambiguous because of the omission of vowels in writing and the existence of diacritics and clitics. Some researchers resorted to the use of character n-grams instead of words for statistical Arabic models (Sawaf et al., 2001). Systems for uniquely identifying clitics and stems for Arabic are highly desirable as a preprocessing step for document topic analysis.

Preferable resource: Corpus of modern standard Arabic, labeld with uniquely identified stems (root and pattern) and clitics.

2.2. Segmentation

Current segmentation algorithms are trained unsupervised, i.e., no training data with explicitly labelled segment boundaries is provided. But evaluation requires such data. In the absence of documents labelled with segment boundaries, developers of segmentation algorithms use concatenated documents and try to identify the document boundaries (Choi, 2000; Hearst, 1997; Li and Yamanishi, 2000a). However, this is sub-optimal since segment boundaries *within* a document are expected to represent smaller topic shifts than boundaries *between* documents. We expect that the accuracy of a system evaluated on real document segments is lower than on artificially concatenated documents.

Preferable resource: Corpus of modern standard Arabic, labeled with segment boundaries within documents.

Figure 1: Example topic analysis for a document from the El Hayat newpaper, Apr. 11, 2002. Our segmentation algorithm TopSeg-C identified two parts. The first segment (non-underlined) is about Israeli military operations in the West bank, the second segment is about international efforts to defuse the tension. Keywords to identify the topic of the different segments are given to the right of the text.

2.3. Topic Identification

For English, collections labelled with large numbers of topics are available, e.g., in the Reuters-21578 corpus, each document is labelled with one or more of 90 different topics. Such a corpus is currently unavailable for Arabic. ELRA recently made available a collection of documents that are organized in seven domains. TREC-2001 made a step towards more detailed topics giving 25 topic descriptions but only a small number of documents (those necessary for TREC-2001) were manually labelled. Arabic topic analysis systems would benefit from large collections annotated with more fine-grained topics. This would allow topic identification and keyword evaluation as presented in (Li and Yamanishi, 2000a).

Preferable resource: Corpus of modern standard Arabic manually labeled with a fine-grained set of topic labels and keywords for each document as a whole, and for each segment in each document.

3. Topic Based Segmentation

3.1. TopSeg

TopSeg, our text segmentation system, combines the use of the Probabilistic Latent Semantic Analysis (PLSA) model (Hofmann, 1999) with the method of selecting segmentation points based on the similarity values between pairs of adjacent blocks. PLSA represents the joint probability of a document d and a word w based on a latent class variable z:

$$P(d,w) = P(d)\sum_{z} P(w|z)P(z|d) \qquad (1)$$

A model is fitted to a training corpus $\mathcal{D}$ using the Expectation-Maximization algorithm (EM) to maximize the log-likelihood function $\mathcal{L}$:

$$\mathcal{L} = \sum_{d\in\mathcal{D}}\sum_{w\in d} f(d,w)\,log P(d,w). \qquad (2)$$

After a model is trained, the model parameters $P(w|z)$ obtained in the training process are used in the process of folding-in the new (test) documents into the PLSA model to calculate $P(z|q)$ for new documents q. In the folding-in process, the Expectation-Maximization algorithm is used in a similar manner to the training process: the E-step is identical, in the M-step $P(w|z)$ is constant for all w and $P(z|q)$ is recalculated at each iteration. Usually, a very small number of iterations is sufficient for folding-in.

To segment a document, the document is first preprocessed by tokenizing the document and identifying sen-

tence boundaries. For English, two additional steps, downcasing and stemming, are performed. Next the text is broken in *blocks* of sentences. Candidate points of segmentation are identified and correspond to the locations between the text blocks. In our case, blocks are overlapping (as in a sliding window) and consist of h (e.g., $h = 5$) consecutive sentences.

Folding-in is then performed on each block b to compute the distribution among the set of latent classes, $P(z|b)$, where z is a latent variable, and b is a block. The estimated distribution of words for each block b, $P(w|b)$, is then computed as

$$P(w|b) = \sum_z P(w|z)P(z|b) \quad (3)$$

for all words w, where $P(w|z)$ is taken from the PLSA clustering of the training documents. The distribution of words in adjacent blocks b_l and b_r is compared using a similarity metric based on the Hellinger distance (Basu et al., 1997), also known as the Bhattacharyya distance (Kailath, 1967):

$$\mathrm{sim}_{\mathrm{Hel}}(b_l, b_r) = \sum_w \sqrt{P(w|b_l)P(w|b_r)}. \quad (4)$$

Dips are local minima in the similarity of adjacent blocks. We expect larger dips to correspond to stronger changes in topic. In our evaluation task, the number of segments is known is in advance, and we select the locations of the largest dips as segementation points.

3.2. TopSeg Using Combined Models

Training a PLSA model using EM starting with a random initialization yields a locally optimal model that is reached from the given start position. In general, different initializations yield different locally optimal models, which in turn might yield significantly different segmentation error rates.

One possibility to reduce the effect of different initializations is to generate several PLSA models, each with a different initializations. Then similarity values between adjacent blocks are computed according to the different models, and the resulting similarity values are averaged, yielding an *averaged similarity* curve.

The algorithm for combined models, TopSeg-C, generates k different PLSA models from the same training set, starting with different initializations. Each of the k models is used for folding-in the blocks of the test documents, and similarities between the blocks are calculated according to the k models. Now, the k similarity values for each pair of adjacent blocks are combined by calculating the average similarity value, yielding the average similarity curve. Local minima (dips) are determined in this resulting curve, and the largest dips are identified as the segment boundaries.

Similarly, we can use PLSA models with different numbers of latent classes to generate an averaged similarity curve. This was suggested by (Hofmann, 1999). However, we found that averaging over different initializations (with the same number of latent classes) yields slightly better results.

Table 1: The two corpora used in the experiments.

	Reuters-21578 (training set)	Arabic (training set)
Corpus		
# documents	7,769	6,482
# tokens	1,156,828	1,156,156
# types	41,343	70,148
# topics	90	–
Vector Space Model		
# terms	22,142	67,270
# terms $f > 1$	11,042	38,358
# n-grams	–	222,986
# n-grams $f > 1$	–	133,362

4. Topic-Based Segmentation Experiments

We performed first segmentation tests for Arabic using TextTiling and our PLSA-based model, TopSeg. Experiments and results are reported in this section. The TextTiling experiments serve as a baseline for our new segmentation model that we are currently developing for Arabic.

4.1. Data

Most of the resources outlined in section 2. are not available yet. We therefore resort to basic preprocessing and evaluation methods for performing the task of Arabic topic-based segmentation.

We prepare Arabic documents in a similar manner as Li & Yamanishi (Li and Yamanishi, 2000a) prepared documents from the Reuters-21578 corpus. 500 test documents are generated by randomly choosing two documents from the AFP Arabic Newswire Corpus (year 1994) and concatenating them into one. The task is to detect the document boundary. The system uses 6,482 documents for training[1] (training and test set are disjoint). Information about the Reuters-21578 set and the Arabic set that we prepared are provided in table 1. The sizes of the data sets are roughly comparable, but with the Arabic documents longer on average. The difference in the number of terms is even larger since we applied stemming to the English data.

Optimal values for the block size h for each model and the number of clusters Z for TopSeg and TopSeg-C were determined in preliminary experiments. For the following experiments, we set $h = 6$ for TextTiling, and $h = 5$, $Z = 256$ for TopSeg and TopSeg-C.

4.2. Results

We use the probabilistic error measure suggested by Beeferman et al. (1999) to report the results of our experiments. It is the probability p_{err}^{kw} that two *words* at distance k_w words are incorrectly identified to belong to the same/to different segments. For comparison, we present segmentation results on English data using TextTiling and STMs,

[1]The AFP Arabic Newswire Corpus is available from the Linguistic Data Consortium. The document identifiers of our concatenation of the training and test documents are available at `http://www.parc.com/istl/groups/qca/arabic-data/`

Table 2: Segmentation sentence error rate. Results marked with * are taken from (Li and Yamanishi, 2000a; Li and Yamanishi, 2000b).

Corpus	Algorithm	Terms	p_{err}^{kw}	p_{err}^{ks}
* Reuters-21578	TextTiling	stems	-	8.5 %
* Reuters-21578	STM	stems	-	9.2 %
AFP Arabic	TextTiling	fullform	8.09%	9.40%
AFP Arabic	TextTiling	n-grams	5.83%	7.49%
AFP Arabic	TopSeg	fullform	3.10%	3.88%
AFP Arabic	TopSeg	n-grams	3.05%	3.94%
AFP Arabic	TopSeg-C	fullform	**2.26%**	**2.91%**
AFP Arabic	TopSeg-C	n-grams	**2.30%**	**2.94%**

which were given in (Li and Yamanishi, 2000a; Li and Yamanishi, 2000b). They used a slightly different measure, i.e., the probability p_{err}^{ks} that two *sentences* at distance k_s sentences are incorrectly identified to belong to the same/to different segments. We therefore give both measures, p_{err}^{kw} and p_{err}^{ks}, for our results. k_w and k_s are set to be half the average length (in words and sentences, respectively) of a segment.

Table 2 presents the results on English and Arabic documents. We compare three different algorithms: TextTiling, our new algorithm using PLSA (TopSeg), and its variant using several PLSA models that are combined (TopSeg-C). Each of the three algorithms is run using full forms and using n-grams. For TextTiling, n-grams yield significantly better results than full forms (5.83% vs. 8.09% word based segmentation error rate). TopSeg yields almost identical results for n-grams and full forms. This may be explained by the property of PLSA to cluster semantically similar words, which is absent in the TextTiling algorithm. Results for using stems in Arabic are unknown yet, since no Arabic stemmer producing unique stems was available to us. In order to avoid variation that is due to different initializations of the PLSA models, we repeated each experiment using single models four times and report averaged results.

Combined models (using four different initializations) perform significantly better than single PLSA models. The word based error rates are 2.26% vs. 3.10% for full forms, and 2.30% vs. 3.05% for n-grams. Each experiment using four different random initializations is repeated four times, averaged results are reported.

Overall, TopSeg and TopSeg-C perform much better than TextTiling. The best result of 2.26% is a 61% reduction in error rate compared to TextTiling using n-grams.

Error rates for TopSeg using full forms and TopSeg using n-grams are almost identical. However, processing fullforms is much faster because the vocabulary generated from the training set only contains 38,358 different full forms, while it contains 133,362 different n-grams with $f > 1$. Computation times on a 1.7 GHz Pentium-III running Linux are as follows. For full forms, training one PLSA model with 256 classes and 20 EM iterations takes approx. 2 minutes, performing segmentation on the Arabic test set with 500 documents takes approx. 13 minutes. For n-grams, training takes approx. 9 minutes, segmentation approx. 52 minutes.

5. Conclusion

Ideally, Arabic document topic analysis would be based on a uniquely identified stem for each word, on a training collection with long documents with manually assigned segment boundaries, on manually assigned topic labels, and on manually assigned keywords word the document and its segment. Until such resorces are available, we use unlabeled documents and either full-forms or character n-grams instead. We applied our segmentation system TopSeg to Arabic newswire texts, yielding a 61% error reduction compared to TextTiling, a state-of-the-art approach for English. Our best system, using a combination of PLSA models with different random initializations, achieved an error rate of 2.26%. The system achieved approximately the same error rate when using full forms and when using n-grams as terms.

Abstract

The Cross-language information retrieval track at the 2001 Text Retrieval Conference (TREC-2001) produced the first large information retrieval test collection for Arabic. The collection contains 383,872 Arabic news stories, 25 topic descriptions in Arabic, English and French from which queries can be formed, and manual (ground truth) relevance judgments for a useful subset of the topic-document combinations. This paper describes the way in which the collection was created, explains the evaluation measures that the collection is designed to support, and provides an overview of the results from the first set of experiments with the collection. The results make it possible to draw some inferences regarding the utility of the collection for *post hoc* evaluations.

1. Introduction

For the Tenth Text Retrieval Conference (TREC-2001), the U.S. National Institute of Standards and Technology (NIST) developed the first large Arabic information retrieval test collection. This was the eighth year in which non-English document retrieval was evaluated at TREC, and the fifth year in which cross-language retrieval has been the principal focus of that work. Prior TREC evaluations have explored retrieval from Spanish, Chinese, French, German, and Italian document collections. Retrieval from European-language collections is now evaluated in the Cross-Language Evaluation Forum (CLEF) (Peters, 2001), and retrieval from Asian languages is now evaluated at the NTCIR Evaluation (Kando, 2001).

Information retrieval test collections at TREC are designed to model the automatic portion of an interactive search process. They consist of a set of documents to be searched, a set of topics for which relevant documents are to be found, and a set of judgments that identify the documents known to be relevant. In the TREC-2001 Cross-Language Information Retrieval (CLIR) task, the goal of each team was to use English, French, or Arabic queries to rank the set of Arabic documents in order of decreasing likelihood of relevance to the query. In this paper, we describe how the three components of the test collection were created, describe some characteristics of the collection that were observed in TREC-2001 experiments by ten research teams, and and give an overview of the retrieval techniques that those teams explored. The paper concludes with some brief remarks about plans for future development of this test collection.

2. Test Collection

As in past TREC CLIR evaluations, the principal task was to match topics in one language (English or French, in this case) with documents in another language (Arabic) and return a ranked list of the top 1,000 documents associated with each topic. Participating teams were allowed to submit as many as five runs, with at least one using only the title and description field of the topic description. Evaluation then proceeded by pooling the highly-ranked documents from multiple runs and manual examination of the pools by human judges to decide binary (yes/no) relevance for each document in the pool with respect to each topic. A suite of statistics were then calculated, with the mean (over 25 topics) uninterpolated average precision being the most commonly reported.[1]

2.1. Topics

Twenty-five topic descriptions (numbered AR1-AR25) were created in English in a collaborative process between the Linguistic Data Consortium (LDC) and NIST. An example of one of the topic descriptions used in the evaluation is:

<top>
<num> Number: AR22
<title> Local newspapers and the new press law in Jordan
<desc> Description:
Has the Jordanian government closed down any local newspapers due to the new press law?

[1]Uninterpolated average precision is the mean over the ranks of the relevant documents for a topic of the density of relevant documents at or above that rank.

<narr> Narrative:
Any articles about the press law in Jordan and its effect on the local
newspapers and the reaction of the public and journalists toward the new
press law are relevant. The articles that deal with the personal suffering
of the journalists are irrelevant.
</top>

Through the efforts of Edouard Geoffrois of the French Ministry of Defense, the English topics were translated into French and made available to participants which wished to test French to Arabic retrieval. The French version of the topic shown above is:

<top>
<num> Number: AR22
<title> Les journaux locaux et la nouvelle loi sur la presse en Jordanie
<desc> Description:
Le gouvernement jordanien a-t-il interdit un journal local à cause de la nouvelle loi sur la presse?
<narr> Narrative:
Tout article concernant la loi sur la presse en Jordanie et ses effets sur les journaux locaux ainsi que la réaction du public et des journalistes à la nouvelle loi sur la presse est pertinent. Les articles traitant des souffrances personnelles des journalistes ne sont pas pertinents. </top>

The LDC also prepared an Arabic translation of the topics, so participating teams also had the option of doing monolingual (Arabic-Arabic) retrieval. Participating research teams were responsible for forming queries from the topic descriptions using either automatic or manual techniques. Any technique that did not involve human intervention in the formulation of specific queries was classified as automatic. The most common automatic technique was to use all of the words in some set of fields, often the title and description fields. Manual runs were those cases in which people formed queries by hand. All are available on the TREC Web site at http://trec.nist.gov/data.

2.2. Documents

The document collection used in the TREC-2001 CLIR track consisted of 383,872 newswire stories that appeared on the Agence France Press (AFP) Arabic Newswire between 1994 and 2000. The documents were represented in Unicode and encoded in UTF-8, resulting in a 896 MB collection. A typical document is shown in Figure 1. The document collection is distributed by the LDC as Catalog Number LDC2001T55 using one of three arrangements:

- Organizations with membership in the Linguistic Data Consortium (for 2001) may order the collection at no additional charge.[2]

Figure 1: An Arabic document from the collection.

- Non-members may purchase rights (that do not expire) to use the collection for research purposes for $800.
- The Linguistic Data Consortium may be able to negotiate a license at no cost for research groups that are unable to pay the $800 fee, but in such cases the scope and term of the license would be limited to a specific research project.

3. Relevance Judgments

The ten participating research teams shown in Table 1 together produced 24 automatic cross-language runs with English queries, 3 automatic cross-language runs with French queries, 19 automatic monolingual runs with Arabic queries, and 2 manual runs (one with English queries and one with Arabic queries). From these, 3 runs were selected from each team in a preference order recommended by the participants for use in forming assessment pools. The resulting pools were formed from 15 cross-language runs with English queries (14 automatic and 1 manual), and 15 monolingual runs with Arabic queries (14 automatic and 1 manual). The top-ranked 70 documents for a topic in each of the 30 ranked lists were added to the judgment pool for that topic, duplicates were removed, and the documents then sorted in a canonical order designed to prevent the human judge from inferring the rank assigned to a document by any system. Each document in the pool was then judged for topical relevance, usually by the person that had originally written the topic statement. The mean number of relevant documents that were found for a topic was 165. The relevance judgments are available on the TREC Web site at http://trec.nist.gov/data.

Most documents remain unjudged when pooled relevance assessments are used, and the usual procedure is to treat unjudged documents as if they are not relevant. Voorhees has shown that the preference order between automatic runs in the TREC ad hoc retrieval task would rarely be reversed by the addition of missing judgments, and that the relative reduction in mean uninterpolated average precision that would result from removing "uniques" (relevant documents found by only a single system) from the judgment pools was typically less than 5% (Voorhees, 1998). As Figure 2 shows, this effect is substantially larger in the TREC-2001 Arabic collection, with 9 of the 28 judged automatic runs experiencing a relative reduction in mean uninterpolated average precision of over 10% relative when

[2]Information about joining the LDC is available at http://www.ldc.upenn.edu/

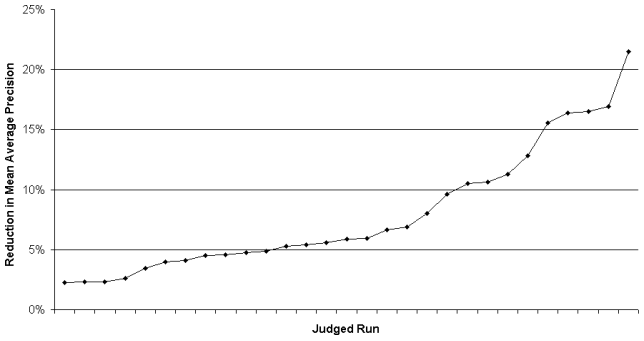

Figure 2: Effect on 29 judged runs of removing "uniques" contributed by that run.

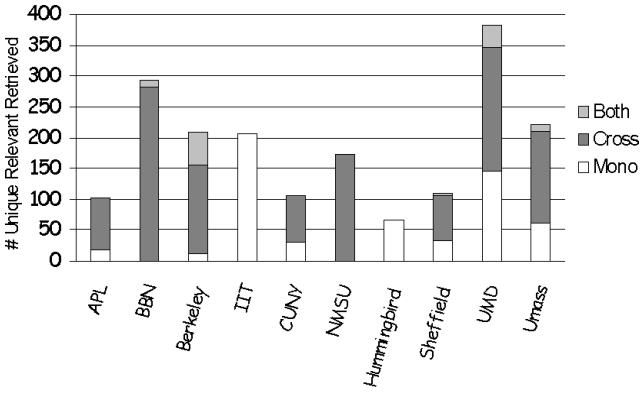

Figure 3: Unique relevant documents, by research team.

the "uniques" contributed by that run were removed from the judgment pool.

Figure 3 helps to explain this unexpected condition, illustrating that many relevant documents were found by only a single participating research team. For 7 of the 25 topics, more than half of the known relevant documents were ranked in the top-70 in runs submitted by only a single research team. For another 6 of the 25 topics, between 40 and 50 percent of their relevant documents were ranked in the top-70 by only one team.

These results show a substantial contribution to the relevance pool from each site, with far less overlap than has been typical in previous TREC evaluations. This limited degree of overlap could result from the following factors:

- A preponderance of fairly broad topics for which many relevant documents might be found in the collection. The average of 165 relevant documents per topic is somewhat greater than the value typically seen at TREC (100 or so).
- The limitation of the depth of the relevance judgment pools to 70 documents (100 documents per run have typically been judged in prior TREC evaluations).
- The diversity of techniques tried by the participating teams in this first year of Arabic retrieval experiments at TREC, which could produce richer relevance pools.
- A relatively small number of participating research teams, which could interact with the diversity of the techniques to make it less likely that another team would have tried a technique that would find a similar set of documents.

Team	Arabic Terms Indexed			
	Word	Stem	Root	n-gram

UC Berkeley	A,E	X	X		
U Maryland	A,E	X			X
U Mass	A,E	X	X		
U Sheffield	A,E,F	X			

Table 2: Translation resources used by participating teams.

The first two factors have occasionally been seen in information retrieval evaluations based on pooled assessment methodologies (TREC, CLEF, and NTCIR) without the high "uniques" effect observed on this collection. We therefore suspect that the dominant factors in this case may be the last two. But until this cause of the high "uniques" effect is determined, relative differences of less than 15% or so in unjudged and post hoc runs using this collection should be regarded as suggestive rather than conclusive. There is, of course, no similar concern for comparisons among judged runs since judgments for their "uniques" are available.

As has been seen in prior evaluations in other languages, manual and monolingual runs provided a disproportionate fraction of the known relevant documents. For example, 33% of the relevant documents that were found by only one team were found only by monolingual runs, while 63% were found only by cross-language runs.

4. Results

Tables 1 and 2 summarize the alternative indexing terms, the query languages, and (for cross-language runs) the sources of translation knowledge that were explored by the ten participating teams. Complete details of each

team's runs can be found in the TREC-2001 proceedings (Voorhees and Harman, 2001), so in this paper we provide only a brief summary of the approaches that were tried. All ten participating teams adopted a "bag-of-terms" technique based on indexing statistics about the occurrence of terms in each document. A wide variety of specific techniques were used, including language models, hidden Markov models, vector space models, inference networks, and the PIRCS connectionist network. Four basic types of indexing terms were explored, sometimes separately and sometimes in combination:

Words. Indexing word surface forms found by tokenizing at white space and punctuation requires no language-specific processing (except, perhaps, for stopword removal), but potentially desirable matches between morphological variants of the same word (e.g., plural and singular forms) are precluded. As a result, word indexing yielded suboptimal retrieval effectiveness (by the mean uninterpolated average precision measure). Many participating research teams reported results for word-only indexing, making that condition useful as a baseline.

Stems. In contrast to English, where stems are normally obtained from the surface form of words by automatically removing common suffixes, both prefixes and suffixes are normally removed to obtain Arabic stems. Participating teams experimented with stemming software developed at three participating sites (IIT, NMSU, and U Maryland) and from two other sources (Tim Buckwalter and Shereen Khoja).

Roots. Arabic stems can be generated from a relatively small set of root forms by expanding the root using standard patterns, some of which involve introduction of infixes. Stems generated from the same root typically have related meanings, so indexing roots might improve recall (possibly at the expense of precision, though). Although humans are typically able to reliably identify the root form of an Arabic word by exploiting context to choose between alternatives that would be ambiguous in isolation, automatic analysis is a challenging task. Two participating teams reported results based on automatically determined roots.

Character n-grams. As with other languages, overlapping character n-grams offer a useful alternative to techniques based on language-specific stemming or morphological analysis. Three teams explored n-grams, with values of n ranging from 3–6.

Term formation was typically augmented by one or more of the following additional processing steps:

Character deletion. Some Unicode characters, particularly diacritic marks, are optional in Arabic writing. This is typically accommodated by removing the characters when they are present, since their presence in the query but not the document (or vice-versa) might prevent a desired match.

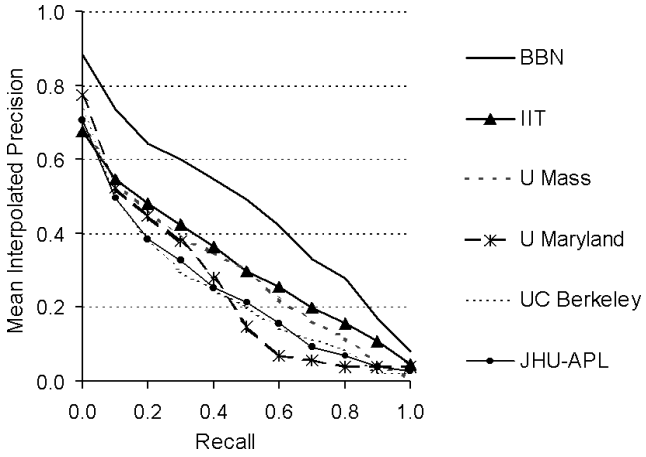

Figure 4: Cross-language retrieval effectiveness, English queries formed from title+description fields, automatic runs.

Character normalization. Some Arabic letters have more than one Unicode representation because their written form varies according to morphological and morphotactic rules, and in some cases authors can use two characters interchangeably. These issues are typically accommodated by mapping the alternatives to a single normalized form.

Stop-term removal. Extremely frequent terms and other terms that system developers judge to be of little use for retrieval are often removed in order to reduce the size of the index. Stop-term removal is most commonly done after stemming or morphological analysis in Arabic because the highly productive morphology would otherwise result in impractically large stopword lists.

Nine of the ten participating research teams submitted cross-language retrieval runs, with all nine using a query-translation architecture. Both of the teams that tried French queries used English as a pivot language for French-to-Arabic query translation, so English-to-Arabic resources were key components in every case. Each team explored some combination of the following four types of translation resources:

Machine Translation Systems. Two machine translation systems were used: (1) a system developed by Sakhr (available at http://tarjim.ajeeb.com, and often referred to simply as "Ajeeb" or "Tarjim"), a system produced by ATA Software Technology Limited (available at http://almisbar.com, and sometimes referred to as "Almisbar" or by the prior name "Al-Mutarjim"). At the time of the experiments, both offered only English-to-Arabic translation. Some teams used a machine translation system to directly perform query translation, others used translations obtained from one or both of these systems as one source of evidence from which a translated query was constructed. A mark in the "MT" column of Table 2 indicates that one or more existing machine translation systems were used in some way, not that they were necessarily used

to directly perform query translation.

Translation Lexicons. Three commercial machine readable bilingual dictionaries were used: one marketed by Sakhr (also sometimes referred to as "Ajeeb"), one marketed by Ectaco Inc., (typically referred to as "Ectaco"), and one marketed by Dar El Ilm Lilmalayin (typically referred to as "Al Mawrid"). In addition, one team (NMSU) used a locally produced translation lexicon.

Parallel Corpora. One team (BBN) obtained a collection of documents from the United Nations that included translation-equivalent document pairs in English and Arabic. Word-level alignments were created using statistical techniques and then used as a basis for determining frequently observed translation pairs.

Transliteration. One team (Maryland) used pronunciation-based transliteration to produce plausible Arabic representations for English terms that could not otherwise be translated.

When multiple alternative translations were known for a term, a number of techniques were used to guide the combination of evidence, including: (1) translation probabilities obtained from parallel corpora, (2) relative term frequency for each alternative in the collection being searched, and (3) structured queries. Pre-translation and/or post-translation query expansion using blind relevance feedback techniques and pretranslation stop-term removal were also explored by several teams.

To facilitate cross-site comparison, teams submitting automatic cross-language runs were asked to submit at least one run in which the query was based solely on the title and description fields of the topic descriptions. Figure 4 shows the best recall-precision curve for this condition by team. All of the top-performing cross-language runs used English queries.

As is common in information retrieval evaluations, substantial variation was observed in retrieval effectiveness on a topic-by-topic basis. Figure 5 illustrates this phenomenon over the full set of cross-language runs (i.e., not limited to title+description queries). For example, half of the runs did poorly on topic AR12, which included specialized medical terminology, but at least one run achieved a perfect score on that topic. Five topics, by contrast, turned out to be problematic for all systems (AR5, AR6, AR8, AR15, and AR23). Examining retrieval effectiveness on such topics may help researchers identify opportunities to improve system performance.

No standard condition was required for monolingual runs, so Figure 6 shows the best monolingual run by team regardless of the experiment conditions. Several teams observed surprisingly small differences between monolingual and cross-language retrieval effectiveness. One site (JHU-APL) submitted runs under similar conditions for all three topic languages, and Figure 7 shows the resulting recall-precision graphs by topic language. In that case, there is practically no difference between English-topic and Arabic-topic results. There are two possible explanations for this widely observed effect:

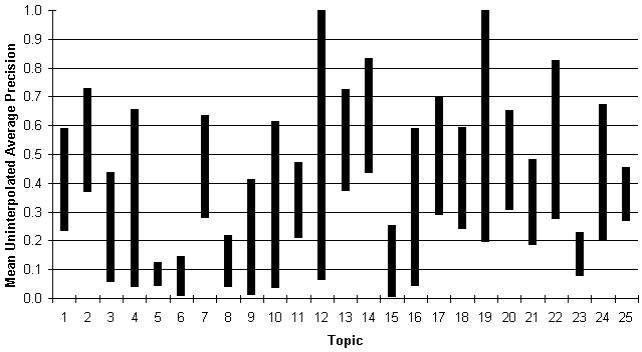

Figure 5: Cross-language topic difficulty, uninterpolated average precision (base of each bar: median over 28 runs, top of each bar: best of the 28 runs).

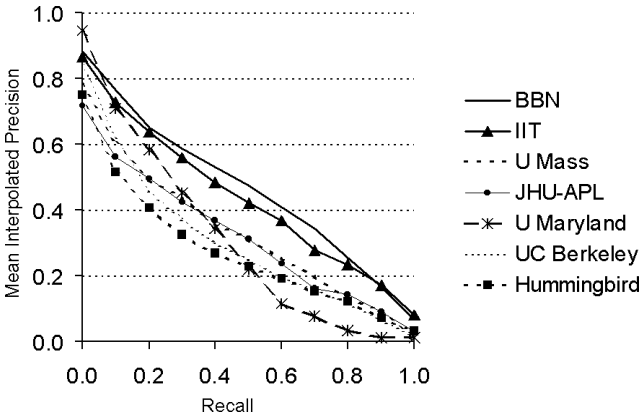

Figure 6: Monolingual retrieval effectiveness, Arabic queries formed from title+description fields (except JHU-APL and UC Berkeley, which also used the narrative field), automatic runs (except U Maryland, which was a manual run designed to enhance the relevance assessment pools).

- No large Arabic information retrieval test collection was widely available before this evaluation, so the monolingual Arabic baseline systems created by participating teams might be improved substantially in subsequent years.
- The 25 topics used in this year's evaluation might represent a biased sample of the potential topic space. For example, relatively few topic descriptions this year included names of persons.

Several teams also observed that longer queries did not yield the improvements in retrieval effectiveness that would normally be expected. One site (Hummingbird) submitted runs under similar conditions for three topic lengths, and Figure 8 shows the resulting recall-precision graphs. In this case, longer queries showed no discernible benefit; indeed, it appears that the best results were achieved using the shortest queries! The reasons for this effect are not yet clear, but one possibility is that the way in which the topic descriptions were created may have resulted in a greater concentration of useful search terms in the title field. For example, the title fields contains an average of about 6 words, which is about twice as long as is typical for TREC.

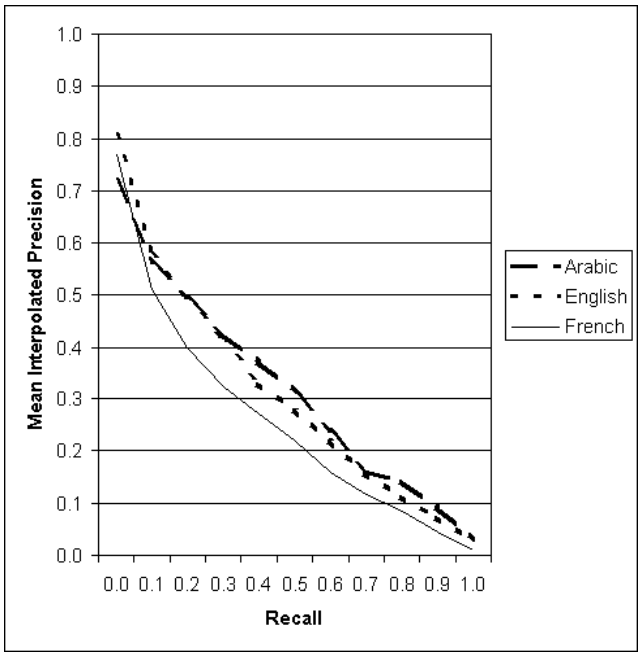

Figure 7: Topic language effect, title+description+ narrative.

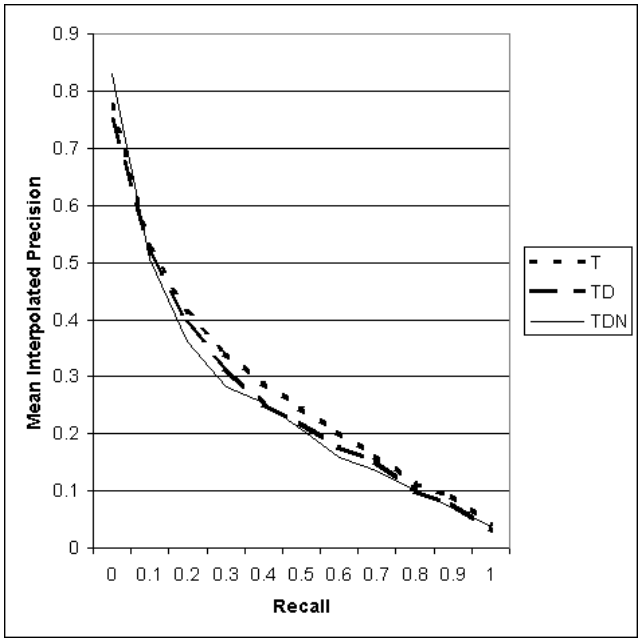

Figure 8: Query length effect, Arabic queries. (T=title, D=Description, N=Narrative).

5. Summary and Outlook

The TREC-2001 CLIR track focused on searching Arabic documents using English, French or Arabic queries. In addition to the specific results reported by each research team, the evaluation produced the first large Arabic information retrieval test collection. A wide range of index terms were tried, some useful language-specific processing techniques were demonstrated, and many potentially useful translation resources were identified. In this paper we have provided an overview of that work in a way that will help readers recognize similarities and differences in the approaches taken by the participating teams. We have also sought to explore the utility of the test collection itself, providing aggregate information about topic difficulty that individual teams may find useful when interpreting their results, identifying a potential concern regarding the completeness of the pools of documents that were judged for relevance, and illustrating a surprising insensitivity of retrieval effectiveness to query length.

The TREC-2002 CLIR track will continue to focus on searching Arabic. We plan to use 50 new topics (in the same languages) and to ask participating teams to also rerun the 25 topics from this year with their improved systems as a way of further enriching the existing pools of documents that have been judged for relevance. We expect that the result with be a test collection with enduring value for post hoc experiments, and a community of researchers that possess the knowledge and resources needed to address this important challenge.

Acknowledgments

We are grateful to Ellen Voorhees for coordinating this track at NIST and for her extensive assistance with our analysis and to the participating research teams for their advice and insights along the way.

Logical Aspects of Unification Based-Arabic Semantic Construction

Abstract

This paper addresses issues related to employing logic-based semantic construction as meaning representation formalism for Arabic. Since semantic formalism has to be compositional on the level of semantic representation, λ-conversion based on the Discourse Representation Theory can be utilized for realization of semantic construction for Arabic.

Keywords: Logical Form, Arabic Semantic Representation, λ-DRT, Unification-Based Semantics, HDPSG

1. Introduction

For the last two decades concentration on Arabic processing has focused on Arabic from the *morphological* and *syntactical* points of view. In this field, significant progress has been reported (Beesely 2001; Ouersighni 2001; Ditters 2001; Al-Fedaghi and Al-Anzi 1989) and many others.

Despite the importance of *semantic processing* for achieving the *understanding capability*, there was little work reported on *semantic representation* and *semantic analysis* of Arabic (Haddad and Yaseen, 2001; Khayat 1988; Al-Johar and McGregor 1997; El-Dessouki et al. 1988, Al-Muhtaseb and Mellish, 1997) and others. Therefore, we believe that there is an ultimate need to make more effort to develop an *adequate model* for *semantic processing* for Arabic, even though there is no existing *formal theory* capable to provide a complete and consistent account of all phenomena involved in Arabic semantic processing.

Semantic processing has to carry out different tasks on different levels to achieve the *understanding facility*. One of the most important of these levels is the *construction* and *composition* of *meaning representation formalisms* for Arabic sentences. This semantic level plays a decisive role for other semantic processing steps, i.e. *semantic resolution* and *evaluation.*

Lexical and *unification*, especially HDPSG related system development is ongoing in numerous university and industrial settings for different languages. HDPSG is based on GPSG, LFG and Categorial Grammar. In such a grammar the *lexicon* plays a pivotal role, where *semantics* and *syntax* can be integrated in the same grammar. A central concept of a *unification-based grammar* is the notion *"feature"* or *"attribute"* which is characterized *by feature value pairs.*

Applying the operation of *unification* to *two compatible feature values structures* yields a new *feature value structure* containing *all the information* involved in the two original feature structures. The importance of the concept might be residing in the fact that we can solve the problem of finding the right level of *granularity* in classifying words into categories having *internal structures*. Furthermore, the *unification* allows us to combine information from *multiple feature structures*, as long as it is consistent (Pollard and Sag 1994; Bender et al. 1999).

Simulating the *λ-conversion process* in a *feature logical formalism* within a *unification-based grammar* such as HDPSG enables a realization of *unification based semantic construction formalism for Arabic.*

Inspired by the work of (Bos et al. 1994) we propose in this paper to integrate the semantic construction model presented in (Haddad and Yaseen, 2001) in a *unification-based semantic Grammar.*

2. Logical Semantic Representation

Assuring the *modularity constraint* in a natural language understanding system requires a *compositional semantic formalism* on the level of meaning representation. Despite the fact that *predicate logic represents* well-studied formal representation formalism, it does not provide any *compositional facilities. λ-abstraction* offers an important framework for achieving such a goal in particular for the meaning construction of Arabic sentences (Haddad and Yaseen 2001; Pinkal 1995; Montague 1974).

In this context we have achieved some success in developing a model for *construction of meaning rep-*

resentation forms for Arabic sentences. Based on some *compositional rules* expressing the meaning of *syntactical categories of Arabic*, our approach employs a *λ-conversion process* to construct *logical forms representing the meaning of Arabic sentences* (Haddad and Yaseen, 2001).

In this model *determiners* play a central role in constructing *semantic constituents*. For example, the Arabic determiners such as "ال$_n$", "كل", "بعض", etc., could be considered as *quantifiers*. Generally the meaning of a quantifier, ||Quant||, can be expressed as follows:

$$||\text{Quant}|| \Rightarrow \lambda R \lambda S(Quantifier(R,S) \quad (1)$$

The definite determiner "ال$_1$" combines in general two things together: a *restriction R and a scope S:*

$$||\text{ال}_1|| \Rightarrow \lambda R \lambda S(\text{ال}_1\ (x, R \wedge S)) \quad (2)$$

The following example in *"figure 1, three-branch quantifier tree representation"* might illustrate the basic concept of this approach. Details about this concept are found in [Haddad and Yaseen, 2001].

The *function* of the determiner "ال$_1$" in the sentence "يتعلم الولد العربيه" can be formulated as follows:

$$||\text{VS}|| \xrightarrow{sem} ||\text{Subj}||\ (||\text{Obj}||\ (||\text{Verb}||)) \quad (3)$$

Applying of (3) to ||ال$_1$|| yields the following logical representation:

$$\lambda R \lambda S(\text{ال}_1\ (x, R \wedge S))\ (||\text{ولد}||)\ (||\text{يتعلم ال عربية}||) \quad (4)$$

$$\lambda S(\text{ال}_1\ (x, \text{ولد}(x) \wedge S))\ (||\text{يتعلم ال عربية}||) \quad (5)$$

$$\text{ال}_1\ (x, \text{ولد}(x) \wedge \text{ال}_1\ (y, \text{عربية}(y) \wedge \text{يتعلم}\ (x, y))) \quad (6)$$

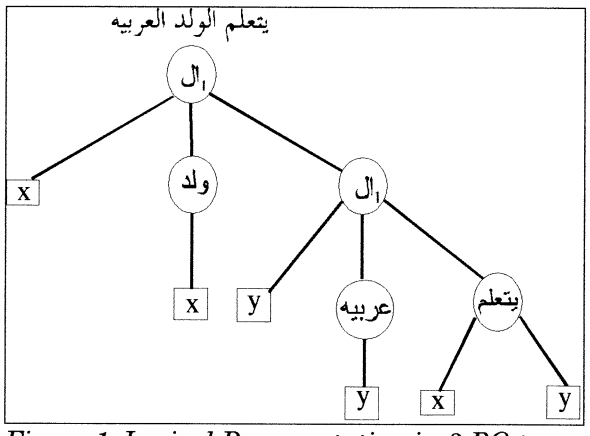

Figure 1: Logical Representation in 3-BQ tree

3. DRT-Based Compositional Aspects for Arabic

Despite the importance of logic-based *compositional models* for achieving Arabic understanding, such methods are rather constructed to deal with Arabic *sentence semantics* and in general they are *inappropriate* for treating *text semantics*.

The *Discourse Representation Theory (DRT)* is capable of capturing problems involved in representing *anaphoric aspects* and *text semantics* (Kamp, 1981; Bende-Farkas and Kamp, 2001).

In this approach the semantic function of sentences consists in constructing of *Discourse Representation Structures (DRS)* by applying certain *DRS construction rules dynamically* within the context of the *referents* in a text.

For instance, the function of a *definite article* seems in the view of *DRT*, not in interpreting it as a *unique quantifier*. It has rather to be understood as a *referent to a certain object in a nominal expression.* Moreover, the interpretation of the *indefinite article* appears *in the first place* not to be as an *existential quantifier. An indefinite article introduces* rather a *new referent to the context.*

In addition, one of the most important aspects of *DRT* is its interesting interpretation of *pronouns*. The interpretation of *a pronoun* is not *a variable,* which has to be *locally bound,* but much more as a *definite label* with the function of *making a reference to a previously introduced discourse referent*. Therefore, *a DRT-based semantic construction of Arabic* has to be in the first place not in constructing the logical meaning in an *isolated mode* but much more in a *dynamic and modifiable one.*

Example:

تدرس ماريا لغه تحبها

(Maria studies a language she likes)

The interpretation of this *discourse* starts with an empty *DRS*. After interpretation of the first part of the sentence "تدرس ماريا لغة" (Maria studies a language), the *DRS* is expanded by adding the next *referents* and *conditions*. The referent *e* represents an *event of studying* "تدرس". The *referent n* is used to denote the *time of speech* (see the following figures):

x y e n
"ماريا" *(x)*
لغة*(y)*
e: تدرس*(x,y)*
$n \subseteq e$
DRS for تدرس ماريا لغة

y e n z w s
"تدرس" *(x)*
لغة*(y)*
e: تدرس*(x,y)*
n ⊆ e
s: تحب*(z,w)*
$n \subseteq s$
$z = x$
$w = y$
DRS for تدرس ماريا لغة تحبها

In the final stage of representation the resulting *Discourse Representation Structures* are interpreted in *model theory* based logical forms.

It is obvious that *DRT-based semantic construction* proceeds from another point of view than the *Montague-style* in the construction process and it is therefore *not compositional*. Furthermore, the semantic construction is given in *top-down manner* and is *not declarative*, that means the processing order effects the binding possibilities (Pinkal, 1995).

3.1 Compositional Semantics for ARABIC

The Integration of *lambda conversion* in *DRT* extends *DRT* to be *compositional* without losing the important feature of representing *text anaphoric*. In this approach the semantic function of sentences consists in constructing of *Discourse Representation Structures* by applying some *DRS construction rules* within the context of the *referents* in a text. The DRS_n, for instance, consists of a pair: *a universe of discourse*, DR_n, i.e. *a set of Discourse Referents and a set of conditions*, $COND_n$, *about the* DR_n. An additional feature of the language of *λ-DRT, we adopted the merge operation* ⊗, which combines *two DRS's* by taking the *union* of the sets of discourses and conditions separately (Bos et al., 1994):

$$\langle DR_1, COND_1 \rangle \otimes \langle DR_2, COND_2 \rangle \equiv \langle DR_1 \cup DR_2, COND_1 \cup COND_2 \rangle \quad (7)$$

For example the meaning representation for constructing the *DRS* for sentence "كل طالب يجتهد" could be represented in terms of *λ-DRT as follows (see also (1)):*

$$||\text{كل}|| \Rightarrow \lambda R \lambda S \langle \{x\}, \{ x: Any \} \rangle \otimes R(x) \xrightarrow{\text{كل}} S(x) \quad (8)$$

$$||\text{طالب}|| \Rightarrow \lambda y \langle \{\}, \{y: Individual, \text{طالب}(y)\} \rangle \quad (9)$$

$$||\text{يجتهد}|| \Rightarrow \lambda z \langle \{\}, \{e: Event, z: Individual, \text{يجتهد}(e, z_{<agent>})\} \quad (10)$$

The *DRS* in (10) means, that there is an *event* "يجتهد" which takes an *individual* as an *argument* and plays the role of an *agent*.

Simulating the basic aspects of the *λ-conversion process* presented in [Haddad and Yaseen, 2001] and applying it to the *DRS's* established above would lead in a simplified form to the following semantic representation:

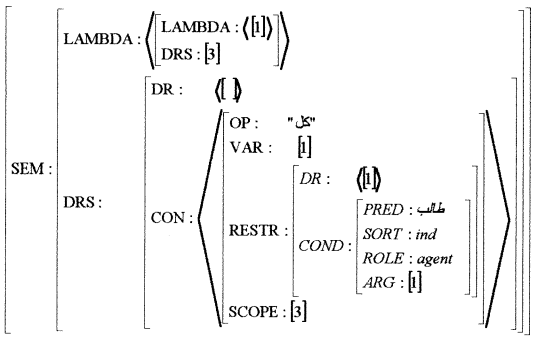
$$\langle \{x\}, \{x: Individual, \text{طالب}(x_{<agent>})\} \rangle \xrightarrow{\text{كل}} \langle \{\}, \{e: Event, \text{يجتهد}(e, x_{<agent>})\} \quad (11)$$

3.2 Unification-based Semantic Construction for Arabic

A *λ-Expression* representing the meaning of an *Arabic constituent* (Haddad and Yaseen, 2001) could be formulated in terms of *feature structures*. Such structures might be represented by a LAMBDA and a DRS *feature structure*. A LAMBDA *feature structure* specifies a *list* of the appropriate *arguments, which are* involved in the expression, while *a DRS feature structure represents the body of the λ-expression.* Furthermore, additional *pragmatic notations* could be *also embedded in the DRS feature structures.* Compositional rules expressing the meaning of syntactical constituents are also integrated in the *lexical entries* of a *DRS*.

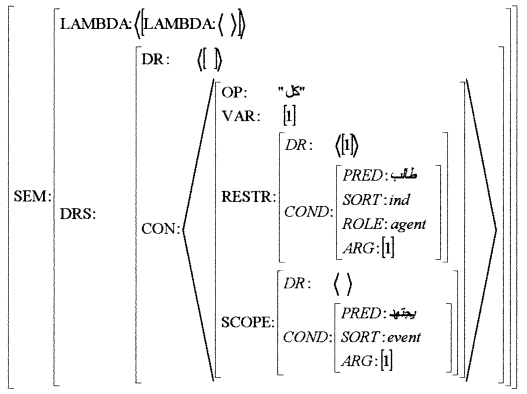
A *unification-based semantic construction* can be achieved by *unifying* the values of a *LAMBDA feature structure* with *the representations of the feature structures involved in the arguments*. And then storing the results of the unification in the *DRS feature structure of processed syntactical constituent*. This process corresponds to *λ-conversion proposed in* (Bos et al. 1994).

Constructing the meaning of "كل طالب" in the sentence "كل طالب يجتهد" requires the application of the *feature structures* involved in (8) to the *feature structures* in (9) (see also "figure 1" and (3), (4), (5), (6)):



(12)

To construct the meaning of the whole sentence "كل طالب يجتهد" , "DRS: [3]" has to be applied to the composed DRS in (12):



(13)

It is obvious that (13) corresponds to the logical form in (11).

4. Conclusion

Semantic processing is a non-trivial topic in natural language understanding. We believe that the progress that has been made in recent years is also *applicable to Arabic. Semantic construction* is a substantial task in achieving the basic steps of Arabic understanding. Problems involved in treating *text anaphoric* can be treated *dynamically* by simulating *λ-conversion presented in (Haddad and Yaseen, 2001) within an adapted DRS for Arabic.*

Additionally, this paper is an attempt to direct the attention of research concerned with Arabic processing, in particular to the techniques concerned with *DRT-based and unification-based semantic processing.* At present, our research is concerned with developing such a model by adopting these additional features.

¶Dept. of Computer Engg abandah@ju.edu.jo
University of Jordan, Amman – Jordan

Abstract

Arabic character recognition of handwriting is addressed. A novel approach for the Arabic Character Recognition is presented based on statistical analysis of a typical Arabic text is presented. Results showed that the sub-word in Arabic language is the basic pictorial block rather than the word. The method of approximate stroke sequence is applied for the recognition of some Arabic characters in their stand-alone form. This method could be extended further for more accurate results. It is recommended that research in Arabic OCR systems in the future is based on the basis of the sub-word as the basic block rather than the word.

1. Introduction

Automatic recognition of handwriting has become a mature discipline at the beginning of the 21st century. On-line systems are now available on handheld computers with acceptable performance. Off-line systems are less accurate than on-line systems. However, they are now good enough for specialized systems such as interpreting handwritten postal addresses on envelopes and reading currency amounts on bank checks (Plamondon 2000).

The recognition of Arabic characters is particularly difficult due to the necessity of segmentation even for printed text. In order to get an insight into the Arabic word structure, it becomes necessary to do some statistical analysis on some typical Arabic text in order to assess the nature of problems facing the workers on Arabic OCR systems. For this purpose, a reasonable size of Arabic text was selected and analyzed. Based on the results of this analysis, a new procedure is suggested for building Arabic OCR systems. As a first step in the implementation of such systems, recognition of Arabic characters in their stand-alone form is addressed. The method of approximate stroke sequence matching is applied and the results are shown.

The paper gives some literature survey on previous work done in the field. It then gives the main characteristics of Arabic writing, presenting the importance of the sub-word structure of the Arabic word, showing the statistical results proving this phenomena, and proposing a new procedure for Arabic OCR system. The newly proposed method suggests the treatment of the sub-word as the basic block in the recognition of Arabic characters. The size of the sub-word should be treated as a decisive factor in the method of recognition of the characters contained in the sub-word. The method of approximate stroke sequence matching is described and then applied to an example of unknown character and compared with two standard characters. A text containing different shapes of Arabic characters was written by 48 different persons and samples of these characters under test were copied for this study. Some results of applying this procedure onto different characters is given. The paper discusses the results obtained and ends up with some conclusions and suggestions for future work.

2. Previous Work in Arabic Character Recognition

Several good literature review papers were published for various research topics on Arabic character recognition (Jambi, 1991; Ahmed, 1994 and Amin, 1997). A recent comprehensive one is given by Ahmed in 2000. Here we shall give some elaboration on some of the effort spent in this direction.

Classical optical off-line recognition of handwriting is composed of a pre-processing stage, character segmentation, feature extraction and a classification stage (Casey 1996). Pre-processing consists of several operations like thresholding, noise removal, page orientation, skewing of lines removal, line segmentation, word segmentation, and pictures and figures removal. There is little difference in these processes between Arabic language and Latin-alphabet-based languages (Abdulla, 1988; Mahmoud, 1991; Hussain & Cowel, 2000; Hussain & Zalik, 2000).

Work on isolated printed Arabic characters and numerals took a lot of shapes. Overall vertical level of the character compared with the baseline was studied (Talba 1987). The chain code describing the sequence of character strokes using the 8-direction strokes was followed by the majority of researchers (Alshebeli, 1997). However, hexagonal sampled procedure was also found (Khellah, 1994). Different methods for matching the unknown character with the standard characters were followed.

Segmentation of characters is an important step in character recognition for cursive writing whether hand written or printed. There are three strategies for segmentation: the classical approach in which segments identification is based on “character-like” properties, the recognition-based segmentation strategy, in which the system searches the image for components that match classes in its alphabets, and the third strategy is the holistic method, in which the system seeks to recognise words as a whole, thus avoiding the need to segment into characters (Casey 1996) Different algorithms were followed to apply one of the above methods or the other, like hierarchical syntactic procedure (Haj-Hassan, 1990), quadratic discriminating functions (Udpa, 1992), the method of moment invariant algorithm (El-Khaly, 1990), accumulative invariant moment was used as an identifier

in character recognition (El-Dabi, 1990), and even segmentation of printed Arabic characters was tried without the thinning process (El-Sheikh, 1988). Use of clustering technique was chosen for classification (El-Desouky, 1992) or tree representation for the description of various characters (Al-Waily, 1989; Saleh, 1994 & Saleh, 1996). Use of tree representation and fuzzy constrained graph models which tolerate large varieties in writing styles were reported also (Abuharba, 1994).

Recognition of different fonts of Arabic printed text was tried using pre-processing and structural feature extraction (Kavianifar,1998). Parallel Arabic OCR systems were also proposed (Alherbish, 1997).

Hidden Markov models which proved to be very successful in the area of automatic speech recognition was tried in the area of omnifont, open-vocabulary Arabic OCR system (Bazzi, 1999).

Work on limited hand-written Arabic text database was tried. A system based on four types of basic features, namely the end points, corners, the strokes and the branch points gave reasonable results (Jambi, 1991).

Recognition of Typewritten Arabic characters gave good results using external features such as character area ratio, n-th quadrant ratio, vertical line ratio, horizontal line ratio, number of upper edges, and other similar features (Al-Ohali, 1995).

Online character recognition uses the feature extraction process results in a sequential manner which is called the chain code. Treatment of secondary characters (mainly the points above and below the characters) is definitely an integral part of the recognition process (El-Gwad, 1990).

Neural Network was used in some work (Said, 1998 , Al-Kadi, 1995, Altuwaijri, 1995 and Al-Sharaidah, 2000).

3. Main characteristics of Arabic Writing

Arabic text is written from right to left and is always cursive. The shape of an Arabic character changes according to its location in the word. An Arabic character has up to four different shapes; the shape of a character depends on the type of character to its right and its position within the word. Table 1 shows the Arabic character set in the four different shapes.

The Arabic character set is composed of 28 basic characters. Fifteen of them have dots and 13 are without dots. Dots above and below the characters play a major role in distincting some characters that differ only by the number or location of dots. Take the example the letters: ب ت ث ي ن . In their middle form, all these five letters are written the same way as: بـ تـ ثـ يـ نـ . They differ only by the number or the locations of the dots.

There are four characters which may take the secondary character "Hamzah ء". Those are "Alif أ إ ", "Waw ؤ" , "Yaa ئ" and "Kaf ك".

There are also some other secondary characters used above and below the characters to indicate vowels but we shall exclude them now from our discussions.

Arabic characters do not have fixed width or fixed size, even in printed form.

3.1 An important phenomena in Arabic writing

Arabic writing is known to be cursive even in printed form. However, it differs from cursive handwriting of English in that some characters can be connected from one side only. Out of the 28 basic Arabic characters, six can be
connected from the right side only while the other 22 can be connected from both sides. These six characters are:dal (د), raa (ر), waw (و), alef (ا), thal (ذ) , and zay (ز). These six characters have only two forms, the stand-alone form and the final form. Whereas the rest of the characters can appear in any of four forms: the initial, the middle, the final, and the stand-alone form. Consequently, an Arabic word may consist of one or more sub-words. A sub-word can be defined as the basic stand-alone pictorial block of the Arabic writing. Any optical character recognition of Arabic characters should treat the sub-word as the basic block for processing whatever the method it uses for preprocessing, segmentation, recognition, or classification.

This is because each sub-word is separated from other sub-word by a space. Although spaces between sub-words are usually shorter than those between successive words, still they are surrounded by space. A word may contain one or more sub-words. Some of these sub-words may even consist of a single character in its stand-alone form. Hence, their recognition does not need segmentation.

Shape of the letter in the text differs according to the location of the character in the sub-word, i.e. a character at the end of sub-word, has exactly the same shape when it comes at the end of a full word. Take the example of the

Letter	Stand-alone	Initial	Middle	Final	Other shapes
Alef	ا			ـا	ى ى
Ba'	ب	بـ	ـبـ	ـب

% characters			23.4%	27.8%	21%	27.8%

Table 2: Sub-words and Shapes Statistics

word رجال . It consists of 3 sub-words, containing 1, 2, and 1 character respectively.

3.2 Test Sample and Results

In order to give a fair idea about sub-words, a sample of Arabic text consisting of about 1.4MB was collected. It was randomly selected from old books, modern books, newspapers, and other available sources on the web. Statistics presented here about this sample text may give an idea about the structure of Arabic words in terms of sub-words and the four character shapes. Table 2 shows the analysis for this sample.

The sample consists of 262,647 words with 1,126,420 characters. This means that the average word length is 4.3 characters per word. The number of sub-words is 574,383. This means that on the average there is 2.2 sub-word per word. The number of sub-words consisting of one character is 263,065 which makes about 45.8% of the total number of sub-words (and 23.4% of the total number of characters). This means that, in the process of optical character recognition, slightly less than one half of the sub-words need no segmentation at all (whether printed or handwritten). The number of sub-words that consist of two characters is 159,995 which makes 27.9% of the total number of sub-words. This means that about 30% of the total number of sub-words need segmentation into two characters only. The table also shows that on the average the four different shapes of characters are almost equal with the middle form slightly less (23.4% stand-alone, 27.8% for each of the initial form and the final form, as the number should be equal, and 21% for the middle form).

3.3 Proposal for a New Procedure for Recognition of Arabic Characters

According to the above discussion, the approach suggested here is to separate the text into three groups:

1. Sub-words consisting of one character that is in the stand-alone form. This is to be recognised directly without any segmentation.
2. Sub-words consisting of two characters. The first one is in the initial form and the second one is in the final form. This needs segmentation in two parts only. If there is a pre-knowledge of the number of characters to be segmented in the sub-word, then the task becomes easier.
3. Sub-words consisting of more than two characters. The first one is in the initial form, the last one in the final form, and the rest are in the middle form.

Figure 1 shows the flow diagram for this procedure.

4. Approximate Stroke Sequence String Matching

Given two character images, there is no universally accepted definition for similarities or differences between them. If the two images are converted into a one-dimensional string, then the task will be easier to define. Distance between two histograms of angular measurements was the subject of some literatures (Cha 2000).

The stroke sequence is based on the 8-direction stroke convention shown in Figure 2.

Stroke sequence string matching (Cha 1999) is based on the individual distance $d_{i,j}$ between the i'th stroke in letter a_1 and the j'th stroke in letter a_2 where

$$d_{i,j} = |a_1(i) - a_2(j)| \quad \text{if } |a_1(i) - a_2(j)| \le 4$$

This value is to be modified so that the $d_{i,j}$ value is replaced by the value $8\text{-}d_{i,j}$ when it exceeds the value of 4. This is equivalent to taking the smallest angle between the two directions whether the rotation is clockwise or counter-clockwise. Hence $d_{i,j}$ gives the minimum number of necessary steps to turn from the direction given by $a_1(i)$ and $a_2(j)$.

Allowing a cost function of c=2 which allows a mini-

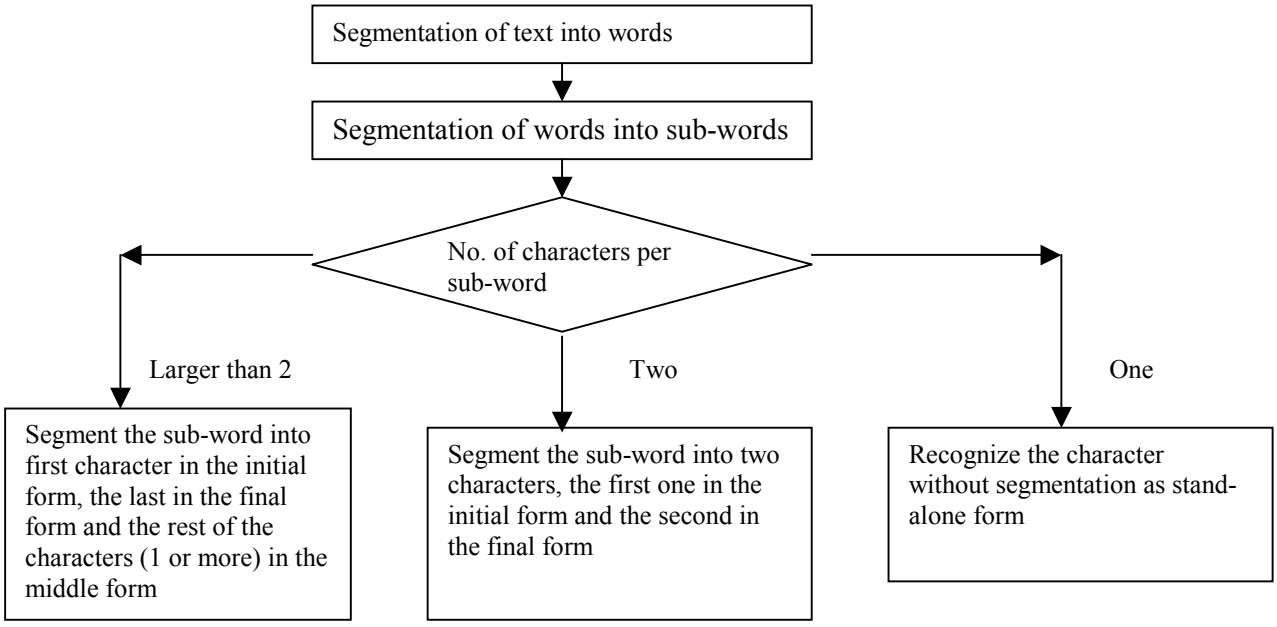

Figure 1: Proposed Procedure for Arabic Character Recognition

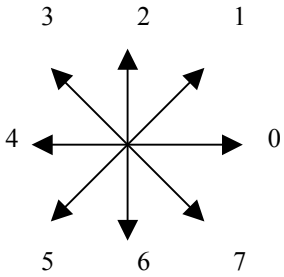

Figure 2: The 8-direction stroke convention

mum edit distance between two stroke sequence strings.

Figures 3a and 3b show the Arabic characters ح and ع taken as standard shapes. The stroke sequences corresponding to each of them is shown in the upper row of Tables 3 and 4, respectively. Figure 3c shows a supposed unknown character to be compared to each of them. However, this is a hand-written letter ع. The stroke sequence for this character is shown in the left-hand column of both Tables 3 and 4. They also show the computed distance tables between the unknown character and each of the two characters which are nearest in shape to it. Its distance to the letter ع is 8 while its distance to the letter ح is 10. This gives the result that the unknown character is ع and not ح .

The individual strokes on the top and left hand side of the table (starting row and column) are t_i and l_j simultaneously. The calculations involved in the shown Tables takes into consideration that

T(i,j) is the minimum value of T(i-1 , j-1) $+d_{i,j}$ and the two values T(i-1, j) +c when t_i is missing and T(I, j-1) +c when l_j is missing.

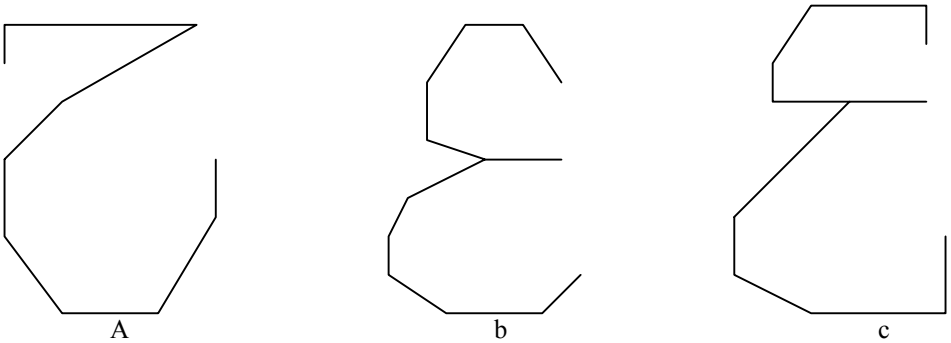
Table 4:String matching between the unknown character and character ع



A b c

Figure 3: a: Character ح b: character ع d: unknown character to be matched with a and b

Figure 4: The letter ع hand written by 48 different persons

1. Results and Discussion

The above algorithm was applied to various Arabic stand-alone characters collected from 48 different persons. Figure 4 shows such character from the different handwriting of the 48 persons for the letter ع. These persons were asked to copy the same text without any restrictions on their writing style. The handwritten pages were scanned and then normalized to nearly the same overall sizes. The stand-alone characters were then copied and analysed by the above algorithms. Results showed recognition rate of about 80% for characters such as ا , ص , ه while the rate of recognition was much less than that for similiar characters such as ب & ف or ق & ن.

6. Conclusions

A statistical analysis on a sample of Arabic text, showed that the average Arabic word contains about 4.3 characters with an average of 2.2 sub-words. This shows that the basic block to be dealt with in Arabic OCR systems should be the sub-word rather than the word. The size of the sub-word varies from a single character up to 8 characters. The method of recognition of sub-words of different lengths ought to be different. For sub-words with a single character, the matching for recognition may be made only with characters of the stand-alone form. For sub-words with two characters only, a single shot segmentation has to be made dividing the sub-word into two characters. The first one is in the initial form and the second one in the final form. Sub-words of lengths longer than 2 characters need to be segmented into three characters or more. The first is of initial form, the last of final form and the rest

of middle form. Design of Arabic OCR system when taking these facts into account would be much simpler. However, the classification of sub-words according to the number of the characters they contain, still ought to be addressed.

As a first step, the recognition of the sub-words with a single character of a stand-alone form has been treated using the approximate stroke sequence string matching. Promising results are shown. Further refinement of the algorithm used need to be carried out for better rate of recognition.

7. Acknowledgement

The authors are grateful to the grant offered by The Higher Council for Science and Technology, Jordan and to the University of Jordan for offering the facilities to do the research. The authors also thank Mr. Samer Alayysh for helping in getting some of the results

Challenges in Arabic NLP

Achraf Chalabi

Sakhr Software Co.
Sakhr Building, Nasr City, Free Zone,Cairo, Egypt
ac@sakhr.com

Abstract

Arabic language poses many challenges to Natural Language Processing . The present paper briefly describes some of those characteristics of Arabic language adding extra complexities and challenges to NLP compared to its English counterpart . Among others, the omission of diacritics in written text , the relatively free word-order, the presence of elliptic personal pronouns and the rich morphology, represent the main language features making Arabic NLP an even more sophisticated task.

1. Introduction

Arabic language is formally written using characters and diacritics. By analogy with Latin languages, characters in Arabic represent Latin consonants, while diacritics represent vowels. There are 3 basic diacritics in Arabic, namely, fatha (a), kasra (i) and damma (ou). In addition to these basic diacritics, there is a shadda , which is used in combination with any of them to produce three new "geminated" vowels. Moreover, each of the three basic vowels, could be doubled to produce a "nunated" vowel. While the basic three vowels and their corresponding geminated ones have direct impact on the linguistic interpretation of Arabic words, "nunated" vowels have a musical rather than linguistic role, and are involved more with the sound accompanying Arabic text.

2. Lack of Diacritics

Although Arabic should be written with full diacritics to avoid misinterpretations , or with mandatory diacritics to minimise ambiguities, most of written Arabic text, except for religious domain, lack diacritics fully. A "human" person reading Arabic text is performing contextual analysis in permanence, and sometimes even backtracking in order to reach the correct interpretation of each word and hence the right diacritics to be applied to the word prior to pronouncing it. Therefore, in reading Arabic text, the application of "reading" rules is the easiest part, and unlike Latin languages, must be preceded by analysis, disambiguation and interpretation.

Just to feel the task, read the following English sentence : " jst t fl th tsk, rd th fllwng nglsh sntnc"
which is the non-vowelized version of the sentence before, and in which
"fl", could represent (file/foil/fool/feel/fly/flee/…..)
"rd" could represent (rod/road/read/red/raid/ride…)
Therefore, computational processing of Arabic language is considered one order of magnitude more complex than its Latin counterpart, assuming only the absence of diacritics problem, which increases significantly the amount of morphological and lexical ambiguities , hence resulting in a combinatorial chain of syntactic ambiguities.

3. Rich Morphology

Arabic language has a very rich morphology. Words in Arabic are constructed out of prefixes, stem, infixes and suffixes. The stem itself is composed of two basic elements : the root and the morphological pattern (or diacritical pattern). The root could be a "tri root", consisting of three characters, or a "quad root" composed of four characters. The application of a morphological pattern to a root generates a stem, which is the basic form of an Arabic word token. Arabic language consists of about 6 000 roots and 700 morphological patterns. Not all patterns could be applied to a given root. The actual valid root-pattern combinations in Arabic generate around 150,000 stems. Two thirds such stems are considered classical Arabic and only the remaining 50 000 stems are those actually used in daily life.

Arabic stems allow attachment of a multitude of prefixes and suffixes, hence constructing final form word tokens. Just to name some, prefixes in Arabic could be:

- Prepositions ل → to / for
  ب → with
  ك → as
- Conjunctions و → and
  ف → then
- Adverbs ف → so
- Auxiliary verb س → will
- Interrogative أ → did-have

On the other side of the word, suffixes have a much wider range of values, such as:

- Case ending suffixes (nominative/ accusative/ genitive)
- Number suffixes (dual/ proper plural)
- Gender suffixes (masculine/ feminine)
- Personal pronouns
- Object pronouns
- Genetive pronouns
- Possessive pronouns

By catenating prefixes and suffixes to a stem, a whole English sentence could be represented in one single Arabic word.
Ex.

Arabic : فسأقابلكما

English : Then I will meet both of you

The rich morphological nature of Arabic words represents an additional major obstacle for computational processing, especially on the morphological level:

Ex.

فضل → (فَضْلٌ)
(فضَّلَ)
(فَ + ضَلٌّ)
.
.
.

In the above example, among the seven possible morphological interpretations for the input non-diacritized word (فضـــل), two will consider the first character an adverbial prefix, assuming a root totally different from the other five alternatives.

While the highly inflectional nature of Arabic poses many complexities in morphological analysis and disambiguation, it does however, in combination with the syntactic constraints of verb-subject and noun-adjective agreement, provide on the syntactic level, many useful clues serving structural analysis and disambiguation.

4. Free Word-Order

Arabic has a relatively free word-order syntax. Tokens constituting an Arabic sentence could be freely moved, without affecting the syntactic validity or the semantic interpretation of the sentence.

Ex.

Ate the man the apple	أكل الرجل التفاحة
Ate the apple the man	أكل التفاحة الرجل
The man ate the apple	الرجل أكل التفاحة

One major problem arising from such flexible word-order, is the ability to swap subjects and objects, which would enable interpretations such as (the apple ate the man) that are syntactically valid but semantically wrong. Therefore, processing Arabic sentences requires syntactic analysis to permanently work in a "hand-shake" mode with semantic analysis. Any attempt to attach a noun phrase to a verb as a subject, object, complement or even adverb, has to consult the semantic analyser prior to attachment.

Many years of intensive work were needed in order to build the selection restrictions data used in ***Sakhr's*** proprietary Arabic semantic analyser. In recent years, the increasing availability of Arabic text in electronic form enabled the construction of very large Arabic text corpora, which in turn, opened new horizons for Arabic Natural Language Processing by combining statistical methods with rule-based techniques.

Arabic free word-order requires also a much more complex formal grammar, compared with its Latin counterpart, in order to reach a comprehensive coverage of valid Arabic structures. A PS-grammar has been written in ***Sakhr*** to drive its single-stack multi-level parser which runs simultaneously with the semantic analyser, and form together the core engine for Arabic sentence processing.

5. Elliptic Personal Pronoun

One main characteristic of Arabic Language is the presence of an elliptical personal pronoun, which is always single but may be masculine or feminine. In combination with the omitted diacritics, elliptical pronouns create one of the most complex problems to Arabic computational processing. Consider the word "أكل" , without diacritics, this word could be one of eight possible words. Two such possibilities are

(i) أَكَلَ (eat),

(ii) أَكَّلَ(feed).

Although both word forms have a common root (ء ك ل), making them belonging to the same semantic cluster, different morphological patterns have resulted in totally different meanings and lexico-syntactic features. One such feature, relevant to our context, is "transitivity". While (أكَـــلَ) could be intransitive or transitive; (أكَّـــلَ) can be transitive or ditransitive. Based on the above, the sentence: أكـــل الولـــد تفاحـــة Could have the following two interpretations :

(i) the boy ate an apple أَكَلَ الوَلَدُ تفاحةً

(ii) (He) fed the boy an apple أَكَّلَ الولدَ تفاحة

Where (i) has assumed the transitive alternative for the verb (أكـــل) and (ii) the ditransitive one. Resolving this issue necessitates robust and intelligent syntactic analyser, supported by a mandatory pronominal reference resolver.

6. Conclusion

Challenges imposed by Arabic language nature push NLP to the extreme, motivating creativity and exhaustive exploitation of every single bit of already available techniques and linguistic resources. The recent emergence of Arabic electronic texts (newspapers, magazines, books, Web sites,…etc) is paving the road to the implementation and integration of new statistical-based modules within the originally rule-based system resulting in a more powerful and accurate hybrid system.

Sakhr has been involved in Arabic NLP since 1985 and has released the first Arabic morphological analyser two years later. It has since, pursued and intensified its Research and Development efforts in this line, building a solid infrastructure for Arabic NLP , including the Arabic Lexicon , Grammar, Parser ,Selection Restrictions, Corpus, Automatic diacritizer …etc, and is now proceeding in the development of its bidirectional Arabic<>English Machine Translation engine powering Sakhr's free on-line translation Web site at http://www.tarjim.com.

OrienTel – Arabic speech resources for the IT market

Abstract

A survey of the language resources market clearly shows that the Arabic language is still a stepchild of international R&D efforts in the field of speech recognition. *OrienTel* for the first time makes an effort to create speech data on a large scale. It does so by profiting from the experience of previous *SpeechDat* projects and from the European Commission's policy to embrace non-EU Mediterranean and surrounding countries. The participants of *OrienTel* will collect Standard and Colloquial varieties of Arabic in Saudi Arabia, the UAE, Egypt, Israel + Palestine, Tunisia and Morocco, supplemented by other languages of the region. Help in creating an Arabic network of speech experts is appreciated.

1. Introduction and goal of the paper

Like all other members of the *SpeechDat* family of data collections, *OrienTel* is driven by an international industrial and academic consortium.[1] This time the co-ordinator is Philips Speech Processing, the other participants being ELDA, IBM, Knowledge, the University of Patras, Siemens, NSC, Universitat Politècnica de Catalunya, and Lucent Technologies. *OrienTel* resembles previous *SpeechDat*-like undertakings[2] insofar as the recordings are supposed to serve the broadest possible application areas, ranging from simple command and control services to unified messaging, information retrieval, customer care, banking, WAP and service portals. It is different from previous projects, however, as it takes *SpeechDat* to a variety of non-European languages such as Arabic and Hebrew, which require far-reaching adaptations to database design and annotation standards. The aim of the present paper is to introduce the broad setup of *OrienTel*, give an account of the present status of database design, and to call for a joint effort in producing language resources for the Mediterranean and the Middle East. In addition to the rather general description of the project presented in the LREC2002 Proceedings, the present paper provides some Arabic-specific problems.

2. Why *OrienTel* now?

The *OrienTel* region is a region of extremes. While Israel ranks as one of the World Bank's 26 so-called 'developed' economies, its next door neighbour, the Palestine Authorities, are having to cope with a GDP per capita figure of just US$ 1,634.[3] The contrasts are even more extreme among the Gulf states. The United Arab Emirates possess the highest GDP per capita of the region - which at US$ 16,800 is on one level with most Western European countries - yet just a few hundred kilometres away Yemen reports an average GDP figure of only US$ 304. From a commercial point of view, therefore, not all countries in the *OrienTel* region are currently of equal interest to the present consortium. In anticipation of high growth rates for future mobile communication services, however, the project boldly aims at covering the whole area between Morocco in the West and Kuwait in the East, from Turkey in the North to Yemen in the South of the *OrienTel* region. Through the development of dialect adaptation techniques it will be possible in the near future, we hope, to adapt acoustic models of one language variety of Arabic to a related one. For the time being, a preselection process based on linguistic and commercial judgements as well as on considerations of sheer manpower has picked 9 out of potential 19 countries in which *OrienTel* will become active.

Despite the diversity between individual markets certain general trends are apparent. Mirroring what has happened in the rest of the developed world, cellular telephony has grown rapidly, particularly in markets where the fixed line infrastructure is inadequate. A case in point is Egypt. With 62 million inhabitants Egypt is the second most populous country in the *OrienTel* region: its fixed line teledensity of 10.97% places it at place 13 in the regional league table of lines per 100 inhabitants, yet it comes third in terms of number of mobile subscribers. While the Egyptian government has attempted to improve the availability of fixed line telephony by setting ambitious targets for state-owned Telecom Egypt, the private sector has been allowed a relatively free rein in the mobile sector. The result has been an explosion in the

[1] Thanks go to the European Commission, who are funding *OrienTel* as an R&D project under the 5th Framework Programme (Contract IST-2000-28373).

[2] Infos on *SpeechDat* and related projects can be gathered from http://www.speechdat.org . Publications focusing on specific members of the *SpeechDat* family are, for example, Höge/Tropf 1996 (*SpeechDat M*), Höge et al. 1999 (*SpeechDat II*), Pollak et al. 2000 (*SpeechDat East*), Moreno et al. 2000a (*SpeechDat Car*), and Moreno et al. 2000b (*SALA*).

[3] All figures of the present section were taken from CIT Publications (2000).

number of cellular subscribers. During 1999 the number of subscriptions rocketed from 187,000 to 890,000. According to Egypt's two mobile operators, France Télécom-backed MobilNil and Vodafone AirTouch's Misrfone, the market doubled in size again during 2000 to 1.8 million. Turkey is in a similar situation. With a fixed line network of 17.4 million lines, Turkey's teledensity of 26.6% places it sixth in the regional ranking table, yet its mobile sector has experienced nothing short of phenomenal growth: at the end of 1996 mobile penetration stood at just over 1.2%, but three years later it had increased ten-fold to 12%, and rose to just below 20% by the end of 2000.[4] Company-internal considerations of some *OrienTel* partners bear further evidence of the current interest in speech applications gradually extending from Europe towards some of the countries covered in the project. A survey of the needs for future language development undertaken by ELRA points into the same direction: particularly Arabic and Turkish are currently on the wish list of many companies active in the field of language and speech. Largely due to such infrastructural and commercial considerations, the *OrienTel* consortium chose nine out of a potential set of 19 countries between Morocco in the West and the Gulf States in the East. The countries treated in *OrienTel* so far are depicted in Table 1:

Country	Partner
UAE	Philips
Saudi Arabia	Lucent
Israel/Palestine	NSC
Egypt	IBM
Tunisia	UPC/ELDA
Morocco	ELDA/UPC
Turkey	Siemens
Cyprus	Knowledge/Patras Univ.

Table 1: *OrienTel* countries and partners

More countries may follow in case new partners decide to join the project.

3. Linguistic settings

From a linguistic point of view, too, the *OrienTel* region is far more diverse than any region covered in previous projects of a similar scope such as the various members of the *SpeechDat*-family or *SpeeCon* (Siemund et al. 2000, cf. also http://www.speecon.com). In order to treat the linguistic peculiarities of the area adequately, *OrienTel* follows a different strategy than previous *SpeechDat* projects. As Table 1 shows, each partner in the consortium is not responsible for a single language but for a whole country. The difference is an important one, since, as will be outlined below, in most *OrienTel* countries everyday-life is governed by more than a single language. One of the first project tasks was therefore to determine the various languages spoken in the *OrienTel* region, taking into account both linguistic and commercial criteria. From the consortium's point of view Arabic, Turkish, Hebrew and Cypriote Greek turned out to be of most immediate concern with Farsi being on the wish list for future stages of the project. Furthermore, English and French turned out to be of commercial interest as the dominant business languages in some *OrienTel* countries and because non-native varieties of European languages constitute a hitherto grossly neglected domain in linguistic research. This is also the reason why *OrienTel*'s language portfolio is complemented by German as spoken by Turks in Germany, who represent the largest linguistic minority of the country.

The most complex linguistic picture of the *OrienTel* region, however, is no doubt presented by Arabic and its variants. Arabic of the *OrienTel* area can be subdivided into four broad dialect regions, as outlined in Table 2:

Dialect region	Countries
Mahgreb Arabic	Morocco, Algeria, Tunisia, parts of Libya
Egyptian Arabic	Egypt, parts of Libya
Levantine Arabic	Syria, Lebanon, Israel + Palestine Authorities, Jordan
Gulf Arabic	Kuwait, Qatar, Bahrain, UAE, Saudi Arabia, Oman

Table 2: Dialect regions of Arabic

In order to represent all dialect regions adequately, all areas are attended to by at least one partner. In each country, the variety of languages spoken is rather large. In Morocco, for example, the official language is Modern Standard Arabic, the rather formal language of religion, the media and of public institutions. In everyday interaction though, people either tend to speak a local colloquial variant of Arabic that is only remotely related to the Standard (not to mention the various non-Arabic languages such as Berber) or, when it comes to commercial interaction, French as the language inherited from Morocco's colonial past. All three (or even more) languages have their place in everyday life and user-friendly applications have to take into account each country's linguistic diversity and its users' preferences. The databases produced in *OrienTel* are depicted in Table 3:

Country	1st language	2nd language	3rd language
UAE	Mod. Std. Arabic	Modern Coll. Arabic	English
Saudi Arabia	Mod. Std. Arabic	Modern Coll. Arabic	English
Israel/Pal. Auth.	Mod. Std. Arabic	Mod. Coll. Arabic	Hebrew
Egypt	Modern Std. Arabic	Modern Coll. Arabic	English
Tunisia	Mod. Std. Arabic	Modern Coll. Arabic	French
Morocco	Mod. Std. Arabic	Modern Coll. Arabic	French
Turkey	Turkish	-	German
Cyprus	Cypriote Greek	-	English

Table 3: *OrienTel* languages

[4] The market analysis is based on *Telecommunications Markets in the Middle East*. Exeter: CIT Publications, 2000.

As can be gathered from Table 3, the *OrienTel* consortium will produce a set of 22 databases in 8 countries, all of which will be made publicly available after the end of the project and a commercially reasonable quarantine period.

4. Linguistic research and dialect adaptation

The rather complicated linguistic situation in the *OrienTel* countries calls for innovative approaches to speech recognition techniques. Thorough research will be conducted into multilingual acoustic modelling and the development of multilingual lexicons, including descriptions of phonetic inventories. An important goal will also be the development of phonetic and orthographic transcription strategies. By default written Arabic and Hebrew orthography depict consonants only. Even though it is possible to render vowels by supra- and supersegmental markers, fluent reading of such "annotated" words is awkward even for native speakers. Strategies will therefore be developed to prompt speakers reliably even if the meaning of, for example, a single command word cannot be gathered from the context of whole sentences. The problem of vowels is of particular importance especially since it is largely the vowels on which current Hidden Markov Modelling heavily relies (cf. Rabiner/Juang 1993). Once parts of the various databases become available, it will therefore be one of the main research tasks to assess the linguistic features of dialect clusters and develop techniques of dialect adaptation across the Arabic-speaking world.

5. Foreign accent adaptation

Apart from the databases representing Standard varieties and local dialects, a separate set of data will be produced for foreign accent adaptation. Due to the *OrienTel* countries' colonial, protectorate or migration history, the most prominent foreign languages in the region are French, English and, for different reasons, German. On the one hand, collecting data of this kind will ensure true multilinguality of applications in the *OrienTel* countries. On the other hand, French, English and German services already under operation in the EU can be adapted to foreign accent variation.

6. Demonstrator development

In order to show that the multilinguality approach taken in *OrienTel* is feasible, the project will produce two demonstrator applications. The exact kind of services will be specified at a later stage of the project. Considerations will, however, take into account the convergence of internet, WAP and voice for service portals, unified messaging, customer care applications, directory assistance and banking. The two demonstrators will reflect two different types of services and will account for two different linguistic regions.

7. Dissemination of information and results

In order to keep the speech recognition community informed about the *OrienTel* efforts, the project will contribute to scientific discussions concerning the languages of the *OrienTel* region at conferences, in publications and through relevant mailing lists. It will furthermore continuously update the project's website with information on *OrienTel* activities and publish the results (cf. section 9 below). The 22 databases will be made publicly available through the European Language Resources Association (ELRA) in due course after the project has ended.

8. Database specification

Due to the linguistic heterogeneity of the region, questions of database specification such as corpus composition, orthographic and phonetic transcription strategies constitute a crucial part of the project. Particularly Arabic and Hebrew pose interesting problems for speech recognition that were never tackled in projects of the *OrienTel* scale before. Cases in point are the rendering of vowels, the right-to-left writing system and the transcription of oral or colloquial speaking styles. While at the time of writing the present paper quite a few design details are still under discussion (the design phase is due for completion before the LREC2002 conference starts), some of the cornerstones can already be reported at the present stage.

8.1. Recording scenarios and platforms

All *OrienTel* databases will be recorded from fixed and mobile networks via ISDN lines and multiple channels, i.e. either through a Basic Rate Interface or a Primary Rate Interface (cf. Senia 1998). A dialogue will be implemented by the application driving the recordings. The dialogues will be designed to make the caller speak and act comfortably.

8.2. Corpus and vocabulary

Data collections will rely on three separate sets of prompt sheets, namely one each for

- the 'foreign' languages in Arabic-speaking countries, i.e. English and French, including Turkish, Greek, Hebrew and German
- Modern Standard Arabic
- Modern Colloquial Arabic

While the specifications for English, French, Greek and German are largely based on previous *SpeechDat* projects and *SpeeCon*, the design for Arabic and Turkish presents a novelty. All three sets of prompt sheets, however, contain the following items, though in varying quantities with at least 47 items per sheet:

- isolated digits
- digit and number strings
- natural numbers
- currency amounts
- yes/no questions
- dates
- times
- application keywords and phrases
- word spotting phrase using embedded application words

- directory assistances names (proper names, place names, company names)
- spellings
- phonetically rich words and sentences
- spontaneous utterances

8.3. Transcription and annotation

The *OrienTel* transcription and annotation conventions are largely based on conventions used by the Linguistic Data Consortium and ARPA in producing the ATIS CD-ROMs[5], and the simplifications made for the *SpeechDat*-predecessors of this project, and *SpeeCon*. The goal of the specification document that should be finished by the time of the present workshop is to define a coarse transcription that can be performed quickly, but covers adequately the acoustic events most important for the training and testing of automatic speech recognisers. The transcription is orthographic (cf. the lexicon section below for phonetic renderings) and includes a few markers representing audible acoustic events (speech and non-speech) present in the corresponding waveform files. The phoneme symbol set aims at the localisation of the main acoustic events according to a coarse categorisation rather than a full description of all possible sounds that may appear during a recording. Extra marks contained in the transcription aid in interpreting the text form of the utterance; markers for non-speech acoustic events and distortions have been chosen such that they can be automatically removed or modified to yield the base transcription. The overall aim is to keep as much speech in the corpus as possible and to avoid the need for deleting recordings from the corpus due to some extra noises, disfluencies, etc. All items for all languages covered will be transcribed in standard orthography and will be Romanized in the label files. A Sampa transliteration will be generated and discussed with the Department of Phonetics and Linguistics at UCL (cf. http://www.phon.ucl.ac.uk/home/sampa/home.htm) if need be. Administrative information on speech files and their properties will be stored in SAM files (cf. http://www.icp.grenet.fr/Relator/standsam.html).

8.3.1. Strategies for recording colloquial Arabic

Dialectal Arabic is exclusively a spoken language and can very rarely be found in the written form. This fact imposes constraints on the recording procedure. There are a number of possibilities with regard to collecting colloquial Arabic speech:

1. recording spontaneous speech only;
2. presenting audio prompts to the speaker who then only needs to repeat what has been prompted;
3. presenting written prompt sheets to the speaker that he/she needs to read. The prompts can be
    a. written in vowelized Arabic script or
    b. transcribed using Latin alphabet.

The first option is likely to provide the most natural results. However, transcription of such spontaneous material would be very difficult as well as time- and money-consuming. That is why it has been decided to include a limited number of spontaneous items in the recordings. An example of such a spontaneous item is asking the speaker to answer a question on, e.g., the sightseeing sites of his/her town. Furthermore, spontaneous speech will be recorded as response to questions concerning dates, natural numbers and proper names. An example is enquiring the speaker's date and place of birth. Such questions are expected to produce short and simple utterances.

Typically, a *SpeechDat*-like database contains a number of items whose content has been defined in advance, such as phonetically rich sentences and application words. For this type of recordings option 2 or 3 need to be taken into account (the audio prompts or prompt sheets). In order to determine the best approach a number of basic experiments have been carried out with Moroccan speakers. These have enabled us to dismiss option 3b (transcription with Latin characters). During the experiments using this prompting approach none of the speakers was able to pronounce words naturally. On the other hand, the best results were obtained using audio prompts. However, this option has been dismissed too since it poses too many practical problems with such a high number of speakers and items which need to be recorded. Colloquial Arabic is difficult to read for most of the speakers since they are not used to reading it. Nevertheless, the majority of the speakers manage to come up with a correct pronunciation after having analysed the prompted text for a moment. Because of that, however, it is important to grant the speakers some extra time to become acquainted with the script before the recording starts.

8.3.2. Strategies for recording standard Arabic

Conventionally, the orthographic representation of standard Arabic relies on consonants. Although it is possible to represent vowels using diacritics (located super- and suprasegmentally), fluent reading of such scripts remains a challenge; most of the speakers are not used to reading texts containing vowel diacritics. In complete sentences it is possible for the speaker to deduce the vowels from the context. However, for isolated words it is necessary to mark the vowels in order to disambiguate between the different options. This situation is similar to that of colloquial Arabic in which the speakers need extra preparation time to be able to read vowelised scripts without hesitation and pauses.

8.4. Specification of speakers

The number of speakers to be recorded is 2000 per country. This number is distributed between the set of databases to be collected. Table 4 on the following page shows the minimum number of speakers per country and recorded language. A maximum overlap of 15% in the total number of speakers per country between the different databases is allowed.

[5] Cf. http://www.ldc.upenn.edu/, http://www.arpa.gov/, and http://www.atis.org , respectively.

Country	Colloquial	Standard	Business
Morocco	1000	500	500
Tunisia	1000	500	500
Egypt	1000	500	500
UAE	1000	500	500
Saudi Arabia	1000	500	500
Turkey	-	1700	300
Israel	500	500	1000[6]
Cyprus	1000	-	1000[7]

Table 4: Number of speakers per database

8.4.1. Gender

The distribution of male and female speakers should be 50% each per database, with an allowed deviation of 5% for the whole database per language. There is no gender restriction for "Age" and "Dialect". For "Environment", the gender distribution must be 30-70% for each sub-category.

8.4.2. Age

Table 5 presents the distribution of speaker age:

Age	16-30	31-45	46-60
Proportion	≥ 30%	≥ 20%	≥ 10%
Requirement	Mandatory	Mandatory	Mandatory

Table 5: Distribution of speaker age

Naïve speakers should be recorded rather than experienced or trained speakers to guarantee more natural speaking styles, voices and dialects.

8.4.3. Dialect

Many (though not all) of the languages spoken in the *OrienTel* regions are not the speaker's actual mother tongue. In such cases, we consider a person who spent most of his/her childhood, or who grew up in the concerned region, as having no foreign accent. Language-specific cases should be documented in the LSPs.

The specific number of dialects relevant to each country should be discussed in the LSP documentation. The distribution of speakers over dialect regions refers only to the colloquial varieties of the language. Speech should be collected from a minimum of three different dialect regions (if possible), with at least 20 speakers recorded for each defined dialect.

The speaker's dialectal region is determined by asking the question *"in which district did you grow up" or "where did you spend most of your childhood"*, not the question *"where do you live"*. The allocation of city/district names to the corresponding dialect region can be determined according to the information provided by each partner in the LSP documentation.

8.4.4. Distribution of environments

The speaker distribution for the mobile network should be between 65 to 75% of the total number of speakers in the database; e.g., if there are 1000 speakers in the database, between 650 and 750 of them should be recorded through the mobile network. At least 30% of each gender must be recorded in each environment.

Both the fixed and mobile networks are further divided into specific environments. Speaker distribution over each environment is shown in Table 6:

	Environment	Speaker distribution
Fixed network 30% ± 5%	Home/office	≥ 75%
	Public place/booth	
Mobile network 70% ± 5%	Home/office	≥ 20%
	Public place/street	≥ 20%
	Vehicle	≥ 15%
	Hands-free car kit (optional)	≥ 5%

Table 6: Distribution of recording environments

8.5. Specification of the lexicon

The lexicon is an alphabetically ordered table of distinct lexical items that occur in the corpus with the corresponding pronunciation information. Each distinct word should have a separate entry, which will be laid down in the order orthography ⇨ frequency ⇨ transliteration (for Arabic and Hebrew) ⇨ phonetic transcription ⇨ variants (optional).

The lexicon is derived from the annotated database and is set up as follows:

- Standard Language: Arabic & Hebrew script, both vocalized and not vocalized.
- European languages: Latin script
- Colloquial Language: Region specific Arabic script (same as in orthographic annotations)
- Acronyms such as *IBM* should appear as complete words in the lexicon, i.e. as letters with no spaces in between. The reason is that there are often different ways of pronouncing them (spelled and expanded).

The phonetic alphabet used will be SAMPA, and is thus case-sensitive. While a Hebrew SAMPA alphabet is currently under negotiation for standardization as part of the *SpeeCon* project, *OrienTel* will make an effort to further standardize Arabic and Turkish SAMPA alphabets. Sampa symbols for each language are defined in the language-specific documents accompanying each database and are considered as a standard set of phonemes for that language.

9. Disclaimer and Contact

Since the specifications outlined in this document are still being discussed at present and are thus still subject to revision, the latest state of the *OrienTel* art can always be gathered from the continuously updated *OrienTel* website at http://www.orientel.org. The co-ordinators of the project can be contacted either via the internet pages or through rainer.siemund@philips.com.

The Semi-automatic Tagging of Arabic Corpora

Mark Van Mol
professor Catholic University Leuven

Dekenstraat 6
B 3000 Leuven
Mark.VanMol@ilt.kuleuven.ac.be

Abstract

At the Institute of Living Languages of the Catholic University of Leuven we developed a system to encode Arabic corpora which enables us to identify strings of characters and to analyse them and disambiguate words. At the institute we developed two kinds of databases, one word-oriented and one sentence-oriented. The word-oriented database contains until now 26,000 Arabic lemmata with all the grammatical information. The second database contains a text corpus of approximatively 4,000,000 tagged Arabic words of which 1,200,000 from spoken Arabic language resources. Both databases will be used in the future in order to develop a semi-automatic tagging of raw Arabic corpora. In order to make Arabic electronic corpora useful for a large variety of purposes a pre treatment seems to be necessary. This treatment comprises three main phases. In the first place the uniformisation of Arabic corpora. The second phase involves the identification of strings of characters and the third phase involves the disambiguation of words on the basis of information coming from both sources. Once the corpus tagged this way, it containes enough detailed information to make scientific searches and analyses.

1. Introduction

In recent years more and more attention has been paid to gather Arabic corpora. Besides the ELRA initiative, numerous groups take the initiative in compiling all kinds of corpora. Many of these initiatives however, suffice with the compilation of raw corpus materials. Unlike other languages, however, the Arabic written language is ambiguous in many respects. The ambiguity of Arabic lies in the first place in the fact that the language is not vocalised. Often it is stated that languages with a rich morphology open much more facilities for tagging. The first problem in Arabic, however is, that written texts are not vocalized except in schoolbooks from primary schools and Coranic texts. All other material remains unvocalised which, of course, raises the level of ambiguity.

2. Levels of ambiguity in Arabic

The ambiguity of Arabic lies on different levels. The first level is the core word itself. Many core words can contain in it different grammatical categories. Below we give a few examples of possible combinations of grammatical categories of unvocalised words. Even if we limit ourselves to the main part of speech categories we find many ambiguous words.

2.1. First level: Core word

2.1.1. Noun - adjective.

Many Arabic word patterns can stand both for a noun and an adjective. Without being exhaustive we mention first the pattern which is most often an adjective, but which can also be a noun. For example, the word (*small*), which, of course, more exceptionally, can be used as a noun meaning the small one. The predictability of the grammatical category of those patterns is not always self-evident. One might suppose that the word pattern most often stands for an adjective, but this is not always the case. Take for instance the word of which it is quite clear, at first sight, that it is a noun, but which in Modern Standard Arabic (especially in North Africa) is often used as an adjective meaning principal.

The same goes for almost all the words ending in a so-called nisba. Indeed, most of those words are, as far as their Arabic pattern is concerned, unpredictably a noun or an adjective. Take, e.g., the word which means *politician* (noun) as well as *political* (adjective). Of course, a completely trained tagged corpus might shed some light on the chance rate of those grammatical categories, but the pattern itself does not say anything on the grammatical category of the word, except that it excludes to some extent the labeling of other categories, such as a verb or a particle. But even this remains in many cases problematic, because the *nisba* characteristic is in many cases not sufficient to exclude other grammatical categories, such as the verb or the particle, especially when unvocalised words are involved. Indeed, forms such as verbs ending with ya' , for instance, the verb (*to stay*) or the particle (*any*) could on the basis of the ending characteristic wrongly be interpreted as being an adjective or a noun.

Other ambiguous word patterns that cover both nouns and adjectives are the patterns · (e.g. noun: *drunk* - adjective: *intoxicated*), (e.g.: noun: *mason* – adjective *constructive*), (e.g. noun: *idler* - adjective: *lazy*)

2.1.2. Participles

Another word pattern, which covers both nouns and adjectives, is the pattern of both active and passive participles , and dervatives. These cases are sometimes even more complicated because they can also be classified from time to time as a preposition (for example: within) but even sometimes as a participle with the function of a verb, such as in he is going inside.

2.1.3. Verb - adjective.

Many verbs have the same shape as adjectives. Often an unvocalised verb with three radicals has the same pattern as an adjective. The three radicals , for example, can both stand for the verb · and the adjective .

2.1.4. Verb - noun.

The most important mingling of word patterns between verbs and nouns occurs with the verbal nouns (*masdar*). The verbal nouns of the fifth and the sixth form often raise confusion. For example (Vth form) can both be a verb (*to meddle*) and a noun (*interference*) and also (VIst form) can both be a verb (*to help*) and a noun (*cooperation*). However, the verbal nouns of the Vth and VIst form are easily detectable in a written text. The verbal nouns of the Ist form, on the other hand, are much more difficult to define as verbal noun, because these forms can often also be used as a noun. But also nouns are mixed up with verbs, such as, for example, the shape which can be a noun (*delegation*) or a verb (*to arrive*).

2.1.5. Verb - noun - adjective

The pattern is even more complicated. This pattern offers at least three possibilities, viz. a noun, an adjective or a verb. The word , for instance, means both *white* as a *white* (a member of the white race). However, it can also have the function of a verb in the sentence *what is his face white*! in which, according to the Arab grammarians, the form is considered to be a verb.

2.1.6. The *taa marbuta* element

One morphological element, which might seem to help to disambiguate words is the *taa marbuta* (Khoja 2002), which is considered in grammar to be the indication of a feminine noun par excellence. There are however exceptions, for instance, the rare forms, such as and (*excellence*) which are masculine and the pattern · in which represents an adjective meaning very learned.

The above elements show that it is not sufficient to take a lexicon and tag it. Many ambiguities are not resolved that way. Only the completely unambiguous forms will be tagged, but it is clear that most of the others will not. This does not mean that the tagging of words in a lexicon is not helpful. One might suppose that when going into more detail, word patterns which can contain two or more grammatical categories, and which are for that reason ambiguous, lose in quite a number of cases this ambiguity when they are translated in their practical word form. The above mentioned word (*calamitous*) for instance is clearly an adjective.

This however remains very tricky, because a word in Arabic, which in its concrete form is clearly an adjective but of which the theoretical form is ambiguous, can always by one Arab author or another be used as substantive. Arab authors often renew the style of the language and the language itself precisely by enlarging the meaning of already existing forms. The case of illustrates this clearly. As one can discover in the dictionary of Hans Wehr, the word (*president*) is definitely only a noun. No other meanings are given in this dictionary. However, corpus analysis of radio texts of Algeria revealed that this word in this pattern is often used as an adjective, meaning principle. Even when basing ourselves on existing lexicons, we cannot guarantee the distinct definition of parts of speech for Arabic words.

2.2. Second level: Derived word forms or conjugated forms

Not only on the level of the core forms there are many ambiguities, the same goes for derived word forms or conjugated forms. Due to the lack of vocalization the conjugation of verbs yields many ambiguous word patterns that are quite difficult to interpret without any valid context. can have four possible meanings*: I wrote*, *you wrote* (m. and f.) or *she wrote*. New ambiguities arise with the conjugated forms of verbs, not only within a conjugational level but also between different conjugational levels. The verb forms in the past tense of the first person singular, the second person masculine singular, the second person feminine singular and third person feminine singular all have the same shape. But new ambiguities arise between, for example, imperative forms and indicative forms. The shape can mean either I write or the imperative form write, but it can also be the third person in the past tense of a verb of the IVth form (*to dictate*).

Also, these derived forms interfere often with similar forms from other words, which makes the correct indication of the tag even more complex. Here too different grammatical categories mix up. In some cases the form does not only lead to the confusion mentioned above, but can even have a form that goes beyond the grammatical categories of a verb such as an elative.

The character combinations of nouns also can have the same shape of conjugated verbs. For example, the first person of the jussive form of the verb (*to build*), which becomes and hence is a pattern of consonants which mixes up with the noun (*son*). Derivate forms of adjectives too can have the same shape as nouns. Many feminine forms of adjectives ending with the nisba do correspond in their shape with feminine nouns. For example the feminine adjective (*personal*) which corresponds to the noun (*personality*).

2.3. Third level: Agglutinative forms of words

Not only isolated morphological forms can be dubious, but also the agglutinative character of the language provokes unexpected ambiguities between strings of

characters between two blanks. The combination of the conjunction with the particle corresponds to the verb (*to take fire*). These new ambiguities can occur with all combinations of particles or conjunctions that are being written directly to the word. The combination of the conjunction with the verb (*to cut*) corresponds to the verb *(to be detestable*). Both the particle and provoke the same kind of ambiguities. For example, the preposition in combination with (*hand*), which corresponds to the subordinate conjunction (*however*). And the preposition , for example, in combination with (*part*), which corresponds to the verb (*to regard*).

3. Automatic vocalization, a solution?

One might argue that the vocalization of an Arabic corpus might solve the problems of tagging. This is only true to a certain extent. First of all, the above shown ambiguities indicate that it is not at all self-evident to make a tagger which disambiguates Arabic raw texts by vocalizing them. Even then, algorithms will have to be written in order to apply the correct grammatical categories to the different lemmas in a text. But even so, in a completely vocalized text, ambiguities remain, as far as grammatical part of speech tagging is concerned, be it that overall ambiguity in a vocalized text is quite lower than in an unvocalized text. It is clear that on all three discussed levels a degree of ambiguity remains.

3.1. Ambiguities on the first level

On the first level, which is the level of the core word, ambiguity remains in the forms , , and in all the words which have the form of a participle, both active and passive, such as those of the form , and all their derived forms. All those forms can be both an adjective and a noun even when they are completely vocalized. On the same level ambiguities remain also between, for example, some verbs and nouns, such as the noun in the meaning of totality, and the verb with the meaning to be tired.

3.2. Ambiguities on the second level

On the second level this is valid for many word forms ending in a nisba followed by a taa marbuta. The complete vocalized word for instance, does not give any more information on the exact grammatical part of speech to apply. The same goes for every word with this pattern.

3.3. Ambiguities on the third level

On the third level also, new problems arise. Word forms, which were not ambiguous on the first level in their core form, become ambiguous and mix up with other words. The very frequent collocation (conjunction - preposition) (and in) has the same shape as the adjective (faithful). There are many other agglutinated word combinations, which mix up with existing core word forms. Another example is (verb = *to brand*), which mixes up with (conjunction + verb = and *he poisoned*). Exclusively basing the tagging of Arabic texts on a lexicon is therefore not sufficient. Indeed, the analysis of in detail tagged corpora gives additional information which might be of great use for the tagging of raw corpora.

4. Information to be derived from tagged corpora

The additional information, to be derived from tagged corpora, is both a statistical one and a grammatical one. Both kinds of information can make a high contribution for the tagging of corpora. Both remain to a certain extent probabilistic.

4.1. Statistical information

The statistical element is evident. Many core word forms in Arabic are no longer used in MSA. The dictionary of Hans Wehr contains many words which seem to be out of use nowadays. In compiling our dictionary MSA-Dutch * Dutch-MSA (Van Mol & Berghman, 2001), which is based on a corpus of 3,000,000 words both from oral and written resources, we discovered that many root patterns did not occur in our corpus. Our corpus contains only words in texts dated from 1980 onward. For instance, no word relating to the stem occurs in the corpus.

The fact that in MSA some word forms are less used is very important for the automatic tagging of corpora. Let us take the form as an example. At first sight this shape is a preposition and a personal pronoun meaning for you. The shape occurs very frequently in MSA. There is, however, an identical form which is a verb meaning to hit with the fist. This form however did not occur at all in our corpus. This means that a count of words in a completely disambiguated corpus can give much relevant information as far as automatic disambiguation of words is concerned or at least it can give a hint about the probability in tagging certain shapes according to the word count statistics.

4.2. The Leuven approach

4.2.1. The encoding system

In order to make preparations for the automatic tagging of Arabic corpora, we developed at the Institute of Living Languages of the Catholic University of Leuven a system to encode Arabic corpora. This system not only enables us to identify strings of characters and to analyze them, it also disambiguates words and makes it possible to label all kinds of strings of characters by the appropriate grammatical information. The disambiguation of words is made by using the Arabic diacritical signs in a special structured systematic way.

As an example we take the root . This shape can be a verb (*to accept*), an adverb (*before*), a noun (*front* part), a preposition *near*) or another preposition (*before*) and even a verb of the second form, if the sjadda is omitted (*kiss*). In order to disambiguate between these different shapes we apply the diacritical signs according to a systematic description. Basically these rules can briefly be summarized as follows:

the basic form of a verb is never vocalized (e.g.). The first consonant of a noun is always vocalized (e.g.). The last consonant of a preposition is always vocalized (e.g.). If there is more than one preposition with the same shape, the second consonant is vocalized as well (e.g.). Adverbs normally take the alif, if not, the last consonant is vocalized, such as in . Derived verb forms, such as those of the second form are always written with the sjadda.

4.2.2. The lexical database

At the institute we develop two kinds of databases, one word-oriented and one sentence-oriented. The word-oriented database contains until now 26,000 Arabic lemmas with all the relevant grammatical information. The words in this database were all disambiguated by way of our encoding system. After every word has been disambiguated by using the diacritical signs in a selective way, the grammatical categories are allocated for those words. Until now this has been done for approximately 20,000 words in this database. Linked to this database is a dictionary Arabic - Dutch v.v. which has recently been published in book form (Van Mol & Berghman, 2001)

4.2.3. The corpus

The second database contains a text corpus of approximatively 4,000,000-tagged Arabic words of which 1,200,000 from spoken Arabic language resources. Both databases will be used in the future in order to develop a semi-automatic tagging of raw Arabic corpora. In order to do so several steps have to be taken, the first of which is uniformisation.

4.2.4. The tagging preparations

In order to open up Arabic electronic corpora for a large variety of purposes a pre treatment seems to be necessary. This treatment comprises three main phases.

4.2.4.1. The uniformisation of Arabic corpora

Uniformisation means that all possible shapes of one word in a raw text are reduced to one identical shape. Due to the fact that, contrary to other languages, there is quite a large freedom in typing Arabic language, the ambiguity or the variety in writing Arabic is quite large. As the computer only recognizes ASCII codes, a minimal amount of standardization seems to be prerequisite.

Even when we have a detailed lexical database of which there are minimum two kinds of information, viz. all the words in their vocalized form, but also in their neutral unvocalised form, it is not always self-evident to find the right matches between words occurring in the database, and words occurring in a raw corpus. A few examples can make this clear. One of the problematic Arabic characters is the *alif*. The *alif* can be written, without a *hamza* or with a *hamza*. This means that when in a database the word (boys) is stored as the unvocalised word form for the vocalized form it is not always certain that this will match with a corresponding word form in the raw corpus, such as, for example, the form , because the ASCII code of both *alif*-forms differs.

Another example is the use of the *alif maqsura*, for example in the word , in Egyptian newspapers, whereas in most other countries the *ya'* is used (e.g.). Other elements which ought to be uniformized is the use of the *sjadda*. Words of which the word pattern contains both alif and sjadda are even more complicated. In those cases uniformization is not a matter of reducing two forms to one. Without counting the vowels, words with alif and sjadda can have up to eight different forms in a raw text. For example, the word (*European*), which can be written , , , , , or .

4.2.4.2. The identification of strings of characters

The second phase involves the identification of strings of characters. In order to do so we develop a two-level approach.

The first approach departs from the word-oriented database from which all possible minimal basic forms of words are generated. For every word we generate all possible, what we might call, minimal basic forms. The minimal basic form contains all the possible prefixes and suffixes which can be added to a word, but which still is part of it. On the other hand we also produce for every word all, theoretic possible, maximal basic forms, which correspond to the possible word combinations between two blanks. All of these forms are given a minimal encoding so that every added linguistic element has an unambiguous shape.

The second approach departs from the sentence-oriented database from which all possible maximal basic forms are retrieved.

The third phase involves the disambiguation of words on the basis of information coming from both sources. Once the corpus tagged this way, it contains enough detailed information to make scientific searches and analyses.

Conclusion

In our view, the best way to make preparations for the automatic annotation of Arabic corpora will be by using a completely in detail annotated corpus which will give a more detailed insight in the distribution of the different Arabic word patterns and their corresponding grammatical category. We hope to give in the near future much more details on the degree of ambiguity on the three word levels, the core word level, the derived word forms or conjugated forms and agglutinative forms of words. Those data will be compared with the data retrieved from the annotated test corpus.

Multimodal Resources and Multimodal Systems Evaluation

Workshop Program

Saturday, June 1, 2002

Palacio de Congreso de Canarias

8:00 a.m. Welcome
Mark Maybury (*MITRE, USA*) and Jean-Claude Martin (*LIMSI-CNRS, France*)

Resources and Annotation: Multimodal

8:30 a.m. Data Resources and Annotation Schemes for Natural Interactivity
Laila Dybkjær and Niels Ole Bernsen
University of Southern Denmark, Denmark

8:50 a.m. Metadata Set and Tools for Multimedia/Multimodal Language Resources
P. Wittenburg, D. Broeder, Freddy Offenga, and Don Willems,
Max Planck Institute for Psycholinguistics, The Netherlands

Resources and Annotation: Gesture and Speech

9:10 a.m. FORM: A Kinematic Annotation Scheme and Tool for Gesture Annotation
Craig Martell, Chris Osborn, Jesse Friedman, and Paul Howard,
University of Pennsylvania, USA

9:30 a.m. Cross-Linguistic Studies of Multimodal Communication
P. Wittenburg, S. Kita, and H. Brugman,
Max Planck Institute for Psycholinguistics, The Netherlands

Resources and Annotation: Facial Expressions, Speech, Integration

9:50 a.m. Development of User-State Conventions for Multimodal Corpus in SmartKom
Silke Steininger, Susen Rabold, Olga Dioubina, and Florian Schiel,
Ludwig-Maximilians University, Munich, Germany

10:10 a.m. Integration of multi-modal data and annotations into a simple extendable form: the extension of the BAS Partitur Format
Florian Schiel, Silke Steininger, Nicole Beringer,
Ulrich Tuerk, and Susen Rabold,
University of Munich, Germany

10:40 a.m. Multimodal Resources Group Discussion
All

11:00 – 11:20 a.m. Morning Break

Annotation Tools

11:20 a.m. Multimodal Corpus Authoring System
Anthony Baldry, Univ. of Pavia, Italy, and Christopher Taylor, Univ. of Trieste, Italy

11:40 a.m. The Observer Video-Pro: Professional System for Collection, Analysis and Presentation of Observational Data
Niels Cadée, Erik Meyer, Hans Theuws, and Lucas Noldus, Noldus Information Technology, The Netherlands

11:20 a.m. Data Resources and Annotation Schemes for Natural Interactivity
Laila Dybkjær and Niels Ole Bernsen
University of Southern Denmark, Denmark

11:40 a.m. Metadata Set and Tools for Multimedia/Multimodal Language Resources
P. Wittenburg, D. Broeder, Freddy Offenga, and Don Willems, Max Planck Institute for Psycholinguistics, The Netherlands

13:00 p.m. Lunch

Multimodal Fusion

14:30 p.m. Prosody based co-analysis of Deictic Gestures and Speech in Weather Narration Broadcast
Kettebekov Sanshzar,Yeasin Mohammed, Krahnstoever Nils, SharmaRajeev, Dept. of CS and Engineering, Pennsylvania State University, USA

14:50 p.m. A Generic Formal Description Technique for Fusion Mechanisms of Multimodal Interactive Systems
Philippe Palanque and Amélie Schyn, LIIHS – IRIT, Université Toulouse, France

Research Infrastructure

15:10 p.m. Eye Bed
Ted Selker, Winslow Burleson, Jessica Scott, and Mike Li, MIT Media Lab, Cambridge, USA

15:40 pm. MUMIN: A Nordic Network for MUltiModal Interfaces
Patrizia Paggio, Center for Sprogteknologi, Copenhagen, Kristiina Jokinen, University of Art and Design, Helsinki, and Arne Jönsson, University of Linköping

System Evaluation

16:00 pm PROMISE - A Procedure for Multimodal Interactive System Evaluation

Nicole Beringer, Ute Kartal, Katerina Louka, Florian Schiel, Uli Türk, University of Munich, Germany

16:30 - 17:00 p.m. **Afternoon Break**

17:00 p.m. Final Group Discussion
All

18:00 p.m. Close

Table of Contents

Table of Contents (Concluded)

Preface

Motivation

Individual organizations and countries have been investing in the creation of resources and methods for the evaluation of resources, technologies, products and applications. This is evident in the US DARPA HLT programme, the EU HLT programme under FP5-IST, the German MTI Program, the Francophone AUF programme and others. The European 6th Framework program (FP6[1]), planned for a start in 2003, includes multilingual and multisensorial communication as major R&D issues. Substantial mutual benefits can be expected from addressing these issues through international cooperation. Nowhere is this more important than in the relatively new areas of multimedia (i.e., text, audio, video), multimodal (visual, auditory, tactile), and multicodal (language, graphics, gesture) communication.

Multimodal resources are concerned with the capture and annotation of multiple modalities such as speech, hand gesture, gaze, facial expression, body posture, graphics, etc. Until recently, only a handful of researchers have been engaged in the development of multimodal resources and their application in systems. Even so, most have focused on a limited set of modalities, custom annotation schemes, within a particular application domain and within a particular discipline. Until now, the collection and annotation of multimodal corpora has been made on an individual basis; individual researchers and teams typically develop custom coding schemes and tools within narrow task domains. As a result, there is a distinct lack of shared knowledge and understanding in terms of how to compare various coding schemes and tools. This makes it difficult to bootstrap off of the results and experiences of others. Given that the annotation of corpora (particularly multimodal corpora) is very costly, we anticipate a growing need for the development of tools and methodologies that enable the collaborative building and sharing of multimodal resources.

Increased International Attention

Recently, several projects, initiatives and organisations have addressed multimodal resources with a federative approach:

- At LREC2000, a workshop addressed the issue of multimodal corpora, focusing on meta-descriptions and large corpora http://www.mpi.nl/world/ISLE/events/LREC%202000/LREC2000.htm
- NIMM is a working group on Natural Interaction and Multimodality under the IST-ISLE project (http://isle.nis.sdu.dk/). Since 2001, NIMM has been engaged with conducting a survey of multimodal resources, coding schemes and annotation tools. Currently, more than 60 corpora are described in the survey. The ISLE project is developed both in Europe and in the USA (http://www.ldc.upenn.edu/sb/isle.html).
- In November 2001, ELRA (European Language Resources Association) conducted a survey of multimodal corpora including marketing aspects (http://www.icp.inpg.fr/ELRA/).
- In November 2001, a Working Group at the Dagstuhl Seminar on Multimodal Fusion and Coordination received 28 completed questionnaires from participating researchers; 21 announced their intention to collect and annotate multimodal corpora in the future. (http://www.dfki.de/~wahlster/Dagstuhl_Multi_Modality/)
- Several recent surveys have focused specifically on multimodal annotation coding schemes and tools (COCOSDA, LDC, MITRE).

[1] http://www.cordis.lu/rtd2002/fp-debate/fp.htm

Other recent initiatives in the United States include:

- NIST Automatic Meeting Transcription Project (http://www.nist.gov/speech/test_beds/mr_proj): "The National Institute of Standards and Technology (NIST) held an all-day workshop entitled "Automatic Meeting Transcription Data Collection and Annotation" on 2 November 2001. "The workshop addressed issues in data collection and annotation approaches, data sharing, common annotation standards and tools, and distribution of corpora. ... To collect data representative of what might be expected in a functional meeting room of the future, [NIST has] created a media- and sensor-enriched conference room containing a variety of cameras and microphones."
- ATLAS (http://www.nist.gov/speech/atlas): Also at NIST, "ATLAS (Architecture and Tools for Linguistic Analysis Systems) is a recent initiative involving NIST, LDC and MITRE. ATLAS addresses an array of applications needs spanning corpus construction, evaluation infrastructure, and multimodal visualisation."
- TALKBANK (http://www.talkbank.org): TALKBANK is funded by the National Science Foundation (NSF). Its goal "is to foster fundamental research in the study of human and animal communication. TalkBank will provide standards and tools for creating, searching, and publishing primary materials via networked computers." One of the six sub-groups is concerned with communication by gesture and sign.

Objective

The primary purpose of this one day workshop (feeding into a subsequent half day Multimodal Roadmap workshop) is to report and discuss multimodal resources, annotation standards, tools and methods, and evaluation metrics/methods, as well as strategize jointly about the way forward. The workshop consists of short presentations and facilitated sessions with the intent of jointly identifying grand challenge problems, a shared understanding of and plan for multimedia resources and applications, and identification of methods for facilitating the creation of multimedia resources.

Scope

The workshop focuses on multimodal resources, annotation and evaluation. Workshop participants were encouraged to annotate multimodal corpora samples using their own coding scheme or tool and report results at the workshop. Topics in the call for papers, listed in its entirety at http://www.lrec-conf.org/lrec2002/lrec/wksh/Multimodality.html, included but were not limited to:

- Guidelines, standards, specifications, models and best practices for multimedia and multimodal LR
- Methods, tools, and procedures for the acquisition, creation, management, access, distribution, and use of multimedia and multimodal LR
- Methods for the extraction and acquisition of knowledge (e.g. lexical information, modality modelling) from multimedia and multimodal LR
- Integration of multiple modalities in LR (speech, vision, language)
- Ontological aspects of the creation and use of multimodal LR
- Machine learning for and from multimedia (i.e., text, audio, video), multimodal (visual, auditory, tactile), and multicodal (language, graphics, gesture) communication
- Exploitation of multimodal LR in different types of applications (information extraction, information retrieval, meeting transcription, multisensorial interfaces, translation, summarisation, www services, etc.)
- Multimodal information presentation
- Multimedia and multimodal metadata descriptions of LR
- Applications enabled by multimedia and multimodal LR
- Benchmarking of systems and products; use of multimodal corpora for the evaluation of real systems
- Processing and evaluation of mixed spoken, typed, and cursive (e.g., pen) language processing
- Evaluation of multimodal document retrieval systems (including detection, indexing, filtering, alerting, question answering, etc.)
- Automated multimodal fusion and/or multimodal generation (e.g., coordinated speech, gaze, gesture, facial expressions)

Table 1 below lists the papers included in the workshop, the primary task focus of the article, the kinds of modalities focused on, and the multimodal research issues addressed in the papers.

TABLE 1. Overview of Contributions

Focus	Contribution	Author(s)	Modality	Research Issues
Resources and Annotation	Data Resources and Annotation Schemes for Natural Interactivity: Purposes and Needs	Laila Dybkjær and Niels Ole Bernsen	multimodal	Natural interactivity, data resources, coding schemes, coding purposes, coding needs

Any international workshop demands the selfless contributions of many individuals. We first thank the authors and participants for their important contributions. We next thank the Organizing Committee for their time and effort in providing detailed and high quality reviews and counsel. And we thank Paula MacDonald at MITRE for her excellent administrative workshop support.

Abstract

This paper reports on work carried out in the ISLE project on natural interactivity and multimodal resources. Information has been collected on a large number of corpora, coding schemes and coding tools world-wide. The paper focuses on corpora and coding schemes and the purposes for which they were developed or which they could serve.

1. Introduction

The long-term vision of natural interactivity envisions that humans communicate, or exchange information, with machines (or systems) in the same ways in which humans communicate with one another, using thoroughly co-ordinated speech, gesture, gaze, facial expression, head movement, bodily posture, and object manipulation [Bernsen 2001]. The idea of multimodality is to improve human-system interaction in various ways by using novel combinations of (unimodal) input/output modalities [Bernsen 2002]. Natural interactivity is by nature (mostly) multimodal. Across the world, researchers and companies are beginning to tap the potential of natural interactive and multimodal systems. This emerging community needs information about what is already there, how they might access it, what they might use it for, etc., in order that fewer people try to re-invent the wheel than would otherwise risk being the case. In many ways, we are only at the start of what could be a revolution in human-system interaction. It will be some time before a new community of researchers and developers, coming from what is currently an archipelago of widely dispersed areas and specialties, has consolidated in this most exciting field of exploration.

This paper provides an overview of selected aspects of the information on data resources (corpora) and annotation schemes that was collected in the European Natural Interactivity and Multimodality (NIMM) Working Group of the joint EU-HLT/US-NSF project International Standards for Language Engineering (ISLE).

ISLE is the successor of EAGLES (European Advisory Group for Language Engineering Standards) I and II and includes three working groups on lexicons, machine translation evaluation, and NIMM, respectively. The NIMM Working Group (isle.nis.sdu.dk) began its work in early 2000 and has now completed three comprehensive surveys. The surveys address NIMM data, annotation schemes, and annotation tools, respectively. Focus has been on producing descriptions which are systematically organised, follow standard formats, have been verified by the resource creators themselves, and provide interested parties in research and industry with the information they need to decide if a particular resource matches their interests. Each resource (data, coding scheme or tool) comes with contact information on its creator(s) and on how to get access to it. To our knowledge, the surveys significantly contribute to our common knowledge of the state of the art in data, coding schemes, and tools for natural interactivity and multimodal interaction. It appears that no other published work has produced comparatively large collections of information on NIMM resources.

The survey of NIMM data resources [Knudsen et al. 2002a] includes a total of 64 resources world-wide, 36 of which are facial resources and 28 are gesture resources. Several data resources combine speech with facial expression and/or gesture. The report also includes a survey of market and user needs produced by ELRA (the European Language Resources Agency) and 28 filled questionnaires collected at the Dagstuhl workshop on Coordination and Fusion in Multimodal Interaction held in late 2001.

The survey of NIMM corpus annotation schemes [Knudsen et al. 2002b] includes 7 descriptions of annotation schemes for facial expression and speech, and 14 descriptions of annotation schemes for gesture and speech. In addition, the survey draws some conclusions on current coding best practices based on the collected material.

The survey of NIMM corpus coding tools [Dybkjær et al. 2001a] describes 12 annotation tools and ongoing tool development projects, most of which support speech annotation combined with gesture annotation, facial expression annotation, or both. Conclusions on requirements to be met by a general-purpose NIMM annotation tool are made and further refined in [Dybkjær et al. 2001b].

Based on the above ISLE NIMM reports, in particular [Knudsen et al. 2002a and 2002b], this paper reviews the purposes for which the surveyed data resources and coding schemes have been used or are intended to be used, and discusses annotation best practices.

2. Purposes of data resources

This section provides an overview of the purposes for which, according to their creators, the data resources collected in ISLE NIMM have been applied or are intended to be applied (Section 2.1). A summary is then presented of selected results from a market study performed by ELRA and included in [Knudsen et al. 2002a] (Section 2.2).

2.1. Data resources

Many of the 64 reviewed NIMM data resources were found via the web. Others were found through proceedings of specialised conferences and workshops [Knudsen et al. 2002a]. When a resource can be downloaded from the web, this is indicated in the report. For each data resource, contact information is provided so that the resource creators can be contacted and asked how to obtain the resource if it is not directly accessible.

The collected data resources reflect a multitude of needs and purposes, including the following (in random order):

- automatic analysis and recognition of facial expressions, including lip movements;
- audio-visual speech recognition;
- study of emotions, communicative facial expressions, phonetics, multimodal behaviour, etc.;
- creation of synthetic graphical interface characters, including, e.g., talking heads;
- automatic person identification;
- training of speech, gesture and emotion recognisers;
- multimodal system specification and development.

In many cases, the people working with the data, in particular those working with static image analysis, have created their own resource databases. Algorithms for image analysis are sometimes dependent on lighting conditions, picture size, subjects' face orientations, etc. Thus, computer vision research groups may have had to create their own image databases with good reason. Image analysis using computer vision techniques remains a difficult task, and this may be the reason why we have primarily found static image resources produced by workers in this field.

In other areas, (dynamic) video recordings - mostly including audio - are needed. For example, studies of lip movements during speech, co-articulation, audio-visual speech recognition, temporal correlations between speech and gesture, and relationships among gesture, facial expression, and speech, all require video recordings with audio.

Across the collected data resources, re-use is a rare phenomenon. If a resource has been created for a specific application purpose, it has usually been tailored to satisfy the particular needs of its creators, highlighting, e.g., particular kinds of interaction or the use of particular modality combinations. Figure 1 provides an overview of the data resources reviewed, including the purpose(s) for which they were created or have been used.

Modalities	**Name of data resource**	**Purpose(s)**
Dynamic face	LIMSI Gaze Corpus (CAPRE)	Track face, nose and eyes.
Dynamic face, audio	Advanced Multimedia Processing Lab	Lip reading, speech-reading techniques for higher speech recognition accuracy.
	ATR Database for bimodal speech recognition	Research, speech recognition and speech-to-lip generation (animated agents, talking face), observations on the differences in lighting conditions, size of lips, and inclination of a face.
	The BT DAVID Database	Research on audio-visual technologies in speech or person recognition, synthesis, and communication of audio-visual signals.
	Data resources from the SmartKom project	Collect data for the training of speech, gesture and emotion recognisers, to develop dialogue and context models and to investigate how users interact with a machine that has far greater communication skills than at present.
	FaceWorks	Enable multimedia developers to create digital personalities.
	M2VTS Multimodal Face Database	User authentication, lip tracking, face recognition, extend the scope of application of network-based services by adding novel and intelligent functionalities enabled by automatic verification systems combining multimodal strategies (secured access based on speech, image and other information).
	M2VTS Extended Multimodal Face Database – (XM2VTSDB)	Lip tracking, eye coordinate determination, face and speech authentication. Large multi-modal database, which will enable the research community to test their multi-modal face verification algorithms on a high-quality large dataset.
	Multi-talker database	Quantitatively characterize optical speech signals, examine how optical phonetic characteristics relate to acoustic and physiological speech production characteristics, study what affects the intelligibility of optical speech signals, and apply the knowledge obtained to optical speech synthesis and automatic speech recognition.

	VIDAS (VIDeo ASsisted with audio coding and representation)	Devise suitable methodologies and algorithms for time-correlated representation, coding and manipulation of digital A/V bit streams.
	/'VCV/ database	Study lip shape characterisation during speech.
	ATR Database for Talking Face	Research.
	Audio-Visual Speech Processing Project	Research.
	Video Rewrite	Facial animation system to automate all the labelling and assembly tasks required to resynchronise existing footage to a new soundtrack.
Dynamic face, audio, gesture	NITE Floorplan Corpus (Natural Interactivity Tools Engineering)	Test resource for cross level, cross modality analysis of natural interactive communication.
	Scan MMC (Score Analysed MultiModal Communication)	Research on facial expression and gesture.
	Multi-modal dialogue corpus	Research on multi-modal dialogue.
Static face	3D_RMA: 3D database	Validation of facial 3D face acquisition by structured light, recognition experiments by 3D comparison.
	AR Face Database	Create a better resource for face recognition and expression recognition.
	AT&T Laboratories Database of Faces	Face recognition research.
	CMU Pose, Illumination, and Expression (PIE) database	Collect material for the design and evaluation of face recognition algorithms (facial expression detection, temporal issues of facial expressions and other kinds of analysis of facial expressions).
	Cohn-Kanade AU-Coded Facial Expression Database	Develop and test algorithms for facial expression analysis.
	FERET Database Demo	Face recognition.
	Psychological Image Collection at Stirling (PICS)	Psychological research (visual perception, memory and processing).
	TULIPS 1.0	Test lip-tracking algorithms.
	UMIST Face Database	Examine pose-varying face recognition.
	University of Oulu Physics-Based Face Database	Face recognition under varying illuminant spectral power distribution.
	VASC – CMU Face Detection Databases	Train and test face detection algorithms.
	Visible Human Project	Studies of anatomy, creation of synthetic models and test image segmentation algorithms.
	Yale Face Database	Research on face recognition.
	Yale Face Database B	Face recognition under various poses and illumination.
	3D Surface Imaging in Medical Applications	Medical applications.
	Facial Feature Recognition using Neural Networks	Face recognition.
	Image Database of Facial Actions and Expressions	Train neural networks to classify facial behaviours based on FACS.
	JAFFE Facial Expression Image Database	Research on facial expression.
	Photobook	Tool for performing queries on image databases based on image content.
Gesture	MPI Experiments with Partial and Complete Callosotomy Patients Corpus	Research on split-brain patients.
	National Center for Sign Language and Gesture Resources	Support research on sign language.
	ATR sign language gesture corpora	Creation of an inventory of the most important words of Japanese sign language as a basis for the development and evaluation of gesture recognition systems.
Gesture, audio	ATR Multimodal human-human interaction database	Provide a source for analysing the relation between speech and gesture.

	CHCC OGI Multimodal Real Estate Map	Compare the linguistic differences and relative ease of processing multimodal input compared with unimodal input.
	GRC Multimodal Dialogue during Work Meeting	Study the patterns of multimodal communication during a work session about collaborative conception.
	LIMSI Pointing Gesture Corpus (PoG)	Basis for specification of a recognition system
	McGill University, School of Communication Sciences & Disorders, Corpus of gesture production during stuttered speech	Study relations between gesture and stuttered speech.
	MPI Historical Description of Local Environment Corpus	Research.
	MPI Living Space Description Corpus	Research.
	MPI Locally-situated Narratives Corpus	Research.
	MPI Narrative Elicited by an Animated Cartoon "Canary Row" Corpus 1	Research.
	MPI Narrative Elicited by an Animated Cartoon "Canary Row" Corpus 2	Research.
	MPI Narrative Elicited by an Animated Cartoon "Maus" and "Canary Row" Corpus	Research.
	MPI Natural Conversation Corpus	Research.
	MPI Naturalistic Route Description Corpus 1	Research.
	MPI Naturalistic Route Description Corpus 2	Research.

Gesture, face, audio	University of California Video Series on Nonverbal Communication	Research on non-verbal communication, including facial expressions, tones of voice, gestures, eye contact, spatial arrangements, patterns of touch, expressive movement, cultural differences, and other "nonverbal" acts.

Figure 1. The reviewed data resources and their purposes.

2.2. Market study

A market study on data resources and user needs was performed by ELRA. A questionnaire was sent to more than 150 people, including ELRA members and people from both industry and academia. 25 responses were received. Among others, the questionnaire included questions on (1) the types of data resources needed, used by, or offered by, respondents, (2) the kinds of task for which data resources are well suited, and (3) the areas in which data resources are being used.

2.2.1. Types of data resources needed or offered

The NIMM data resources in which the respondents seem most interested include audio, video and image resources. Audio is most popular (mentioned by 84% of the respondents) followed by video (mentioned by 52%) and image (mentioned by 28%). If a data resource has also been annotated, this is considered an advantage since value has been added. In many cases, the users of data resources produce the resources they need themselves. Sometimes these resources are also offered to other users.

Authentication: Speech verification (8), Face verification (6), User authentication (5). Other: finger print and signature, biometric authentication (speech, signature).

Recognition: Speech recognition (14), Face recognition (7), Person recognition (3), Expression recognition (3). Other: mimic, music and other sounds, gesture recognition, gestures on a touchscreen.

Analysis: Speech/lips correlation (7), Body movements tracking (lips, hands, head, arms, legs, etc.) (6). Other: co-operation between gesture and speech; acoustics, video, 3D optical, midsagital magnetometry; written language analysis.

Synthesis: Multimedia development (6), Talking heads (5), Humanoid agents (5), Avatars (2). Other: text generation.

Control: Voice control (7), Speech-assisted video (1).

Other: Information retrieval (14), Other: multimodal command languages (speech + gesture), research into cross-modality issues, multimodal dialogue (speech + gesture), linguistic research, information extraction, text summarisation.

Figure 2. Resource application list from the ELRA report in [Knudsen et al. 2002a, chapter 8]. Numbers in parentheses indicate how many respondents gave a particular answer.

2.2.2. What can data resources be used for

The questionnaire mentioned six general task categories for which data resources may be used. For each category, a number of more specific possibilities were listed. Respondents were supposed to indicate the kinds of applications they were interested in. Responses are shown in Figure 2. The primary applications of data resources are information retrieval and speech recognition, each of which were mentioned by 14 respondents. Then follows speech verification mentioned by 8, and face recognition, speech/lips correlation, and voice control, each mentioned by 7 respondents.

2.2.3. Application areas

To get an idea of the overall application or market areas for data resources, the questionnaire listed five possibilities (including "other") among which respondents were asked to choose the ones they found appropriate to their work. The area mentioned most frequently was research (21). Then follows information systems development (e.g. banking, tourism, telecommunication) (14), web applications development (10), education/training (9), and edutainment (6). Other areas proposed include security, control of consumer devices, and media archiving for content providers.

3. Purposes of annotation schemes

This section provides an overview of the purposes for which the reviewed coding schemes [Knudsen et al. 2002b] have been created or used (Section 3.1). Then follows a brief description of practices and best practices as these emerged from the collected material (Section 3.2).

3.1. Annotation schemes

There probably exists a wealth of NIMM annotation schemes most of which are tailored to a particular purpose and used solely by their creators or at the creators' site. Such coding schemes tend not to be very well described. They also tend to be hard to find. The reviewed material includes such coding schemes many of which were created by ISLE participants or people known to ISLE participants, this being the main reason why we were aware of them. Other coding schemes included are fairly general ones, in frequent use, or even considered standards in their field, cf. Section 3.2.

Nearly all the reviewed coding schemes are aimed at markup of video, possibly including audio. A couple of schemes can be used for static image markup.

The collected material comprises schemes for markup of a single modality as well as schemes for markup of modality combinations. Figure 3 provides an overview of the majority of the schemes reviewed, including the annotation purpose for which they were created. The coding scheme descriptions which have not been included below are of a more general nature and do not concern any particular coding scheme and its purpose(s).

3.2. Practices and best practices

In most cases, a coding scheme has been created because a person or site had a particular need, e.g. related to systems development.

In the area of facial expression, MPEG-4 is considered a standard and is being widely used. FACS is also used by many people but is not really well suited for markup of lip movements. ToonFace is good for 2D caricature but not for real (or life-like) facial expression. Other reviewed facial expression schemes seem to have been used by a single person or by a few people only.

In the area of gesture, the picture seems considerably more varied than for facial expression. Where facial expression is often the sole point of focus, gesture often seems to be studied along with other modalities. Only when it comes to the highly specialised area of sign

languages, the schemes we looked at focused solely on gesture. Many other gesture schemes were created to study gesture in combination with one or several other modalities with the purpose of supporting the development of a multimodal system. There are no real standards for gesture markup. HamNoSys seems to be the most frequently used among the schemes we looked at as regards gesture annotation-only. For gesture in combination with other modalities there are many schemes – mostly used by few people - but no standardisation.

The picture, provided by the survey, of a proliferation of home-grown coding schemes is supported by the 28 questionnaires in [Knudsen et al. 2002a], asking people at a multimodal interaction workshop, e.g., which coding scheme(s) they had used or planned to use for data markup. Some people did not answer the question or had not made a decision yet as to which coding scheme to use. However, in no less than 15 cases the answer indicated that a custom-made scheme would be, or was being, used. Only a few respondents also mentioned more frequently used annotation schemes, such as TEI, BAS, or HamNoSys.

Intended for markup of	**Name of coding scheme**	**Purpose of creation**
Gaze	The alphabet of eyes	Analyse any single item of gaze in videotaped data.
Facial expression	FACS (facial action coding system)	Encode facial expressions by breaking them down into component movements of individual facial muscles (Action Units). Suitable for video or image.
	BABYFACS	Based on FACS but tailored to infants.
	MAX (Maximally Discriminative Facial Movement Coding System)	Measure emotion signals in the facial behaviours of infants and young children. Suitable for video or image.
	MPEG-4	Define a set of parameters to define and control facial models.
	ToonFace	Code facial expression with limited detail. Developed for easy creation of 2D synthetic interface agents.
Gesture	HamNoSys	Designed as a transcription scheme for (different) sign languages.
	SWML (SignWriting Markup Language)	Code utterances in sign languages written in the SignWriting System.
	MPI GesturePhone	Transcribe signs and gestures.
	MPI Movement Phase Coding Scheme	Coding of co-speech gestures and signs.
Speech and gesture	DIME (Multimodal extension of DAMSL)	Code multimodal behaviour (speech and mouse) observed in simulated sessions in order to specify a multimodal information system.
	HIAT (Halbinterpretative Arbeitstranskriptionen)	Describe and annotate parallel tracks of verbal and non-verbal (e.g. gestural) communication in a simple way.
	TYCOON	Annotation of available referable objects and references to such objects in each modality.
Text and gesture	TUSNELDA	Annotation of text-and-image-sequences, e.g. from comic strips.
Speech, gesture, gaze	LIMSI Coding Scheme for Multimodal Dialogues between Car Driver and Copilot	Annotation of a resource which contains multimodal dialogues between drivers and copilots during real car driving tasks. Speech, hand gesture, head gesture, gaze.
Speech, gesture and body movement	MPML (A Multimodal Presentation Markup Language with Character Agent Control Functions)	Allow users to encode the voice and animation of an agent guiding a web site visitor through a web site.
Speech, gesture, facial expression	SmartKom Coding scheme	Provide information about the intentional information contained in a gesture.

Figure 3. Reviewed coding schemes and their purposes.

4. Conclusion

Even if we have reviewed a large number of data resources and coding schemes, there probably exist many other NIMM corpora and coding schemes which we did not manage to identify. Many resources are not publicly accessible and their creators do not want to share them with others. Thus, they can be very hard to find. But also, our primary focus has been on resources which are accessible to people other than their creators. We believe that the collected information and resulting reports, although probably far from being exhaustive, reflect quite well the state-of-the-art in the NIMM resources area.

If this is indeed the case, some conclusions are: to a large extent, people still create their own single-purpose data resources and coding schemes without any strong guidance by best practice and standards, and hence without any strong purpose of sharing their resources with others. However, vendors of data resources exist, such as ELRA and LDC, and standards will emerge eventually and become applied. The standardisation process seems to be further advanced for facial expression than for gesture, and for gesture combined with other modalities there is still a long way to go.

In the ISLE project we do not have the resources required for regularly extending the information collected with new data, coding schemes or coding tools. Therefore, a web-based facility will be set up which will enable any interested colleague to upload information about a NIMM resource which has not been included already. We hope that our colleagues in the emerging NIMM community will use the facility to help each other by sharing their information with others and contribute to maintaining an up-to-date and valuable pool of NIMM resource information.

5. Acknowledgements

We gratefully acknowledge the support of the ISLE project by the European Commission's Human Language Technologies (HLT) Programme. We would also like to thank all ISLE NIMM participants for their report contributions which have made the present presentation possible. In particular, we have in this paper drawn on information provided by ELRA, Catherine Pelachaud, Isabella Poggi and Jean-Claude Martin.

Metadata Set and Tools for Multimedia/Multimodal Language Resources

P. Wittenburg, D. Broeder, F. Offenga, D. Willems

Max-Planck-Institute for Psycholinguistics
Wundtlaan 1, 6525 XD Nijmegen, The Netherlands
peter.wittenburg@mpi.nl

Abstract

Within the ISLE Project about International Standards for Language Engineering the IMDI Metadata Initiative developed a complete environment for creating, maintaining and using metadata descriptions for multimedia/multimodal language resources. This environment includes a proposal for a suitable metadata set, tools to create, browse and search in IMDI metadata domains and suggestions about how to organize centers acting as metadata repositories. By using the IMDI approach a formulation in RDF is intended which enable the IMDI set to be integrated in Semantic Web activities.

1. Introduction

In 1999 the Max-Planck Institute for Psycholinguistics started using metadata to organise its multi-media corpora [1]. This project was called "Browsable Corpus" (BC) because it not only used metadata for resources in order to make them locatable by automatic procedure, but it also used metadata for creating a hierarchical structure that can be browsed for the purpose of corpus exploitation. This was achieved by recursively structuring corpora in ever-smaller sub-corpora structures with each one described by its own metadata description pointing to the metadata descriptions of its sub-corpora. Creating browsable structures this way which creates space to integrate many other types of information such as project notes, also formed a basis for efficient corpus management.

The basic concepts of BC were used as one of the inputs to the ISLE Metadata Initiative (IMDI) [2] founded in early 2000. IMDI aims to reach consensus within a representative part of the linguistic community on a standard for metadata descriptions for multimedia/multimodal language resources. The IMDI metadata set is currently being applied within projects such as DOBES [3], the CGN corpus [4] and, of course the MPI's own corpora. Its relevance was checked for several other multimedia corpora such as the SmartKom [5] corpus. A preliminary showcase combined corpus data from 6 European institutions into one browsable and searchable domain.

2. Using Metadata Descriptions

A key issue in the IMDI approach is that a metadata set should be used for corpus discovery and corpus management as well as corpus exploitation. This implies that the metadata set should be able to describe the resources in sufficient detail to allow the resolution of relevant queries for the domain. It also implies that linked networks of metadata descriptions should be available, generated either automatically or manually and that it should be possible to include human readable texts or files with the metadata descriptions that can assist the user when browsing through a corpus. Corpora organized in this way can be easily integrated into bigger domains and they are an extremely useful facility for corpus managers to group all relevant information and knowledge together to facilitate corpus management. In this domain of linked metadata descriptions the user would be able to browse and search and as a result find a single resource or a sub-corpus to work on. Consequently the user is likely to want to start a suitable tool for analysis, i.e. the metadata must contain information which indicates which operations can be executed on the resources found. Within IMDI it was anticipated that each user has his own view on corpora, therefore it was concluded that the IMDI environment should provide users the possibility of creating their own hierarchies so that several views can co-exist in parallel.

Of course, metadata will always exist as a source of information distributed via Internet, therefore all resources including the metadata descriptions themselves have to be specified as URLs. In this way metadata descriptions and connected resources can be accessed on the Internet by using standard HTTP. This simplifies the connection of different corpus domains to one super-domain. To support global searches via, for example, Dublin Core [6] based service providers, the IMDI domain is available for metadata harvesting in compliance with the Open Archives Initiative protocol [7].

Although the concept of metadata descriptions is still fairly new, the community is becoming aware that metadata descriptions will facilitate re-usage of valuable resources. Currently, most of the many resources are hidden in the storage containers of the various institutions and companies. Only few of them are visible via web-sites each having its own style of description. Since metadata are available to everyone, a domain of unified descriptions form an ideal way of informing others about available data even if the resources themselves are not directly accessible.

3. IMDI Metadata Set

IMDI's guiding principles when defining a metadata set have been that the best way to describe linguistic resources is to be able to describe the events and/or performances that are involved in their creation and usage by the community. The descriptions need to contain as much detail as necessary for a user who needs to easily discover resources, quickly check their usefulness and immediately exploit them. This bottom up approach can be compared with the approach in the media and film community which defined the MPEG7 standard [8]. It can and will lead to a more extensive and structured set than, for instance, the Dublin Core set. In taking such an

approach, the metadata set found can be seen as a first step towards a more complex domain ontology.

Some argue that it is necessary to have a low-overhead metadata set, since users may not want to spend too much time in providing all the information defined by the proposed IMDI element set. For IMDI the solution is that efficient tools are provided and that almost all fields are optional. So the overhead argument in case of more elaborate metadata sets does not hold, if elements are optional as in the IMDI case. Flexibility of the set of elements was one of the recurrent requirements, since we deal with a large number of different projects all recording multimedia material. In IMDI, flexibility was introduced by allowing user definable keyword/value pairs at several levels in the metadata structure.

The IMDI set for sessions[1] contains the necessary elements to describe the project a resource belongs to, the responsible scientists who created it, date and location of the recording, its content, its media files and annotations and if available the its derivative source. In the following a list of all elements is given. It is not the purpose of this paper to explain in detail what all the elements represent. For this we refer to the IMDI web-site: http://www.mpi.nl/ISLE. An attribute specifies whether the element is just a string, constrained (c), associated with a closed vocabulary (ccv) as in the case of "Continents" or with an open vocabulary (ov) which is open for extensions, or refers to a sub-block of information (sub).

[1] Sessions are the leaves in a corpus tree and cover units of linguistic analysis or performance including their media and annotation files. The IMDI initiative has defined a few other very similar metadata sets for corpus nodes, published corpora and lexica. They are not discussed in this paper.

[2] Descriptions are a field which the annotator can use to enter prose text intended for quick inspection by the user.

[3] Keys are those fields which guarantee flexibility. Each project or even user can define extensions in form of key-value pairs.

It is important to mention here how multimedia and multimodality can be described in IMDI. The IMDI set allows the user to describe the *Content* of a session which refers to a unit of analysis in the corpus. Each session is associated with the media and annotation resources belonging together. The IMDI set has elements to describe the *Communication Context*, the *Genre*, the *Task*, the *Modalities*, the *Languages involved*, and to add other useful project specific elements.

In most instances the associated vocabularies clarify what the definition of the element is although IMDI has already provided careful definitions. The element *Task* stands for typical experimental tasks occurring in language engineering and field-linguistics such as *info-kiosk situation, route description, wizard-of-oz experiment, frog-story.* The element *Modalities* has, of course, a vocabulary which includes, amongst others, *speech, gesture, sign, facial expression.*

As can be seen, the IMDI set has elements not only to describe content, but also to describe the *Media Files* (type of data, format of file, quality of material, conditions of recording, etc), the available *Annotations* (type of annotation, format of file, etc), and the *Original Media* (cassette, MD, etc) if available. To give the user immediate feedback ob accessibility, IMDI contains elements to describe the access rights and whom to contact to obtain the resources.

As already indicated, Controlled Vocabularies (CVs) associated with elements are an important component of the IMDI metadata set and its tools, since they will guarantee that elements are used coherently by researchers and that search operations will provide the correct resources.

To achieve interoperability with Dublin Core (a more general set of 15 partially vaguely defined elements used to describe web resources used by the general public) a mapping document was created. Based on DC, another set (OLAC [9]) was created to achieve interoperability in the language resource domain. IMDI repositories will be open to OAI [7] type of metadata harvesting to implement the interoperability with DC and OLAC.

The IMDI set is defined in all respects through an XML Schema which is available at the IMDI web-site. All tools generate and operate on these XML files.

4. IMDI Tools

The tools that support the IMDI metadata set and infrastructure are:

- ? The IMDI BCEditor that is used to create IMDI metadata descriptions.
- ? The IMDI BCBrowser. A viewer for the IMDI metadata descriptions that allows navigating the universe of connected IMDI metadata descriptions.
- ? The IMDI Search tool that allows the user to specify a query for specific resources in the IMDI universe.
- ? A number of scripts allowing to work efficiently

All tools were programmed in Java and Perl for platform independence and are downloadable from the web-site: http://www.mpi.nl/tools.

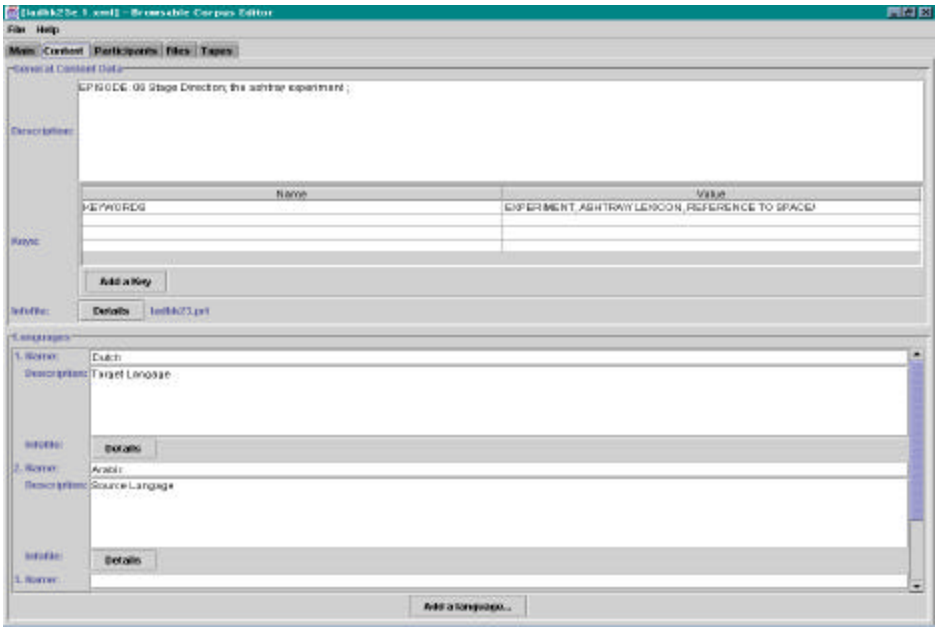

Figure 1 shows a screenshot from the IMDI Editor

The editor presents all the IMDI metadata elements in a structured GUI to the user. It supports the use of Controlled Vocabularies and user definable keyword/value pairs that the IMDI set allows for user or project specific extensions. Also it enforces constraints on the values for some metadata elements where applicable and practical. To aid working efficiency the editor allows the re-usage of a number of element blocks which will recur in many metadata descriptions such as biographical data of the informants and collectors. The editor is programmed to synchronize with repositories providing controlled vocabularies on user command if the computer the editor is running on is connected to the web. This mechanism ensures that the user can download and use the most recent definitions, e.g. of the names of countries. Internationally agreed notation conventions allow differences between different vocabularies. For example, the ISO language lists contain only a few hundred language names and the Ethnologue list [10] contains more than 4000 names. In fact users can add their own

lists but searching would become a problem if there is no mapping definition.

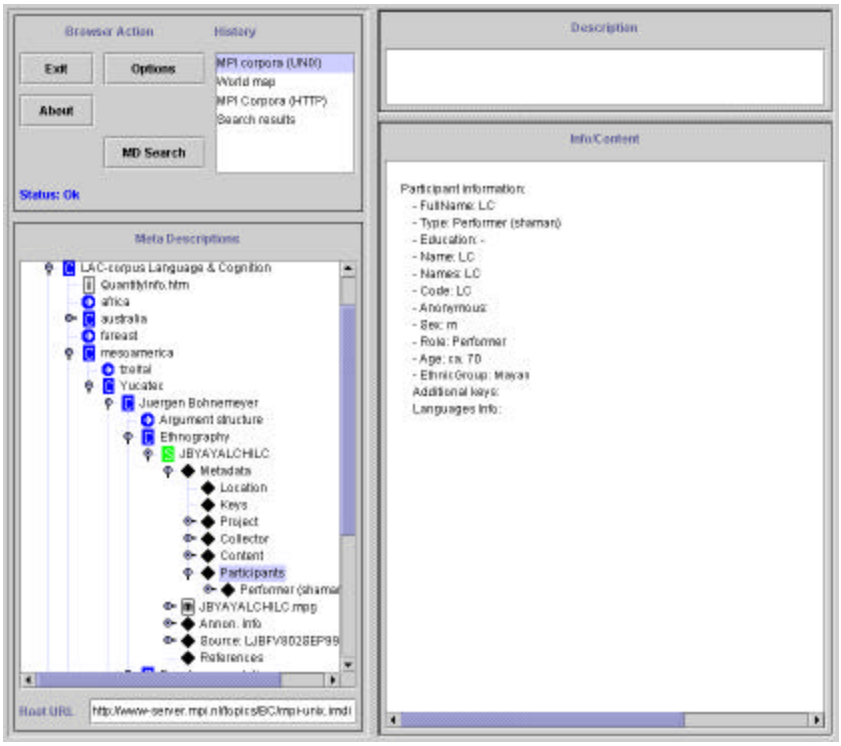

Figure 2 shows a screenshot of the IMDI browser.

The IMDI BCBrowser is the central tool for exploiting the IMDI metadata infrastructure. It allows navigation in the domain of linked IMDI metadata descriptions by clicking on corpus links. The browser keeps track of its position in the browsable corpus structure and displays the metadata and human readable descriptions associated with the sub-corpus in focus. It allows the user to set bookmarks so that easy navigation is facilitated.

The browser is also capable of displaying HTML formatted or PDF files that are often provided as extra documentation for corpora. It is possible to link in such HTML pages or PDF files in the corpus tree. From the HTML pages there may be links back to metadata descriptions making it possible to mix classical HTML browsing with browsing the IMDI corpus universe.

An interesting application of this is a world map that was created as a portal of the MPI corpora. This world map is viewable as an HTML file but has, at the appropriate places, links to metadata descriptions for corpora that correspond to those locations. We are presently engaged in trying to incorporate a professional geographic information system since the HTML world map is not completely satisfactory. The worldmap is just one other alternative view on a corpus since it is organized according to geographical principles.

One of the very important functions of the browser is that It offers the user a set of appropriate tools for further analysing resources once they have been located and it allows for operation in a distributed scenario where all resources are indicated by URLs. Each user or group of users can create a configuration file containing information on how to immediately start a tool and pass over the necessary parameters to start the tool with the discovered resource(s). The browser offers a selection from which the user can choose.

The search tool is the most recent IMDI development. It allows the user to specify a query for sessions whose metadata complies with the specified constraints. The UI offers the user an easy way to specify a query compliant with the IMDI element set, the elements value constraints and CVs used.

Results are presented in the form of URLs for the session metadata description files that comply with the query. The user may make these sessions visible in the IMDI-BCBrowser for further inspection or a special corpus label can be created containing all these sessions that can be saved for future reference and processing. The search tool can, of course, be started from the IMDI-BCBrowser. The search tool has to be extended to support the distributed architecture underlying the IMDI concept and it has to be checked as to how it can support harvesting of other metadata repositories by, for instance, using the OAI protocol. Currently, two teams are working on an improved search tool working in fully distributed scenarios.

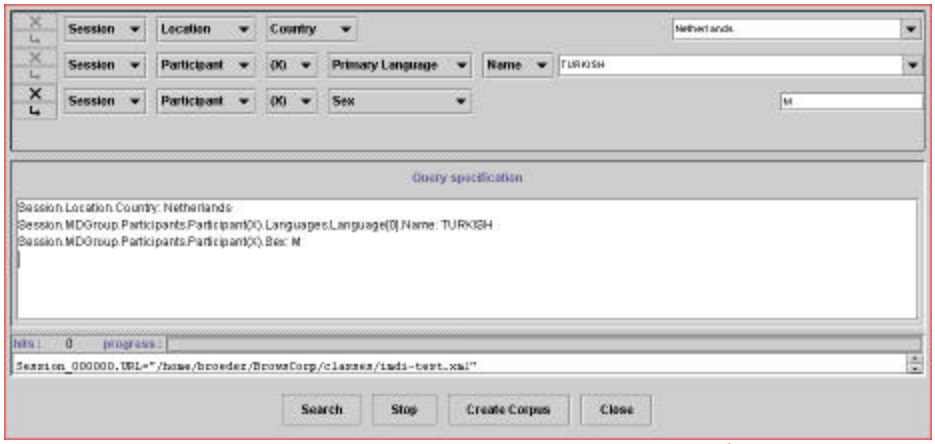

Figure 3 shows a screenshot from the search component.

The IMDI team also created a number of scripts which allow users to efficiently work with IMDI type of metadata descriptions. One such tool is provided to add or change element values in a whole range of MD descriptions by one command. Another allows the user to create metadata descriptions from spreadsheet documents, although this has proved problematic. Spreadsheet entries are not guided by constraints or controlled vocabularies

therefore conformity has to be checked very carefully. There are a few other minor scripts which will hopefully become obsolete when the editor or browser have been extended.

5. IMDI Corpora

At present we have available as IMDI tagged corpora:

- the MPI corpora of the "Acquisition" and "Language and Cognition" group which contains more than 2 TB of media data and more than 7000 multimedia sessions;
- a large second learner language acquisition corpus also containing audio recordings;
- the data of the DOBES project about endangered languages where also audio and video recordings form the basis;
- the data of the CGN (Spoken Dutch Corpus) project.

Furthermore we have been experimenting with converting parts of existing corpora to see if the IMDI set is applicable. These tests range from the well-known "Childes" corpora [11] to language engineering corpora as "TIMIT" [12] and "SmartKom". An interesting project was also the construction of a distributed corpus with examples of (parts of) corpora of six different European institutes. This was demonstrated as a first distributed IMDI scenario during the official opening ceremony of the "European Year of the Language" in Lund in 2001.

6. Future Developments

As a preliminary solution and part of the IMDI showcase, the MPI serves as a focal point maintaining the IMDI web portal as a starting point for the IMDI universe and maintaining the IMDI metadata Schema and CV definitions. However, the MPI does not have ambitions to perform this task in the long run. Such hosting activities are better performed by organisations such as BAS [13], ELRA and LDC. The maintenance of the IMDI set and the related tools by the MPI has been secured for many years by using them in different long-term projects. Besides these organisational problems, there is also a need for further tool development, such as a tool offering users a graphical interface for creating alternative "personal" corpus trees. Maintenance tools are required that allow users to copy parts of corpus trees to other portable media such as CDROM and DVD. In this way they can work under field conditions or make personal archive copies.

A major revision of the IMDI metadata set is expected to occur in 2002, therefore comments on how to improve it are welcome. According to the most recent discussions, it can be concluded that the MD set in general is very mature and stable with the exception of a very few elements such as "Anonymous". But the elements and vocabularies which were defined to describe the content of the resources have to be modified after a year of experience. Here, the elements define the dimensions of descriptions and the vocabularies the values along these dimensions. Although the current definitions are based on linguistic experience, it is obvious that not all contents can be described equally well with them.

Currently, the IMDI definitions are specified with the help of an XML Schema, i.e. the relations between concepts are implicitly defined in the structured IMDI set. To open up the way to the Semantic Web these implicit relations will be explicitly defined with the help of RDF [14]. All RDF Schemas will be put into open RDF repositories so that they can be re-used. It has to be checked whether it will be possible to make use of already existing descriptions within the IMDI set.

Abstract

The Friedman Osborn Martell (FORM) system for annotating gestures has been created for the purpose of producing a corpus of speech and its corresponding gestures. The corpus is open source and will be available to all researchers who wish to use it in their work. FORM attempts to capture the kinematics of gesture using *quasi*-geometric descriptions of the locations/shapes and movements of the arms and hands. Currently, we have a pilot corpus of 22 minutes of gesture-annotated video of Brian MacWhinney teaching a Research Methods course at Carnegie Mellon University. There are plans to extend the corpus to include not only speech transcriptions and syntactic information, but also body-movement and intonational information as well. We are currently gathering other data of various types and in various settings to add to the corpus. All of these data will be be published under the TalkBank project (http://www.talkbank.org).

1. Introduction

In "An Agenda for Gesture Studies" (Kendon, 1996), Adam Kendon outlines a long-term research agenda for a better understanding of gesture and its relationship to the communicative process. A major aspect of that agenda is the development of what Kendon calls the "Kinetics of Gesture":

> Such a programme of work could be linked to, and would contribute importantly, to research on what might be called the 'kinetics' of gesture (in parallel to 'phonetics'). We really have little explicit knowledge about how gestures are organized as physical actions.... An important part of the 'kinetics' research should include a study of just how gesture phrases are organized in relation to speech phrases.

The FORM project began, in large part, as a response to this challenge[1]. FORM is an annotation scheme designed both to describe the kinematic information in a gesture, as well as to be extensible in order to add speech and other conversational information.

Our plan, then, is to build an extensible corpus of annotated videos in order to allow for general research on the relationship among the many different aspects of conversational interaction. Additionally, further tools and algorithms to add these annotations and evaluate inter-annotator agreement will be developed. The end result of this work will be a corpus of annotated conversational interaction, which can be:

- extended to include new types of information concerning the same conversations; as new tag-sets and coding schemes are developed—discourse-structure or facial-expression, for example—new annotations could easily be added;
- used to test scientific hypotheses concerning the relationship of the paralinguistic aspects of communication to speech and to meaning;
- used to develop statistical algorithms to automatically analyze and generate these paralinguistic aspects of communication (e.g., for Human-Computer Interface research).

2. FORM

2.1. The Annotation Scheme

FORM is designed as a series of tracks representing different aspects of the gestural space. Generally, each independently moved part of the body has two tracks, one track for Location/Shape/Orientation, and one for Movement. When a part of the body is held without movement, a Location object describes its position and spans the amount of time the position is held. When a part of the body is in motion, Location objects with no time period are placed at the beginning and end of the movement to show where the gesture began and ended. Location objects spanning no period of time are also used to indicate the Location information at critical points in certain complex gestures. See Figure 1 for a snapshot of FORM implimented using the Anvil tool (Kipp, 2001).

[1]The authors wish to sincerely thank Adam Kendon for his input on the FORM project. He has provided not only suggestions as to the direction of the project, but also his unpublished work on a kinematically-based gesture annotation scheme was the FORM project's starting point (Kendon, 2000).

An object in a movement track spans the time period in which the body part in question is in motion. It is often the case that one part of the body will remain static while others move. For example, a single hand shape may be held throughout a gesture in which the upper arm moves. FORM's multi-track system allows such disparate parts of single gestures to be recorded separately and efficiently and to be viewed easily once recorded. Once all tracks are filled with the appropriate information, it is easy to see the structure of a gesture broken down into its anatomical components.

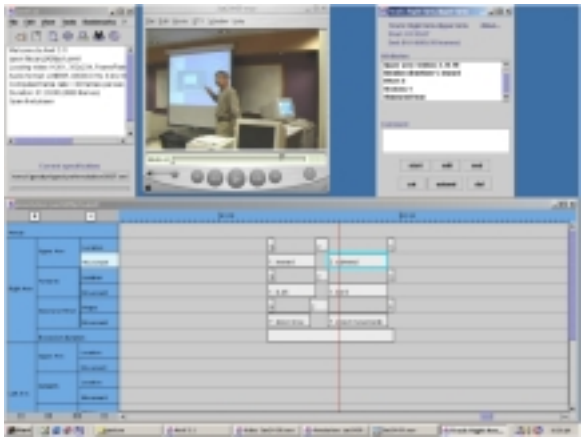

Figure 1: FORM annotation of Jan24-09.mov, using Anvil as the annotation tool

At the highest level of FORM are groups. Groups can contain subgroups. Within each group or subgroup are tracks. Each track contains a list of attributes concerning a particular part of the arm or body. At the lowest level (under each attribute), all possible values are listed. The structure, then, is as follow:

Group

Subgroup

Track

ATTRIBUTE

Value

The following descriptions will follow this structure. The groups described are Right/Left Arm, Gesture Obscured, Excursion Duration, and Two-Handed Gesture. Not described are Head and Torso Movement/Location. These will be implimented in a later version of FORM.

Right/Left Arm

Upper Arm (from the shoulder to the elbow).

Location

UPPER ARM LIFT (from side of the body)

no lift
0-45
approx. 45
45-90
approx. 90
90-135
approx. 135
135-180
approx. 180

RELATIVE ELBOW POSITION: The upper arm lift attribute defines a circle on which the elbow can lie. The relative elbow position attribute indicates where on that circle the elbow lies. Combined, these two attributes provide full information about the location of the elbow and reveal total location information (in relation to the shoulder) of the upper arm.

extremely inward
inward
front
front-outward
outward (in frontal plane)
behind
far behind

The next three attributes individually indicate the direction in which the biceps muscle is pointed in one spatial dimension. Taken together, these three attributes reveal the orientation of the upper arm.

BICEPS: INWARD/OUTWARD

none
inward
outward

BICEPS: UPWARD/DOWNWARD

none
upward
downward

BICEPS: FORWARD/BACKWARD

none
forward
backward

OBSCURED: This is an binary attribute which allows the annotator to indicate if the attributes and values chosen were "guesses" necessitated by visual occlusion. This attribute is present in each of FORM's tracks.

Movement

The next three attributes individually indicate the direction of elbow movement in one spatial direction. When diagonal movement occurs, a non-none (i.e.not *none*) value for more than one of the attributes is chosen. Each attribute has combination values so repeated or back-and-forth motions can be annotated as such.

LINEAR MOVEMENT (HORIZONTAL PLANE: Indicates the direction(s) of inward or outward elbow movement.

none
inward
outward
inward-outward
outward-inward

LINEAR MOVEMENT (MEDIAN PLANE): Indicates the direction(s) of upward or downward elbow movement.

none
up
down
up-down
down-up

LINEAR MOVEMENT (FRONTAL PLANE): Indicates the direction(s) of elbow movement towards or away from the body.

none
towards
away
towards-away
away-towards

UPPER ARM ROTATION: The degree of change of bicep direction. Ranges are exclusive. Direction of change is not included, as it can be inferred from the information in the Location track.

0-45
approx. 45
45-90
approx. 90
90-135
approx. 135
135-180
approx. 180
greater than 180

ARC-LIKE MOVEMENT: This boolean attribute indicates whether or not the elbow movement was arc-like. When checked, Location objects will co-occur to note the location of the elbow at the beginning, apex, and end of the movement.

CIRCULAR MOVEMENT: A non-none value indicates that elbow movement is circular in shape and notes the plane in which the movement is performed as well as its direction (clockwise or counter-clockwise). As was the case for arc-like movements, the Location track will be simultaneously utilized, in this case noting the location of the elbow at the start and halfway mark of the circle. This convention allows the size of the circle to be inferred.

parallel to horizontal plane (c=clockwise)
parallel to horizontal plane (cc=counter-clockwise)
parallel to median plane (c)
parallel to median plane (cc)
parallel to frontal plane (c)
parallel to frontal plane (cc)

EFFORT: Indicates the effort of the movement on a 1 to 5 scale.

1
2
3
4
5

STROKES: Indicates the number of strokes of a movement.

1 . . . 20
More than 20
Indeterminate

OBSCURED

Forearm: the part of the arm extending from the from elbow to wrist)

Location

ELBOW FLEXION: The angle made by the bend in the elbow.

0-45
approx. 45
45-90
approx. 90
90-135
approx. 135
135-180

FOREARM ORIENTATION: Describes the orientation of the forearm if the upper arm were to be by the side and the elbow flexed at 90 degrees.

supine
supine/neutral
neutral
neutral/prone
prone
prone/inverse
inverse

OBSCURED

Movement

ELBOW FLEXION CHANGE: The amount of change in elbow flexion measured in degrees. Direction of flexion change is not indicated, as it can be inferred from information in the Location track.

0-45
approx. 45
45-90
approx. 90
90-135
approx. 135
135-180
approx. 180

FOREARM ROTATION: Direction of change of forearm orientation. Amount of change is not indicated, as it can be inferred from information in the Location track.

none
inward
outward
inward-outward
outward-inward

EFFORT

STROKES

OBSCURED

Hand and Wrist

Shape: Information about the static shape of the hand and orientation of the wrist.

The next two attributes give values to describe the shape of the hand. The values are represented in a catalog of hand-shapes (Figure 2), which is organized as a two-dimensional matrix. This method is employed because the complexity of the hand would make purely physicalistic descriptions too unwieldy.

HAND-SHAPE GROUP: Indicates the group (organized by number of extended fingers with 0 representing fist and 6 referring to miscellaneous shapes) in the hand shape catalog.

0
1
2
3
4
5
6

HAND-SHAPE LETTER: Indicates the appropriate hand-shape within the selected group.

A
B
C
D
E
F
G
H
I
J
K
L
M

TENSION: Describes the amount of tension apparent in the performer's hand. An average amount of tension corresponds to the "slightly tense" variable.

relaxed
slightly tense
very tense

WRIST BEND: UP AND DOWN: How far the wrist is bent towards the upper side or under side of the forearm.

up
up-neutral
neutral
down-neutral
down

Figure 2: Catalog of Handshapes. Based on the HamNoSys catalog (http://www.sign-lang.uni-hamburg.de/Projects/HamNoSys.html)

WRIST BEND: SIDE TO SIDE: How the wrist is bent towards the thumb or little finger.

towards thumb
neutral
towards little finger
extremely towards little finger

PART OF BODY TOUCHED:

none
top of head
eye (same)
eye (opposite)
ear (same)
ear (opposite)
temple (same)
temple (opposite)
nose
cheek (same)
cheek (opposite)
chin
neck (same side)
neck (center)
neck (opposite side)
chest
groin

OBSCURED

Movement

HAND MOVEMENT: Describes type of hand movement (if any). The A joint refers to the knuckle furthest from the fingertip and the B joint refers to the first joint above the A joint. Information about the C joint (the joint closest to the fingertip) is not recorded because C joint movement is usually dependent upon movement of the B joint. The numbering scheme of the first three variables is explained in the Finger Coordination attribute.

none
1) A joint movement
2) B joint movement
3) A and B joint movement
wrist circular
thumb rubbing index finger
thumb rubbing multiple fingers
direct movement between two shapes

WRIST UP-DOWN MOVEMENT: Describes the up-down movement (to the underside or upper side of the arm) of the wrist.

up
down
up-down
down-up

WRIST SIDE-TO-SIDE MOVEMENT

towards little finger
towards thumb
towards little finger-towards thumb
towards thumb-towards little finger

FINGER COORDINATION: Describes the motion of the fingers in relationship to each other. A non-none value is only applicable if one of the choices labeled 1, 2, or 3 was selected from the Hand movement attribute.

parallel movement without thumb
random movement, without thumb
parallel movement, with thumb
random movement, with thumb
movement in sequence

EFFORT

STROKES

OBSCURED

Excursion Duration: Marks the length of the excursion of the arm from a resting position to another resting position. Since there is ambiguity about what constitutes a single gesture, this convention for grouping was adopted.

Gesture Obscured: Similar to above except this attribute refers to the entire gesture duration, rather than just one track.

Two-handed Gestures

RIGHT-HAND CONTACT

none
thumb
index finger
middle finger
ring finger
little finger
palm
back of hand
more than one digit
holding

LEFT-HAND CONTACT: The list of values is identical to that of the Right-hand Contact attribute.

The following seven attributes are all boolean-valued.

MOVING IN PARALLEL

MOVING APART

MOVING TOWARDS

MOVING AROUND ONE ANOTHER

MOVING IN ALTERNATION

CROSSED

OBSCURED

2.2. Ambiguities/Imprecisions in FORM

There are two known ambiguities/imprecisions in the current version of the FORM system.

The first concerns the ***Upper Arm***:*Location* attributes that specify biceps direction. While anatomically it seems more accurate to describe the upper arm rotation by degrees of rotation rather than by using the direction of the biceps in free space, a problem arises when defining the neutral position of the arm rotation. For example, we could define *normal* as the position when the arm is held at the side with palm facing towards the body and the elbow flexed to make a 90-degree angle with the upper arm. If one then lifts the upper arm to the side so it is at 90 degrees with the body and still in the frontal plane, the upper arm has not rotated at all. Let's call this position 1. If, however, one returns to the starting position, raises the upper arm forward so it is at 90 degrees with the body but parallel to the median plane, and then moves the upper arm 90 degrees to the side so that it is in the frontal plane again, it can be seen that this position is also reached without rotating the upper arm. Let's call this position 2. It is clear that position 1 is not the same as position 2, but both were reached by keeping the upper-arm in the *normal* position.

To solve this issue we could define a normal that is rotated 45 degrees when the Upper arm lift is at what we've deemed "approx. 90" and Relative elbow position is "front-outward." This convention, however, is hard to conceptualize by annotators and thus we opted to use the direction of biceps in free space since it is more intuitive. The downside to this approach is that it allows for a large range of positions for each combination of values. Many positions could be called "forward-inward-upward," for example.

The second area of concern is in the ***Upper arm***:*Movement* track. This track describes the movement of the upper arm independent of the forearm, elbow flexion, and hand-and-wrist. This movement can be described either as a combination of linear movement in different planes or as arc-like movement (using Location points to denote points along the curve). Since the upper arm is only

able to move on a partial sphere with the shoulder as the center, it does not make sense anatomically to describe its movement as linear. However, since most movements are small enough not to appear as distinct arcs, linear values sufficiently approximate the movement.

3. The Current FORM Corpus[2]

3.1. Pilot Corpus

We currently have a pilot corpus of about 22 minutes of Brian MacWhinney teaching a Research Methods course at Carnegie Mellon University. These data were chosen since they were freely available via the the TalkBank project (http://www.talkbank.org). They have been very useful for the pilot phase of the project as people often gesture in a clear and exaggerated fashion while teaching. See (Martell, 2002) for a further description of the data format (Annotation Graphs (Bird and Liberman, 1999)), as well as examples of the video and of tool currently being used (Anvil (Kipp, 2001)).

3.2. Annotation Complexity

An experienced annotator can create approximately 3 seconds of annotation per hour. He/she can annotate at most for 6 hours per day, generating 18 seconds/day. Accordingly, it will take an experienced annotator 5 work days to annotate a 90-second video of conversational interaction.

Generating only 90 seconds of annotation per work week makes such an annotation project seem a daunting task. However, the amount of information contained in conversational gesturing is substantial—on the order of 3500 distinct ATTRIBUTE:Value pairs per minute. This underscores the potential value of such a corpus, viz. there is seemingly much more information in 90 seconds of communicative interaction than we are currently capturing by only transcribing speech.

3.3. Preliminary Inter-Annotator Agreement Results

Preliminary results from FORM show that with sufficient training, agreement among the annotators can be very high. Table 2 shows preliminary interannotator agreement results from a FORM pilot study.[3] The results are for two trained annotators for approximately 1.5 minutes of Jan24-09.mov, the video from Figure 1. For this clip, the two annotators agreed that there were at least these 4 gesture excursions. One annotator found 2 additional excursions. Precision refers to the decimal precision of the time stamps given for the beginning and end of gestural components. The *SAME* value means that all time-stamps were given the same value. This was done in order to judge agreement with having to judge the exact beginning and end of an excursion factored out. *Exact* vs. *No-Value* percentage refers to whether both the attributes and values matched exactly or whether just the attributes matched exactly. This distinction is included because a gesture excursion is defined as all movement between two rest positions of the arms and hands. For an excursion, the annotators have to judge both which parts of the arms and hands are salient to the movement (e.g., upper-arm lift and rotation, as well as forearm change in orientation and hand/wrist position) as well as what values to assign (e.g., the upper-arm lifted 15-degrees and rotated 45-degrees). So, the *No-Value%* column captures the degree to which the annotators agree just on the structure of the movement, while *Exact%* measures agreement on both structure and values.

The degree to which inter-annotator agreement varies among these gestures might suggest difficulty in reaching consensus. However, the results on *intra*-annotator agreement studies demonstrate that a single annotator shows similar variance when doing the same video-clip at different times. Table 3 gives the intra-annotator results for one annotator annotating the first 2 gesture excursions of Jan24-09.mov.

Gesture Excursion	Precision	Exact%	No-Value%
1	2	3.41	4.35
	1	10.07	12.8
	0	29.44	41.38
	SAME	56.92	86.15
2	2	37.5	52.5
	1	60	77.5
	0	75.56	94.81
	SAME	73.24	95.77
3	2	0	0
	1	19.25	27.81
	0	62.5	86.11
	SAME	67.61	95.77
4	2	10.2	12.06
	1	25.68	31.72
	0	57.77	77.67
	SAME	68.29	95.12

Table 1: Inter-Annotator Agreement on Jan24-09.mov

Gesture Excursion	Precision	Exact%	No-Value%
1	0	5.98	7.56
	1	20.52	25.21
	0	58.03	74.64
	SAME	85.52	96.55
2	2	0	0
	1	25.81	28.39
	0	89.06	95.31
	SAME	90.91	93.94

Table 2: Intra-Annotator Agreement on Jan24-09.mov

For both sets of data, the pattern is the same:

- the less precise the time-stamps, the better the results;
- *No-Value%* is significantly higher than *Exact%*.

It is also important to note that Gesture Excursion 1 is far more complex than Gesture Excursion 2. And, in both sim-

[2] Most of this section is taken from (Martell, 2002)

[3] Essentially, all the arcs for each annotator are thrown into a bag. Then all the bags are combined and the intersection is extracted. This intersection constitutes the overlap in annotation, i.e., where the annotators agreed. The percentage of the intersection to the whole is then calculated to get the scores presented.

ple and complex gestures, inter-annotator agreement is approaching intra-annotator agreement. Notice, also, that for Excursion 2, inner-annotator agreement is actually better than intra-annotator agreement for the first two rows. This is a result of the difficulty for even the same person over time to precisely pin down the beginning and end of a gesture excursion. Although the preliminary results are very encouraging, all of the above suggests that further research concerning training and how to judge similarity of gestures is necessary. Visual information may need very different similarity criteria.

4. Future Directions and Open Questions

As mentioned in the introduction, the goal of the FORM project is to create a corpus to be used for both scientific and technological research concerning gesture and its relationship to the rest of the communicative process. However, in order to build a corpus suitable for these goals, a number of issues have to be addressed.

Augmentation of the FORM corpus with other aspects of communication is necessary. Over the next 3 years, as we continue to build the FORM corpus, we will also be augmenting it with:

- Speech transcriptions and syntactic information;
- Body movement, in the form of head and torso information; and
- Intonation and pitch contour information.

Much research is needed to discover the best annotation schemes for each of these aspects, as well as to discover which algorithms are best for uncovering the correlations among them.

Better methods of annotation need to be developed. Although we belief it will prove necessary to continue to annotate at a fine-grained level of detail, it is currently too expensive to make using FORM practical. We intend to use the hand-annotated corpus, as it grows, to explore automatic or semi-automatic methods of annotation.

Visualization and Animation Tools which will "play back" an annotation are needed to allow an annotator to better judge the correctness of his/her annotation. Additionally, these visualization tools may be able to help ease the annotation process. If we are able to develop a close enough mapping between the animated character and the annotation scheme, we may be able to use a movable animated character as a means to input the data. Research is need to see if this will indeed speed up the process.

New Metrics for Inner-Annotator Agreement need to be explored. As mentioned in Section 3.3, above, our current numbers are based on the bag-of-arcs technique. However, as the scores there indicate, often annotators agree to a large degree on structure, but differ only on exact beginning or ending timestamp, or on the value of an attribute. Unfortunately, small differences in timestamp and value are judged incorrect to the same degree as large differences. Visual feedback, as just described, will allow us to discover whether small differences in coding actually have little difference visually. If this proves to be the case, then we will need to experiment with more geometrically-based measures of similarity, e.g., distance in n-dimensional space.

Statistical Experiments using FORM are already underway. If FORM is to be successful, it must be shown that our fine-grained analysis sufficiently captures the phenomena in question. To do this we are conducting two sets of experiments.

- We have annotated some of the corpus with Preparation-Stroke-Retraction information. Using standard training-set/test-set methods, we are building Preparation-Stroke-Retraction recognizer system. If the results of these experiments are sufficiently high, we will have demonstrated that FORM captures at least as much information as a more coarse-grained annotation scheme.
- However, only showing that FORM is a as good as coarse-grained annotation scheme is not sufficient justification for using FORM. Accordingly, we are also working on a Statistical Gesture Generation System (SGGS). Given some input set of sentences, the SGGS, if successful, will be able to output those sentences augmented with a FORM description of valid accompanying gestures. This, then, could be used with the above described annimation tool to automatically generate animated gesture excursions.

5. Conclusion

The FORM project has develped a geometrically-based gesture annotation scheme and a 22-minute pilot corpus of gesture-annotated video. Over the next few years, the corpus will be augmented and new tools and algorithms will be developed. The envisioned goal of the project is a large-scale corpus of multi-modal annotations suitable for both scientific and technological research concerning the relationships among different aspects of communicative interaction.

Wundtlaan 1, 6525 XD Nijmegen, The Netherlands
peter.wittenburg@mpi.nl

Abstract

Gestures are culture specific forms of arm movements which are used in communication to transfer information to the listener, to guide the planning of the speech production process and to disambiguate the incoming speech. To understand the underlying mechanisms gestures have to be analyzed in cross-linguistic processes. Large projects are necessary covering speakers from various cultural background and many recordings. Such projects can only be successfully carried out, when suitable gesture encoding schemes, generic annotation schemes, powerful tools supporting the schemes and efficient methods for easy resource discovery and management are available. At the Max-Planck-Institute all aspects were tackled.

1. Introduction

The MPI for Psycholinguistics has a long history of research on the synchronization between different modalities in human communication. In the 1980s eyetracking signals and signals about pointing gestures produced important information about the mental processes responsible for speech production [1, 2]. Such signals were typically recorded in relation to spoken utterances. The equipment used was designed to make automatic fine grained temporal analysis possible. For gesture registration IR-light based methods were used. Mort recently, ultrasonic equipment was used for this purpose identifying the location of maximally 8 sources. This tradition is still continued in the baby labs where eye tracking is recorded to study, for example, the focus of childrens' attention during linguistic tasks. In recent years brain imaging methods (EEG, MEG, PET, MRI) have often been added to get online information about brain activities during speech production and perception task.

In the last few years, research using multimodality shifted towards observational methods in communicative situations of various sorts. Child-caretaker interaction is studied with the help of extensive video recordings to better understand how childrens' language learning is influenced by input and environmental factors. The use of various types of gestures (pointing, iconic and emblematic) is studied in different situations. The following studies should be mentioned in particular: (1) ethnography of pointing gestures; (2) gestural facilitation of speaking or understanding; (3) gestural expression of motion events; (4) speech dysfluencies and gestures; (5) influence of gestures on recipients' gaze movement; (5) hemispheric specialization of types of gestures [3, 4, 5, 6, 7, 8]. In addition, studies about sign language and their comparison to gestural patterns were carried out. The goal of these recordings is fundamental research about the relation between language and thought and the role of gesture in human communication. Since gestures are very much dependent on language and culture, most of the recordings are cross-linguistic, i.e. various countries and cultures are included.

Nowadays the study of multimodal communication based on video recordings is much easier. Information technology allows science to work with digitized video greatly facilitating the analysis work. For the last two years, all recordings at the MPI have been digitized. yielding an online multimedia corpus consisting of more than 7000 sessions (units of linguistic analysis). Gesture studies form a substantial part of these recordings. Powerful corpus management with the help of metadata descriptions and multimodal annotation tools were developed at the institute to enable the type of research explained. Annotations are stored in well-documented formats well adapted to capturing the complexity of the annotation which are typical of multimodal studies.

2. Multimodality Research

Multi-modal records allow us not only to approach old research problems in new ways, but also open up entirely new avenues of research. An old issue, for example, is just how 'modular' language processing is, that is to what extent non-linguistic processes can intervene in the course of linguistic processing. This can be studied by looking at the interaction between two entirely different behaviour streams, gesture and speech. A large multi-media corpus of natural dialogue shows, for example, that when speakers self-edit speech, gesture inhibition actually occurs earlier, suggesting interaction between the speech and gesture execution systems. Similarly, in the comprehension process it can be shown that gesture content is incorporated into the immediate 'message'. Eye-tracking shows that speakers can manipulate the likelihood of this by looking at their own gestures, which are then more often fixated by listeners. More fundamentally, we can look at the role of the two cerebral hemispheres in the production of the two behaviour streams, speech and gesture. Careful studies of the gestures of split-brain patients show that gesture production is largely driven from the right hemisphere, while language of course is normally processed in the left.

In addition to contributing to such long-standing theoretical issues, annotated multimedia records also make possible entirely new lines of research. For example, we have been interested in whether the semantic character of a specific language leads to a special construal of a scene to be described. The study of gesture during online production shows that the way a language 'packages' information has a demonstrable effect on the depiction of

a scene in gestures. Turkish for example packages movement with direction in a single clause but puts manner of motion into a separate adverbial clause ('The ball descended, rolling') – while English allows manner and direction to occur in the same simple clause ('The ball rolled down'). Turkish speakers tend to produce separate gestures for direction and manner, while English speakers tend to fuse them. In a similar way, we have been able to study spatial thinking as it occurs in non-spatial domains, by examining the gestures of speakers talking about e.g. kinship relations.

Sign languages are another domain which has been opened up by multi-media technology. Sign languages are fully-expressive languages which utilize not only the hands, but also the face, gaze and even body-posture to construct complex utterances with phonology, morphology, syntax and 'prosody'. These different 'articulators' express different distinctions in overlapping time windows, where the offset can indicate e.g. the scope of a question. Even the simplest description of a signed utterance therefore requires a multi-tiered annotation of a video-record, and the development of such annotation tools make possible systematic databases for sign language research for the first time. Fascinating questions can now be pursued about effects of modality on language – for example does the spatial nature of the visual-gestural channel have profound effects on the nature of sign languages, andgive sign languages an underlying commonality? Most deaf signers are exposed to the gestural systems of the surrounding spoken language, and we can also ask to what extent these gestural systems are recruited into the sign language. Preliminary results from the study of a sign language in the process of standardization (Nicaraguan sign language) suggests that there is such an interaction.

These examples should serve to indicate just what a revolution in our understanding of language and its relation to other aspects of cognition is being made possible by the new technologies. There are also fundamental advantages to archiving multi-media records for all branches of the language sciences. For example, studies of the acquisition of language are hugely enriched by having available the very scene available to the infant language user – we now know for example that unexpressed arguments (e.g. subjects and objects) in Inuit care-takers' speech are often recoverable by the child just because they are most likely in the child's field of view at the moment of utterance. Similarly, records of dying or endangered languages are greatly enhanced by having visual information correlate with the language use. In all these cases, richly annotated multi-media records make possible the extraction of systematic information about the correlation of linguistic and non-linguistic events.

3. Gesture Encoding Schemes

General

This variety of studies all based on observational methods (i.e. audio and video, sometimes also gaze) required many different gesture encoding schemes on the different linguistic levels, efficient procedures and powerful tools. Since our researchers are involved in international projects broad agreements on the methods for encoding multimodal behavior are very important. Yet for international standards it seems to be too early, the discipline is too young, although it would facilitate integrating and comparing the data of all the scholarly work.

Most of the studies require careful encoding of the articulator movements[1] and their global timing pattern. Naturally, we are faced with similar problems to those for identifying the articulator movements in the case of speech production. The articulator movements form a continuum, are overlapping and have tolerances dependent on the situation. Therefore, it is not only difficult to make proper time segmentation, but also to classify them.

For gestures which are movements of the arms and its parts accompanying verbal communication acts, it is sufficient to annotate their type and meaning in addition to the articulators. The type of a gesture is a taxonomic classification of its principle purpose and role in communication. It is widely accepted to separate between pointing, iconic and emblematic gestures. Pointing gestures refer to a spatial point or a movement. They appear either as isolated gestures where the meaning is obvious to the listener or mostly in overlap with verbal utterances where the gestures are much more simple to generate and interpret than verbal descriptions. Their meaning is easy to describe by the object they refer to and their intrinsic purpose. Also iconic gestures appear spontaneously as co-speech activities while emblematic gestures stand alone. Iconic gestures have a culturally bound meaning since they are widely accepted within an area.

Gestures often correlate with emotional state, are used to facilitate the planning of speech production and to facilitate speech perception due to their disambiguation capability. Emotional state can be described, although there are no clear conventions yet.

Articulators in Gestures

The basis of all scientific work when studying gestures is an encoding scheme for the articulator movements. It was soon perceived that an exhaustive gesture encoding including all relevant characteristics would be ideal but impossible (except for small segments). On the other hand the recordings were perceived as so valuable that re-usage for various research questions was anticipated. To cope with this contradiction it was realised that only an iterative encoding approach would suffice where the needs of primary research projects do not hinder the addition of gesture encodings dedicated to completely different research interests. To support research, the underlying

[1] For gestures we have as articulators the arms and its parts up to the fingers. Characteristic movements of the head and the eyes in communicative situations are not treated as part of the gesture although they have similar purposes.

scheme should be exhaustive to define a grid allowing easy computational comparison. Therefore, for a number of recordings focused on in the Institute's gesture project, a thorough study was carried out to attain a general gesture encoding scheme that would allow comparative analysis to be made easily.

Based on Kendon's work a more accurate scheme was developed by v. Gijn, vd Hulst and Kita [9] to separate various phases in a gesture. A *MovementUnit* therefore can exist of several *MovementPhrases*. Basically, each of these can be seen as a sequence of a *Preparation* phase, an *ExpressivePhase* and a *Retraction* phase. An *ExpressivePhase* which covers the meaningful nucleus of a gesture is either an *IndependentHold* or a sequence of a *DependentHold*, a *Stroke*, and another *DependentHold*.

*MovementUnit = MovementPhrase**
MovementPhrase = (Preparation) => ExpressivePhase => (Retraction)
ExpressivePhase = IndependentHold
ExpressivePhase = (DependentHold) => Stroke => (DependentHold)
Preparation = (LiberatingMovement) => LocationPreparation >> HandInternalPreparation
Retraction (if subsequent movement) = PartialRetraction

*= consists of, * one or several, => discrete transition, () optional, >> normally blended out, occasionally discrete transition*

The authors developed a set of descriptive criteria to identify the phases and their usefulness was shown in several studies which were successfully annotated by student assistants.

v. Gijn, vd Hulst and Kita also developed an encoding scheme to describe mainly the articulator movements in the *ExpressivePhase* [10]. It is this phase where annotators are confronted with all the about 60 degrees of freedom and where not only the location and shape has to be described but also for example changes in motion and direction. The following aspects are described: *PathMovementShape (straight, circle, round, iconic, 7-form, ?-form, x-form, +-form, z-form), PathMovement Direction ([up|down], [front|back], [ipsilateral| contralateral]), HandOrien-tationChange ([supination| pronation], rotation, [flexion | extension], nodding, [ulnar flexion|radial flexion], lateral flexion), HandShape Change ([opening | closing], [abduction |adduction], [hinging |dehinging], [clawing |declawing], wiggling, opening wave, closing wave, rubbing, cutting), HandOrientation ([up| down], [front | back], [ipsilateral| contralateral]), and HandShape*. For the latter basically the HamNoSys scheme was re-used.

To support the various gesture related research activities simple encoding schemes are most often derived from this exhaustive scheme. The reference back to the unified exhaustive scheme together with the online availability of the annotated multimedia document allows easy re-usage and an enhancement of the annotations. This can either be corrections of the existing or the addition of new tiers.

When encoding gestures it is of great importance to understand the exact time relationships with the verbal utterances. This is not part of the gesture annotation scheme, but the annotation structure scheme has to provide adequate mechanisms.

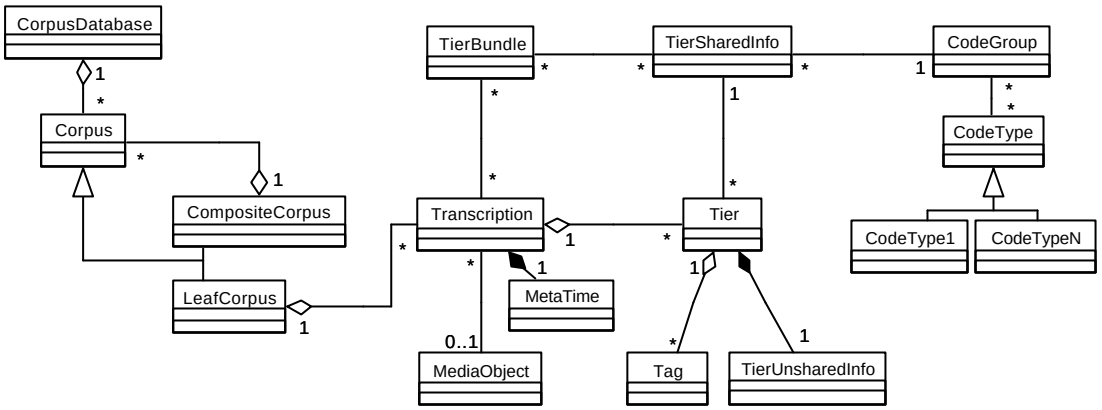
4. Annotation Structures

While the encoding scheme describes how to encode the linguistic phenomena (a close handshape in gestures is encoded as "*close*"), the annotation structure scheme describes the expressive power in structural respects. It has to provide mechanisms for all possible structural phenomena. From our long experience with gesture and sign language studies we know that the annotations can become very complex. There are projects which try to solve this complexity by merging the annotations associated with different linguistic levels into one tier. This method, which is known especially from traditional annotation schemes such as CHAT [11], is also used in new projects. The resulting annotation includes many relations implicitly, i.e. it is the tool which has to include all the knowledge. At the MPI this method was not seen as useful for the future. Different linguistic levels should be separated and all relations such as interruptions, parallelism, semantic correlation should be made explicit. This is the only way to easily modify the coding later.

In many cases different linguistic interpretations of a gesture are possible. The annotation scheme has to take this into account. Essentially, we follow the indicated way: add another tier which can be used by a new annotator. If only adaptations of the existing annotations are intended, a copy action may be useful for bootstrapping the tier.

The structural phenomena which can occur in annotations are described in detail in [12]. We can summarize the main points:

- The number of tiers can become comparatively high and cannot be seen in advance. It will increase due to various annotators and due to new research goals which require additional information.
- There are all kinds of temporal relations between gesture components and especially between annotations associated with different streams like gestures, speech, facial expression, gaze and others. The complexity makes it necessary to link annotations to periods of time and not to encode overlap and other phenomena in the annotations as older formats require.
- In some occasions spatial relations have to be encoded. They can be encoded as other annotations, i.e. individual or group of coordinate pairs can be linked to time periods.
- In many types of annotations hierarchical relationships have to be included to express linguistic phenomena. These can be token or type oriented. Type specific dependencies are defined at the level of



tier type definitions. Token specific dependencies occur randomly and are defined per linguistic unit.

- Cross-references are very relevant in many cases of linguistic annotation. They describe certain relations which the user wants to draw between two different linguistic units which can be on the same tier or on a completely different one. Comments on some annotation can be interpreted as such cross-reference.

5. Abstract Corpus Model

To design the Abstract Corpus Model informal use-case driven method was chosen. In addition a number of existing and well-known annotation formats were analyzed and discussions with linguists about their requirements were carried out. The resulting model defined in UML is more of an operational model than a mere data model.

ACM is realized in first instance as a set of abstract classes that implement common behavior. These abstract classes each have concrete subclasses, one for each of the annotation file formats that ACM currently supports (CHAT, Shoebox [13], relational database [14], Tipster [15], several varieties of XML).

The method calls from ACM's interfaces can be used by a range of annotation related tools. The interfaces are uniform to the tools although the actual objects that implement those interfaces may be instantiated from differently formatted files or even from a relational database. For example, the tools are not aware whether they work on a CHAT file or on a set of database records.

Most ACM objects are implemented as remote objects using Java's RMI facilities (Remote Method Invocation). This means that these objects can exist on a central annotation server while the annotation related tools that use their services run on local clients on the network. Method calls to a set of remote interfaces, with arguments and return value, offer a natural way to organize protocols for an annotation server. This type of support for remote objects is efficient since only data that is asked for is sent over the network, i.e. a tier name instead of a complete tier or annotation document. It also forms the basis for a collaborative annotation environment since remote objects can be simultaneously accessed by multiple users. For a class diagram of the first generation of the ACM see figure 1.

It is not the intention of this paper to discuss the part of the class diagram depicted in figure 1 in detail. For this we refer to [16]. But an example can demonstrate how to read it. In this version of ACM, *Tags* have begin and end times that can be specified or unspecified. To make this possible the order of all unaligned *Tags* (i.e. tags which have no specified time marks yet) in a *Transcription* has to be stored explicitly. The object responsible for this is called *MetaTime* and is associated with *Transcription*.

ACM Revision

Recently, the ACM was revised considerably to include new features. Merging the more elaborated BC (BrowsableCorpus) [17] and EUDICO models of corpora required the introduction of a Session class in ACM. The direct association between Transcriptions and MediaObjects is now administered by a Session object. The composite Corpus structure in ACM is maintained, but as an alternative to BC Corpus hierarchies. There was also a need to introduce Metadata, MetadataContainer and LanguageResource interfaces into ACM as a way to merge in behavior that is needed for BC.

In the first version of ACM, new objects were usually instantiated by their direct ancestors in the corpus tree e.g. Transcription objects were instantiated from LeafCorpus objects. The exact type of the LeafCorpus determined the exact type of the Transcription to be instantiated. In the case of instantiation of a Transcription from a browser over generic corpus trees (like the BC browser) we needed another way to specify the exact type of the Transcription object, and a separate mechanism for creation of this object has to be available.

We were also confronted with a number of related cases where the issue of specifying type and location, and subsequent instantiation of the proper object played a role. For example, in the case of the Spoken Dutch Corpus, currently all digital audio data is delivered on a number of CDROMs. Pointing at and accessing this data, including prompting for the proper CDROM, can be solved by a similar mechanism. For the same corpus, a variation of stand-off annotation is used for annotation documents, where separate annotation tiers are kept in separate XML files in separate directories. Instantiation of an annotation document requires pointing at and combining of these separate files.

To solve this range of problems a design was finished that makes use of the standard mechanisms that Java offers to deal with URLs. Based on a generalization of URL syntax and content type the required access mechanisms (like login prompt, prompt for media carrier) are triggered automatically and the proper type of object is instantiated. In case of ordinary URLs and content types everything automatically falls back on Java's built-in URL handling.
As said, new projects required more complex relations between annotations than the ACM could deal with in its original form. For example, for the Spoken Dutch Corpus both utterances and individual words can be (but don't have to be) time aligned, and each word can have a number of associated codes on different tiers. The Spoken Dutch Corpus also required support for syntactic trees.
For the DoBeS project a wide range of legacy material has to be incorporated in the archive and the EUDICO based archive software has to be able to cope with that. Much of this data is Shoebox or Shoebox-style MS Word data. Therefore interlinear glossing formats have to be supported at the level of ACM. Within the DoBeS community, the maximal format requirements are well described by Lieb and Drude in their Advanced Glossing paper [18].
To support all of these structures two basic types of Annotations were added: AlignableAnnotations and ReferenceAnnotations. While AlignableAnnotations has the necessary characteristics to link annotations to time periods, ReferenceAnnotations provide the necessary mechanisms to draw relations between annotations independent of their tier.

In almost every annotation system or format the concept of a tier exists as a kind of natural extension of the concept of a database field applied to time-based data. It is an old idea to "put different things in different places". A tier is the place to put similar things. A tier is a group of annotations that all describe the same type of phenomenon, that all share the same metadata attribute values and that are all subject to the same constraints on annotation structures, on annotation content and on time alignment characteristics.

Metadata attributes for example can be a participant, coder, coding quality, or reference to a parent tier. Constraints on annotation structures can be aspects such as that annotations on the tier refer to exactly one associated parent annotation on a parent tier (*1-n*) or that Annotations on the tier must be ordered in time.
Also annotation content can be constrained by for example a specific closed vocabulary and by a range of possible characters such as Unicode IPA. Constraints on time alignment can also be of various sort such as: Annotations on this tier may not overlap in time.

Explicitly including these types of constraints in the ACM makes tool support for a wide range of use cases and for user interface optimizations possible. For example, known begin or end times of annotations can be reused for new annotations or as constraints on the time segment of other annotations. Text entry boxes can be set up automatically with the proper input method for IPA, annotation values can be specified using popup menus.
Tier metadata, with attribute values specified or not specified, combined with the tier constraints could be reused as a template for the creation and configuration of new tiers, either in the same document or in another. One step further, a set of tier templates could be part of a document template, making it possible to reuse complete configurations of tiers for other documents.

6. Interchange Format

A direct consequence of the ACM is the definition of a suitable and powerful enough annotation interchange format. It is seen as a framework allowing to make ACM content persistent. Here our intentions are fairly comparable with what is currently worked out especially at NIST - called the ATLAS Interchange Format (AIF) [19]. Since AIF could not yet handle all necessary requirements (AIF did not yet support a tier concept) a EUDICO Interchange Format was defined (EAF, see Appendix). However, we would like to join the AIF train to achieve a high degree of interoperability world-wide. Its main structural components are: (1) Time slot values referring to as many as needed concrete time values; (2) information about the tier types and (3) as many AlignableAnnotations or ReferenceAnnotations as necessary. While the first refer to time slots, the latter refers to annotation IDs.

7. Tools

To provide researchers with an efficient annotation and analysis environment, the Institute began early on to setup digitization lines and to build true multimedia tools. The first was the MAC-based MediaTagger annotation tool [20] built in 1994. Consequently, the Institute decided to fully rely on all-digital techniques, i.e. all video and audio signals were digitized. For video it was decided to rely on MPEG1 (after an initial phase of using MJPEG and CINEPAK). Due to its limited resolution, for example, to identify facial expressions in field recordings, it was now decided to change to MPEG2 as a basis for the multimedia archive which has a factor of about 3 more data and bandwidth.

The development of the Java-based EUDICO Tool Set for annotating and exploiting multimedia signals was begun in 1998 and has now reached a flexibility and functionality which makes it one of the most advanced tools for multimodal work. Its nucleus is based on ACM, i.e. it has a comprehensive internal representational power. It has a flexible and easy-to-use annotation and time linking component which allows the user to define his tier setup, which can work with audio and/or video signals in the same way and which makes it possible to do the annotation in various writing systems. It has input methods, for example, for IPA, Chinese, Cyrillic, Hebrew and Arabic. Annotations can either be linked to moments in time in the media stream or to other annotations. It is possible to include hierarchical annotations which is necessary, for example, for an interlinearized representation of morphology.

The EUDICO tool set also provides various views on the multimedia data which can be sound, video, or annotation tracks or other types of signals such as eye tracking tracks. There are a number of stereotypic views on the annotations scientists prefer, therefore EUDICO supports different views and more views can be added according to individual scientists' needs. An important feature is that researchers can easily select and arrange the data tracks they want to see. All viewers in EUDICO are synchronized, i.e. whenever the cursor in a viewer is set to a certain time or segment, all other viewers will move to that instance. The tool set also has a flexible search interface which allows the user to define patterns and associate them with annotation tiers (including all supported input methods) making it possible to enter complex patterns covering several tiers and distances between the patterns. The EUDICO tool set can work in a fully distributed environment where annotation and media tracks are at different locations and support media streaming of fragments. An XML-based generic interchange format was defined (EUDICO Annotation Format), but other formats such as rDBMS, CHAT and Shoebox are also supported.

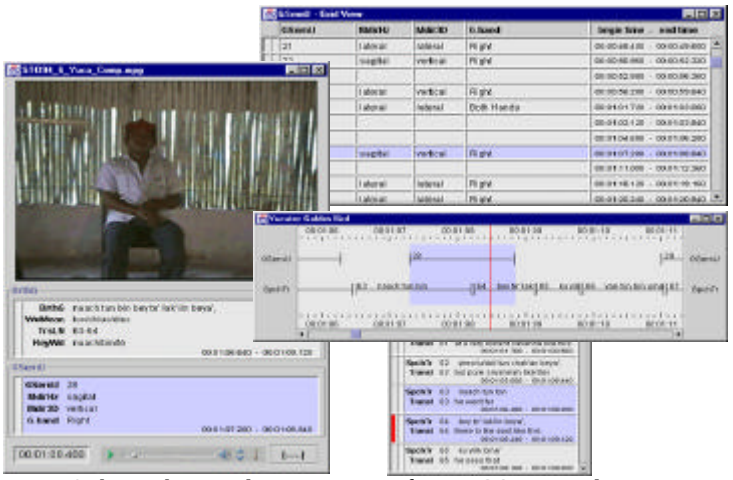


Figure 8 shows the visualization power of EUDICO. Dependent on the project different stereotypic visualizations of the material can be selected. The type of output, the tiers and the order of tiers can be selected by the user. The range of viewers covers dynamic subtitles, a time line view and text viewers with compressed texts.

Tier types can be defined including controlled vocabularies and constraints. Pixel management is very important when dealing with complex tier structures. The user can define the tiers he wants to see and specify the order of presentation. Currently, MPEG1 streaming is supported. MPEG2 is also supported, however downsizing of the video widget is absolutely necessary in order to see the annotations as well.

Further details about the EUDICO Tool Set can be seen on the web-page [21].

8. Conclusions

At the MPI for Psycholinguistic the study of gestures has a long tradition. Gesture recordings are used to better understand the basic mechanisms of the speech production and comprehension processes. Further the usage of gestures in various cultures could help clarifying the relationship between language and thought. Gestures are very much dependent on the culture and the languages spoken in these cultures.

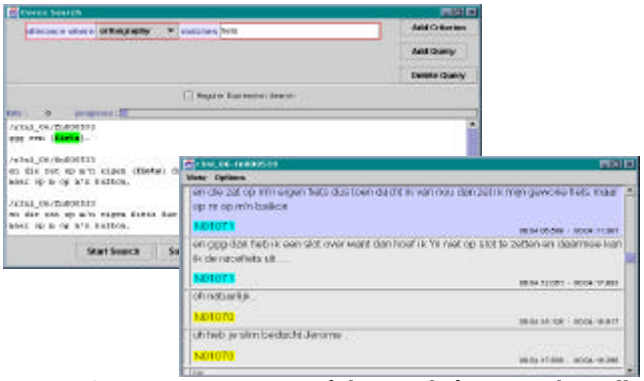

Figure 9 gives an impression of the search feature. It basically allows the user to define search patterns, associate them with tiers and logically combine these patterns to a complete query where also distances can be specified. The result is a list of hits which can be clicked to directly yield the corresponding fragment.

To support this research a large cross-linguistic gesture corpus had to be built including annotations of the speech acts and the gestures. Currently, large international projects have been setup to further investigate the scientific questions raised in this paper.

Such research was only possible by a consequent digitization policy of the institute, by building efficient multimodal annotation and exploitation tools and by powerful mechanisms which help the user to manage large corpora. With the EUDICO and Browsable Corpus technology which was extended within the ISLE project the researchers can rely on tools which will be supported for many years. Since the file formats of both technologies is XML based it can be expected that they will be widely used.

Development of the User−State Conventions for the Multimodal Corpus in SmartKom

Silke Steininger[†], Susen Rabold[†], Olga Dioubina[†], Florian Schiel[*]

Abstract

This contribution deals with the problem of finding procedures for the labeling of a multimodal data corpus that is created within the SmartKom project. The goal of the SmartKom project is the development of an intelligent computer−user interface that allows almost natural communication with an adaptive and self−explanatory machine. The system does not only accept input in form of natural speech but also in form of gestures. Additionally the facial expression and prosody of speech is analyzed.
To train recognizers and to explore how users interact with the system, data is collected in so−called Wizard−of−Oz experiments. Speech is transliterated and gestures as well as user−states are labeled. In this contribution we will describe the development process of the User−State Labeling Conventions as an example for our strategy of functional labeling.
Key−words: multi−modal, annotation, user−states, human−machine interaction, coding conventions.

1. Introduction

The goal of the SmartKom project is the development of a multimodal dialogue system that allows the user to interact almost naturally with the computer. Among other things the emotions of the user are taken into account by the system. Since not much is known about the role emotions play in a human−machine dialogue, data is collected in Wizard−of−Oz experiments. The analysis of the interaction of the users with the simulated system can reveal which emotions occur in such a situation, in which way the emotions are expressed and in what connection. For such an analysis the data has to be labeled[1].

This contribution deals with the problem of how to define a labeling procedure for emotions, respectively. user−states[2]. We will first describe shortly how the data was collected that was used for the development of the labeling procedure. Then we describe the requirements the procedure had to meet. After that we give an overview over the steps of the development process of the procedure and some open questions.

2. Collection Of Multimodal Data

The data collection is done with the Wizard−of−Oz technique: The subjects think that they interact with an existing system but in reality the system is simulated by two humans from another room.

In each Wizard−of−Oz session spontaneous speech, facial expression and gestures of the subjects are recorded with different microphones, two digital cameras (face and sideview hip to head) and an infrared sensitive camera (from a gesture recognizer: SIVIT/Siemens) which captures the hand gestures (2−dimensional) in the plane of the graphical output. Additionally, the output to the display is logged into a slow frame video stream. Each subject is recorded in two sessions of about 4.5 minutes length each. For more information on technical details of the data collection see Türk (2001).

3. Developing the Labeling Procedures − Starting Point

3.1 Goals

The labeling of user−states in SmartKom serves two main functions:

1. The training of recognizers.
2. The gathering of information how users interact with a multimodal dialogue system and which user−states occur during such an interaction.

These two goals had to be satisfied with the labeling procedures we had to define. For practical and theoretical reasons we decided against a specific system like the "Facial Action Coding System" of Ekman (1978) where the precise morphological shape of facial expressions is coded, but used a simplified, practice−oriented system. The user−states are defined with regard to the subjective impression that a human communication partner would have, if he would be in place of the SmartKom system. This is a functional definition: Not the user−state per se is coded, but the impression the communicated emotion or state generates.

In Steininger, Lindemann & Paetzold (2002a) we already discussed this approach with regard to gestures[3]. The next paragraphs explain our approach relating to user−states.

[1] The development and structure of the gesture labeling is described in detail in Steininger, Lindemann & Paetzold (2002a). The transliteration conventions can be found in Oppermann et al. (2000). The special problem of combining the information of the different labeling steps and the transliteration is discussed in Schiel et al. (2002) at this workshop.

[2] The name “emotion labeling” was changed in “user−state labeling” because the targeted episodes in the data comprise not only emotional, but also cognitive states.

[3] Our gesture coding system also defines hand gestures functionally (not morphologically). A labeled unit is coded with regard to the intention of the user, i.e. with regard to his (assumed) discrete goal.

3.2 Practical Requirements

To satisfy the two goals of the labeling process mentioned above the following requirements had to be met. They apply to transliteration, gesture and user−state labeling.

1. The labels should refer to the functional level[4], not the morphological level. For theoretical reasons we want to use a functional coding system (see below). However, the decision is also made for practical reasons since the structural coding of e.g. facial expressions is exceedingly time consuming.

2. The labels should be selective. Functional codes (as indirect measurements) are not as exact as direct methods, therefore exceptional care has to be taken to find labels that are well−defined, easy to observe and unproblematic to discriminate by means of objective (communicable) criteria. This is even more true for user−states than for gestures because communicable criteria for the discrimination of functional user−state categories are hard to find.

3. The coding system should be fast and easy to use.

4. The resulting label file should facilitate automatic processing (a consistent file structure, consistent coding, non−ambiguous symbols, ASCII, parsability) and preferably should be easy to read.[5]

5. The main categories and most of the modifiers should be realized as codes and not as annotations, in order to heighten consistency. Annotations (free comments and descriptions that don't follow a strict rule) are more flexible, but codes (predefined labels from a fixed set) increase the conformity between labelers.

4. Definition of the User−State Coding System

The questions that have to be solved to detect user−states automatically are: Which features of the face and of the voice contribute to an emotional impression − and in which degree does each feature contribute to the impression? Which of these features can be detected automatically?

If we already knew the answers it would make sense to define coding conventions that mark these features in the data. But since we are far from answering these questions conclusively we decided to use another strategy: The labelers mark beginning and end of a user−state sequence and sort it into one of several subjective categories.

A human in a conversation with another human is able to judge which emotion or user−state his or her communication partner shows. Therefore he or she should be able to discriminate relevant user−states in a video. Of course the labeler does not know which emotion is truly present in his communication partner/a human in a video and he or she will make mistakes. But he or she should be good enough to use his emotion−detection capability to keep the conversation smooth. This goal is the same for the system − it should be able to detect which user−state is present in its communication partner to keep the conversation smooth.

This consideration we used for the definition of the user−state coding system.

4.1 First Step: Pretest − Labeling with some defined subjective categories

First we decided to look for several categories that were deemed interesting for user−state recognition: "anger/irritation", "boredom/lack of interest", "joy/gratifi−cation (being successful)", "surprise/amazement", "neu−tral/anything else". A few sessions were labeled with these categories. Beginning and end were defined by an observable change in the emotional state of the user. It was marked if the user−state seemed "weak" or "strong".

In the first step each session was labeled by at least two different labelers. After the labeling the categories were discussed. "Boredom/lack of interest" was excluded because it could not be distinguished from "neutral". "Neutral" and "anything else" were separated into two different categories because many sequences were found where the users definitely did not show a neutral expression but no meaningful label could be given. Two new categories were included to describe user−states that occurred quite often in the data and are important in the context of human−computer interaction: helplessness and pondering/reflecting.

The label "anything else" comprises three cases:

1. Grimaces with no emotional content, for example playing with the tongue in the cheek, twitching muscles etc. (about 65%).

2. Emotional sequences that have no label in our system, for example disgust (about 5%).

3. States that seem to have an emotional or cognitive meaning, but cannot be decided upon by the labelers (about 30%).

The three cases were put together into one category because they all comprise sequences that are not suited as training material.

Cases like number 2 (disgust etc.) are very uncommon in our context and because of this an extra category was not deemed worthwhile. Cases like number 1 (grimaces for physiological reasons) sometimes look very similar to user−states, but have a different meaning − therefore they have to be distinguished from neutral.

Cases like number 3 would be interesting to analyze further because the comprise complex or difficult to understand user−states. They are sorted into the "anything else" category simply for practical reasons: The other labels should be selective, therefore any label that cannot be categorized for certain has to be sorted into "anything else".

4.2 Second Step: Holistic labeling with the conventions

In a second step the sessions were labeled with the following fixed set of categories:

− joy/gratification (being successful)
− anger/irritation
− helplessness

[4] "Functional code" or "functional unit" is sometimes defined differently by different authors. We use the term in accordance with Faßnacht (1979) for a unit that is defined with regard to its effect or its context.

[5] Many of the practical criteria were adopted from the transliteration conventions for speech in SmartKom, see Oppermann et al. (2000).

− pondering/reflecting
− surprise
− neutral
− unidentifiable episodes

Consistency was achieved by two correction steps. Final correction was done by the same corrector for every session. Difficult episodes were discussed.

Figure 1: Example of the front view that is used for the holistic and the facial expression labeling. The picture was taken from an episode that was labeled as "anger/irritation" in the holistic labeling step.

4.3 Third step: Finding features

The categories are assigned according to the subjective impression of the labelers. Nevertheless the goal is to find detectable features. Additionally the categories have to be describable with observable criteria − otherwise no one else apart from the labelers will be able to understand the content of the labels.

Therefore, for each category some characteristic features were listed. A feature was included in the list if it occurred regularly or if it seemed very distinctive of a category for some subjects.

This step of the development process is still in progress. At the moment the features are simply an aid for labeling. However, the feature list could be studied with objective methods to judge which features are good candidates to be "indicators" for a category.

4.4 Fourth Step: Overcoming some limitations

With the holistic labeling system we were relatively sure to catch all relevant user−state episodes and to sort them into selective categories. However, a serious problem had to be solved: For the recognition of facial expressions the coding system was not well suited. Because of the holistic approach the labels included not only information from the facial expression, but also from the voice and from the context. This is a problem because a facial expression recognizer derives information only from the facial expressions and a prosody recognizer derives information only from the voice.

First, we tried to solve the problem with a special marker of the source for a category: voice or face. But it turned out that it was very difficult to make the judgment with regard to the source. Additionally, only very few episodes with the source "voice" could be found.

We abandoned the source marker and included two different labeling steps: Labeling of the facial expression without audio and prosodic labeling.

For the facial expression labeling a different labeler−group watched the videos without audio. The labelers started with a pre−segmented file (from the holistic labeling) to avoid missing subtle episodes that are hard to perceive without audio and context information. This pre−segmentation was derived from the holistic labeling − the names of the categories (apart form "neutral") were deleted, the borders were retained.

Since it seemed to be difficult to use the functional approach with regard to the voice, we adopted a formal coding system that was used in Verbmobil (Fischer, 1999) and changed it to suit our needs in SmartKom.

For the prosodic labeling the transliteration files are filtered: Only the orthographic transcript remains so that the transliteration labels don't divert the prosodic labelers. For the labeling prosodic features like pauses, irregular length of syllables and other prosodic features which could reveal the emotional state of the particular user are marked. There are nine categories for the prosodic labeling:

1. Pauses between phrases
2. Pauses between words
3. Pauses between syllables
4. Irregular length of syllables
5. Emphasized words
6. Strongly emphasized words
7. Clearly articulated words
8. Hyperarticulated words
9. Words overlapped by laughing

The labels were chosen according to the requirements for the User−State recognition group in SmartKom and are thought to represent prosodic features that are indicative of emotional speech. Hyperarticulated words for example, can be indicative of anger. However, it is still not known very well which prosodic features occur during which emotional states. Nevertheless, by the comparison between the holistic labeling and the prosodic labeling it should be possible to detect relevant user−states in speech. For more information on the usage of prosodic features as indicators of emotional speech please refer to Batliner et al. (2000).

For a detailed description of the labels and concrete examples for the labeling procedure please refer to our paper at the main conference (Steininger, Schiel & Glesner, 2002b).

4.5 Open Questions

We have to state clearly that the user−state labeling procedure is work in progress. The description of the categories, along with some formal criteria to help differentiate categories that can be mixed easily is not complete. After it's completion, the intercoder agreement has to be measured. At the moment, we can only use the extent of corrections that are done in each correction step

as a rough indicator how reliable the labeling procedure probably is:

Holistic labeling: About 20% of all labels are changed with regard to content. About 10% of the segment borders are changed. This is the case for correction step 1 as well as 2.

Facial Expression labeling: Only one correction step exists. Segments borders have to be corrected almost never. Changes of labels with regard to content occur in about 20% of the cases.

Prosodic labeling: Only one correction step exists. Changes of labels with regard to content occur in about 20% of the cases. Changes of time markers occur in about 50% of the cases.

One other problem that remains are mixed emotions. Since there is no category for mixed emotions, all such cases have to be sorted into "anything else". However, the problem is not as big as it seems: Since we use categories that are defined mainly by subjective impression not mainly by formal criteria, it is rare that a labeler has the impression of a mixed emotion[6]. As already mentioned, the labeler take the viewpoint of a communication partner and try to discern which state his opponent is in. On this level, there almost always is an integrated impression of only one emotion at a time. Many emotional states are mixed of course if one analyses them closely. With a formal system like FACS (Ekman, 1978), mixed emotions correspond to mixed expressions: The face may show anger (for example with a frown) and surprise (for example with an open mouth). In a functional system like ours the viewpoint is taken that it is not known if a frown always means anger and an open mouth always means surprise. If the frown and the open mouth leave the observer (labeler) with the impression of reflecting then this label is given. That is to say that a mixed state on the formal level can lead to a new (holistic) impression on the functional level. Actually this is quite often the case. In most instances there is a clear message for a communication partner. We label only this "clear message", not the subtle undercurrents.

Of course the overall impression can also be of a mixed state. In this case the label “anything else” is given since only very few mixed states were found. Since for the voice a formal system is used and in one labeling step the facial expression is judged without the audio information mixed states for speech and facial expression can occur. In some cases they will be real mixed states but in some cases they will occur because of labeling mistakes.

In our view, formal and functional systems can complement each other, but cannot replace each other because they refer to different levels.

A third important open question is the “anything else” category. For practical reasons some of the most interesting cases “disappear” into this category, namely the episodes that cannot be categorized neatly. Of course it would be of great interest to analyze these difficult episodes further. How could this be done? It is no option to ask the subjects what they felt in the case of an unidentifiable user−state, because with the functional approach the emotions are labeled that are transmitted to a communication partner. Introspective evaluation of the emotion by the user will give a different picture because of effects of social conventions (among other things). To include recordings of other modalities could be helpful: Hesitant movements for example could give hints about the user−state “helplessness”. However, we decided against using additional visual context information because we wanted to focus the labelers on the face and on changes in the voice accepting that some episodes remain unidentifiable. Adding such information later can change the impression (which is highly context dependent), therefore the whole labeling process has to be done again. An interesting option would be to have the unidentifiable episodes judged by a group of naive, untrained labelers (without giving them predefined categories). In this way it could be analyzed if the unidentifiable episodes are episodes that are difficult to understand by a communication partner or if at least some of them form a user state not yet identified as important.

[6] With the expeption of “sarcasm”: Cases where the user is smiling and laughing, but it can be suspected that he is also scornful are labeled as “joy/gratification”. Sarcasm is hard to detect reliably, therefore we decided againgst a special label.

5. Conclusion

With the example of the user−state labeling we show a way to handle the problem of finding a labeling system that is consistent, fast and catches the most important episodes in a human−machine dialogue. Since as yet there is not known enough about good indicators for user−state recognition we decided against a formal/morphological system. Instead we define the labels after practical experience with the data, in this way circumventing the danger of missing important aspects by making assumptions about indicators for automatic detection that cannot be justified very well yet.

Additionally, by combining holistic labeling, labeling of the facial expression and a formal system for the speech we can make up for the disadvantages a purely holistic, functional coding system would have. Through comparing the different label files it is possible to analyze and process the data from many different points of view, looking at the whole or at parts at will.

It is also possible to combine the user−state labels with the gesture labels or the speech transliterations. It could be interesting to analyze which kinds of gestures occur during which kinds of user−states. During helplessness there should be less interactional gestures and more searching gestures, for example. The comparison between the gesture labels and the transliterations is especially interesting with regard to reference words that are possibly uttered. A combination of all three modalities could be useful to analyze the question if there are more hesitations and aborts in the speech and gestures during angry and/or helpless episodes.

With the traditional way of annotating input modalities separately such comparisons are not possible. The labeling of data of multimodal systems allows new ways of studying human−machine interaction. However, this will be successful only if the coding conventions allow the combination of the labeling of the different modalities with ease.

Abstract

Multi-modal resources typically consist of very different data in terms of content and format. This paper discusses a practical solution for the integration of different physical signals as well as associated symbolic data into a common framework. There are ongoing efforts like for instance the ISLE project to develop guidelines and best-of-practice for the standardized representation of such data collections. Since these efforts have not yet converged into a widely accepted concept, we suggest as a starting point to use two different already existing frameworks that can be easily combined for this purpose: The QuickTime format for the handling of synchronized multi-modal signals and the (extended) BAS Partitur Format for the handling of all symbolic data. We can show that with this simple approach it is already possible to integrate the rather complex data streams of the SmartKom Corpus into an easy-to-use format that will be distributed via the Bavarian Archive for Speech Signals (BAS) starting in July 2002.

1. Introduction

The last years have seen quite a number of projects starting to work on the processing / recognition / output of multi-modal data in man-machine-interaction systems. However, a quick survey in the Web sites of LDC[1], ELDA[2], CSLU[3] as well as in general search engines shows that such data are not widely available to the scientific community outside of dedicated project groups[4]. On the other hand projects like ISLE[5] started with the aim to extend the EAGLES initiative with guidelines and standards for multi-modal data, but has not produced any recommendations yet. Although standards and role models do not exist, in most scientific projects people had to get started collecting data for their special needs, in most cases gathering material for training and evaluation of multi-modal input devices. Almost like twenty years ago when the creation of language resources started to get going the concerned scientists nowadays collect and annotate data to their needs and with the tools and standards available.

So did we when we started to collect data for the German SmartKom project[6] beginning of 2000. Unfortunately, this MO will very likely aggravate the future use of these corpora, which is a shame considering the very high efforts (and costs) that are invested into these resources.

Meanwhile the SmartKom group at BAS has collected a vast amount of multi-modal data (about 1500 GByte) and has solved most of the technical problems that come with such a task. As reported elsewhere (Tuerk, 2001) the SmartKom data collection consists of 9 different audio channels, two high resolution video streams, one infrared video stream (black and white) and a screen capture (very low frame rate), a HID input and a pen input. Within the last year we were faced with the problem to integrate all these different modalities (signals) together with the various annotation of data streams into a common framework that may be used for the final distribution of the corpus (starting in July 2002 with the first release of SK Public). The two main problems here are that on the one hand different modalities are recorded by different non-synchronized capture devices, on the other hand annotations to different modalities are produced with the use of different – sometimes even self-written – software tools. All this results in a huge variety of resolutions, time bases, file formats that will hinder the easy usage of the corpus by others.

2. Practical solution

In this contribution we would like to give a proposal (to be precise: two independent proposals) how to handle these problems with existing frameworks. We do not claim that our proposal will be the ultimate and best solution. However, it could act as an intermediate step that allows the immediate work with multi-modal data and might make the conversion of multi-modal resources into a future standard (whatever it might be) less painful.

Let us first list a few basic requirements denoting the intended characteristics of the framework for multi-modal resources (FMMR). Our intended FMMR

- should be extensible and flexible.
  In almost all cases a fixed format for data resources is bad news for the scientist or developer, because he then uses a lot of unnecessary time to solve data format problems. Although this has been true for monomodal resources as well, the problem multiplies when

[1] http://www.ldc.upenn.edu/
[2] http://www.elda.fr/
[3] http://cslu.cse.ogi.edu/corpora/
[4] The only exception being the M2VTS biometrical corpus available at ELDA
[5] http://isle.nis.sdu.dk/
[6] http://smartkom.dfki.de/

it comes to multi-modal data. Therefore the framework should not be a fixed definition for different kinds of modalities and how to treat them but rather an extensible framework that can be easily adapted to upcoming needs.

- should be easy to process.
  The reason for this key point is obvious. The conclusion is that we may use a well developed format for which tools are available (for instance XML) or that we use such a simple format that it may be processed with standard tools on the operation system level.

- should not integrate signals and annotations in one file format.
  According to our experience in many cases users of a data resources do not need to access all signals or all annotations at the same time. To simplify handling and distribution we therefore strongly recommend that signal and annotation data are separated in storage but linked together via the time base (like it was done in the SAM and BAS Partitur File (BPF) standards).

With these basic requirements in mind our proposed method can be summarized as follows:

1. To integrate the raw data we use QuickTime (QT)[7] for all data that are measured signals or events.
2. To integrate annotations we use BPF or a similar flexible framework (e.g. annotation graphs (Bird, 2001)).
3. We link both representations through the physical time base only.
4. We use what ever necessary relational/hierarchical linking only between the annotation layers.

Note that although we use the BPF in the following examples, this is exchangeable to any other equally qualified format. The point we want to stress here is not the format but that the symbolic (annotation) data should be kept seperate from the signals, but be grouped into a single framework for easier analysis.

We will discuss the pro and cons of our approach in the following section using the SmartKom corpus as an example.

3. Example SmartKom

To demonstrate that our proposal does actually work we show as an example the integration of a complex data collection in the SmartKom project where a wide range of signals and annotations are currently used.

3.1. Integration of signals in QT

Let us first look at the integration of signals into a QT frame. QT allows the integration of several kinds of media into a single multi-media file. Theoretically every signal format that describes physical measurements (signals or events) may be incorporated, if you provide the necessary interface to QT. Fortunately, interfaces for most of the common file formats do already exist. Therefore, it is possible to integrate for instance video, audio, images, vector graphic and even text into a QT frame without the need to transform the single modalities from their original format; since they remain in their original files, it is also possible to access to the data via other tools than the QT player, if necessary. The only problem is the synchronisation of different time bases, e.g. the synchronisation of a video stream with 25 frames per sec on one computer with an audiostream captured at 48 kHz on another system. We have not found yet an elegant solution to synchronize automatically. At the moment we use a technique quite similar as in movie productions: we synchronize manually with regard to a significant acoustical and visual event at the beginning of each recording. Even more difficult is the synchronization of 2D spatial data with the video signals. In the Smartkom corpus the output of the gesture analyzer consists of a stream of coordinates in the working area indicating pointing gestures of the user. We solved this problem by converting the two-dimensional data into so-called sprites – that are little bit maps that move in the visual plane – and then overlap both pictures to synchronize the infrared picture of the hand with the sprite. Please refer to (Tuerk, 2001) for a detailed discussion of the synchronization problem.

In Smartkom a typical session file contains the following tracks:

- video of the face, frontal, DV format.
- video of upper body, from left, DV format.
- video of infrared camera directed on display to capture hand gestures, from top, DV format.
- audio in 10 channels (microphone array (4), directed mic, headset (2), backround noise (2), system output) captured by a 10-channel audio card with 48 kHz
- graphical system output captured by a screen capture application at 4fps, AVI format.
- combined video frame with face, upper body, system output and infrared, AVI format.
- coordinate logfiles: output of either the gesture recognition system (finger tip) or the output of the graphic tableau (pen tip)

For performance reasons all streams are captured on different computers. Coordinate logfiles are transformed into a sprite track to make coordinates visible in the video signals. Then all raw signals are synchronised and integrated into a QT frame.

3.2. Pros and Cons of QT

As mentioned above QT is an open format that serves some of our intended purposes: it is quite easy to use, it is extensible to new, yet unknown formats, and data are accessible via the QT standard library. The synchronization is still a problem but solvable. The alternative would be a fully synchronized capturing hardware, but that was far out of our budged range. The original formats of the data are still accessible on the distribution media which makes the

[7] http://developer.apple.com/techpubs/quicktime/quicktime.html

access easy for people that do not want to use QT. Furthermore, parts of the synchronized stream may be used across different data collections.

When the SmartKom project started we also discussed other possible formats than QT. The Java Media Framework (JMF) was already out at that time and would have had the advantange to run completely in JAVA. However, this also caused a very low performance compared to QT which is coded in C++ (encapsulated in a JAVA class library). Also, we could not get necessary drivers in JMF for our intended platforms, for instance no recording drivers for Mac and no DV codec.
The other alternative would have been the Microsoft Media Format (MMF, nowadays mostly replaced by AVI). MMF was only available for MS platforms and – being a mere format definition and no consistent system like JMF or QT – was not flexible enough for our needs.

One major drawback of QT is the still missing QT library and QT player for Linux OS (we managed to get a QT player running in a Win emulation environment, but the performance is very bad). We hope that with the further spreading of QT this will be solved in the near future.
Depending on how many video streams are integrated into the QT frame it is sometimes necessary to spread the frame over more than one DVD-5 which makes working with the data difficult. Also the time deviation between the time bases of the capturing devices is getting significant in longer recording sessions. We avoid this by restricting the length of one recording session to 300 sec.

Figure 1 shows four data streams of a SmartKom recording within a single flattened video frame. In the upper left quadrant the video signal of the face camera is shown; in the upper right quadrant the video signal of the body from the left; in the lower left quadrant the displayed output of the system, in the lower right quadrant the output of the system and as an overlay the video signal of the infrared camera that captures the user's gestures. The shown frame is actually from a video stream that was calculated from the original QT frame; the QT Player Pro is principally capable to show many video streams simultaneously, however the performance on a standard Intel platform is still unsatisfying.

3.3. Integration of Annotations into BPF

During the last 5 years we have shown that the BAS Partitur Format (BPF) developed at the Bavarian Archive for Speech Signals in 1995 is very successful to integrate so called 'symbolic information' (that is in most cases some kind of annotation) of speech recordings into a simple text based format (see for instance (Schiel et al., 1998)). A BPF is a simple text file very similar to the first SAM label file standard, but has no fixed format concerning the syntax and semantics of the contained tier information blocks. Therefore it is quite easy to extend the format to new needs as long as the meta structure is followed to. Based on the UNIX filter concepts it is possible to add new tier information blocks to a BPF without the need to re-write existing application software (as long as this software does not need to access to the new tier information, of course). A simple chaining mechanism within the different tiers allows the integration of annotations without any direct link to the physical time base; by following the chaining to such a tier all remaining tiers are automatically projected to their right position within the signal.

Let us have a closer look at the structure of the BPF[8]:
A BPF file is a simple ASCII file in which each line has a three character key followed by a colon at the beginning that defines the syntax and semantic of this particular line. A BPF consists of a mandatory header structure (compatible to SAM) that must contain a minimum of descriptors, for instance:

```
LHD: Partitur 1.2.11
REP: Muenchen
SNB: 2
SAM: 16000
SBF: 01
SSB: 16
NCH: 1
SPN: ABZ
LBD:
```

Most important entry in this context is 'SAM' which denotes the sampling frequency for all time references in the following annotation tiers.
After this header block an arbitrary number of tier blocks may follow marked by their respective line key. Registered BPF tiers together with their syntax and semantics can be found on the BAS Web pages. For instance the tier block

```
ORT:    0       all
ORT:    1       right
ORT:    2       Mister
ORT:    3       Durante
ORT:    4       <uh>
```

transcribes the pure lexical words of a short utterance. The numbers in the second column are 'links' between different tiers. In principle there may any sort of links units defined (for instance chunks, words, syllables, events etc.). At the moment the BPF standard uses only one type of link that is the word unit counted from the beginning of the recording. Therefore BPF tiers come in only 5 basic types:

1. Events attched to a word, a group of words or the time slot between two words.
2. Events that denote a segment of time without a relation to the word structure.
3. Events that denote a singular time point without a relation to the word structure.
4. Events that denote a segment of time associated with a word, a group of words or the time slot between two words.
5. Events that denote a singular time point associated with a word, a group of words or the time slot between two words.

[8] http://www.bas.uni-muenchen.de/Bas/BasFormatseng.html

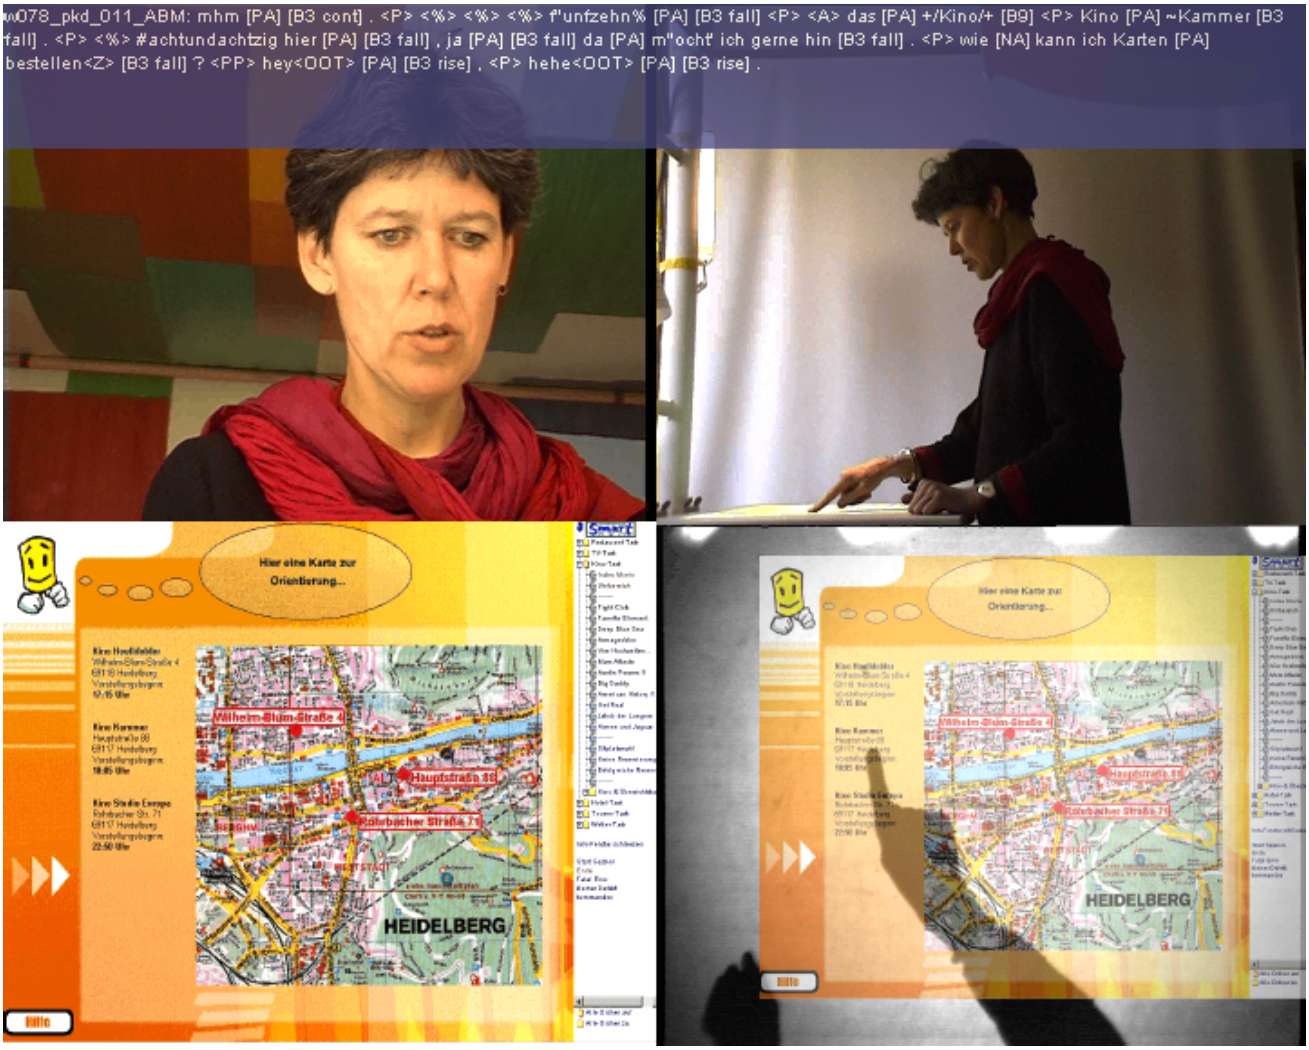

Figure 1: Four synchronized video streams extracted from a SmartKom QT file (see text)

The tier blocks have no preference in order[9] nor hierarchical structure. It is therefore quite easy to cut and paste BPF tiers with standard UNIX tools.

We have shown that the BPF is capable to integrate a variety of symbolic information that was produced within the German Verbmobil project corpus. These data range from simple word alignment over complex syntactic-prosodic tagging up to syntax tree structures. A total of 21 different tiers to the speech signal were used in the Verbmobil corpus (Weilhammer et al., 2002).

Encouraged by this success we started to think about the possibility of integrating symbolic information of multimodal data as well. Surprisingly enough we managed without changing the meta structure of BPF to integrate the following tier information into an BPF (in brackets the corresponding BPF tier keys):

- SmartKom Transliteration of audio channels (TRS,SUP,NOI,ORT,KAN)
- Turnsegmentation (TRN)
- Segmentation and labeling of gestures in the 2D plane (GES)
- Segmentation and labeling of user state (facial and speech) (USH)
- Segmentation and labeling of user state from facial expression only (USM)
- Segmentation and labeling of complex prosodic features to recognize 'emotions' (USP)

Please note that the above annotations are produced with a variety of different software tools (eg. USS, CLAN, Interact). Simple Perl scripts are used to transform the label and segmentation information into the BPF tier information block and add them by concatenation to the existing BPF.

The following example shows an extract from a SmartKom BPF. For better readability the file is abbreviated to the first 12 words of the dialogue and the header block is omitted.

```
TRS:    0       <"ah> [NA] [B2]

In this example the following tier blocks are contained (see references for details about labeling systems and conventions):

- TRS : SmartKom transliteration (Oppermann et al., 2000)
- SUP : Labeling of cross talk between user and system
- ORT : Lexical entity
- KAN : Citation form in SAM-PA
- TRN : Turn segmentation
- NOI : Noise labeling
- USH : User state labeling using video and audio (Steininger et al., 2002b)
- USM : User state labeling using video only (Steininger et al., 2002a)
- USP : Prosodic labeling of features for user state detection
- GES : Labeling of 2D gestures (Steininger et al., 2001)

3.4. Pros and Cons of BPF

BPFs of Smartkom are fully compatible to BPFs of mono-modal resources. For instance we can easily train a speech recognizer with the data of Smartkom as well as the data of Verbmobil together, since the BPFs tier information blocks for this purpose are identical.
Since the BPF is an open format it is very simple to extend it, for instance by a new tier that contains the time synchronized coordinates of the finger tip delivered by an early stage of the gesture recognizer.
As defined in the BPF format the link to the actual physical signals is solely achieved by reference to the physical time base. It is clear that by doing this the format of the individual signals is arbitrary. It may be the QT format that we use; it may be another format or it may be even just an extraction of a certain modality, as long as the time synchrony is maintained.
Software tools that read only a specific tier information do not need to be adapted when the BPF is extended to a new tier (except of course that the tool needs to process the new tier blocks).
Since the BPF is a simple ASCII file it is usable across platforms.

The BPF does not allow free hierarchical structuring as for instance in the EMU system.
There is no provision in BPF to use UNICODE for special languages or for IPA.
There is no general purpose viewer available for BPF. Up to now we use Praat[10] or SFS[11] to view traditional mono-modal BPFs resources. For the SmartKom corpus we use the QT library that allows to blend in time-aligned text labels as can be seen in figure 1.
There is no dedicated databank system for the BPF. Although we have developed a PROLOG based databank system for the Web that allows simple and complex queries, this is not a general purpose tool. However, it is quite easy to import BPF files into any data bank system.
Last but not least: BPF is not XML. We have started to use parsers that convert BPF tiers into XML. However, it turns out that BPF is easier to read by humans than the XML version.

4. Conclusion

Our approach to use two existing data frameworks, QickTime (QT) and BAS Partitur Format (BPF) for multimodal data collections was borne out of the need to get started without having any role models and/or applicable

[10] http://www.praat.org/
[11] http://www.phon.ucl.ac.uk/resource/sfs/

standards. We recognize that our current mode of operation is a compromise with some drawbacks. On the other hand it is quite surprising that the integration of multi-modal signal data together with their annotations went rather smoothly. We hope that our experiences will help other researchers that face similar logistic problems as well as researchers that are in the process of defining best-of-practice procedures in the field of multi-modal speech resources.
The SmartKom corpus will be made accessible for the public beginning July 2002. Following our policies with monomodal speech resources we will provide a free access to the symbolic data of the corpus via simple FTP download from the BAS server[12]. To obtain the QT files on DVD-5 media please contact bas@bas.uni-muenchen.de or consult the general BAS Web documentation[13].

Abstract

Designed by Baldry and Thibault and constructed by Beltrami and Caglio, MCA is a multimodal concordancer that identifies recurrent patterns in films. As an authoring tool, it enables researchers, however imperfectly, to view short pieces of film and simultaneously to write multimodal descriptions of them. Using MCA's editing tool, researchers can segment film into functional units and, while viewing these units, type out detailed annotations relating both to the semiotic resources they deploy and the functions they perform within the film. The incorporated relational database allows researchers to search the corpora thus created and identify patterns in them, all of which leads to a further round of hypothesis formulation, segmentation, description and comparison of results. As exemplified by the work carried out by Baldry and Thibault on a corpus of TV car ads, MCA was initially conceived as part of research into the applicability of the systemic-functional approach to multimodal description (Halliday, Kress and van Leeuwen) and in particular Gregory's concept of phase and transition. MCA has since been experimented in various projects within *LINGUATEL* (claweb.cla.unipd.it/Linguatel/Pavia/MCA.htm). As the article explains, one such project, namely corpus-driven screen translation, has led the MCA interface to be partly redesigned.

1. Introduction

If you are planning your summer holidays abroad this year, you may well decide to learn the local language, or at least just enough to understand what people around you are saying. If you have no time for evening classes, then you will want to do this in your own home. You could, of course, watch a DVD film in the chosen language, switching on the subtitling in that language so as to be able to identify at least some of the words being spoken. But you will soon realise that a DVD presenting your favourite film will not normally allow you to select *all the cases* of a specific activity or the ways in which that activity 'translates' into grammatical structures, whether those of your own language or the foreign language you have chosen to study. Nor will it allow you to check how a particular word or combination of words is typically used in the film. Thus, while DVD may be a great advance over the VHS cassette, when it comes to language learning it has so far provided only limited forms of access to film and video texts. Without the possibility of confirming your intuitions about the way your chosen foreign language works in relation to your own language, you will soon give up. The end of your language learning plans!

Now consider instead watching, and listening to, film texts in a foreign language using an Internet-based multimodal concordancer that carries out targeted searches in film corpora. By definition, such a tool allows you to carry out multiple 'incursions' into film texts, some of which are likely to correspond to your preferred associative patterns and learning strategies. You might, for example, want to take a strictly grammatical approach, searching, for example, for all the cases in a corpus of utterances that correspond to English "you can" carried out in MCA by a query of the type: *AD contains you can*.

Presented, as in any concordance, as a series of rows, a major difference between multimodal concordancing and the linguistic variety lies in the fact that by selecting the player symbol on the left-hand side of each row, you can see and hear *exactly* that part of the film which contains all (and only) the foreign language expressions that correspond to the concordance query (in this case Italian equivalents for "you can"). Moreover, the returned search also transcribes the words used in the foreign language thus assisting word recognition – so important in the initial stages of language learning. The search also indicates the number the text has in the corpus, so that a further query will allow you to listen to your chosen expression in the context of the entire text. Such a query will be of the type: *AD contains n* (where *n* is the number indexing the specific text).

However, your language learning strategies might be such that you tend to shy away from an overtly grammatical approach. You may well prefer listening to a more extensive piece of text using dual-language subtitling. Given that a multimodal concordancer is likely to be based on a *relational* database (in the case of MCA, *Microsoft Sequel Server*), more complex searches can be made – *de facto* a combination of several searches. A set of dual-language subtitles will returned by a query of the type (see Fig. 1): *AD contains text + English subtitle contains + Italian subtitle contains.* Pursuing this approach, you might well decide to select specific grammatical patterns that illustrate and compare, for example, the way questions are formed in the languages under consideration: queries would be of the type: *AD contains text + Italian subtitle contains questions + English contains questions*. You could, of course, mix the

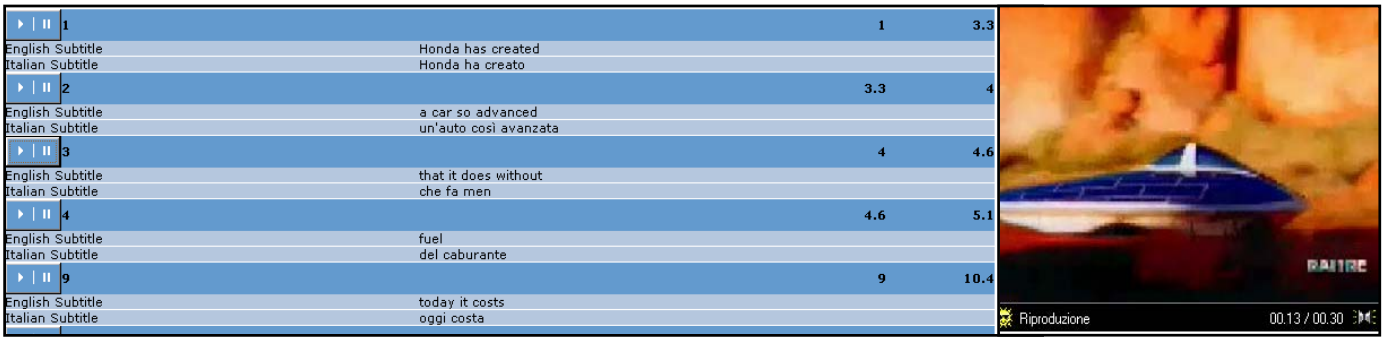

Fig. 1 Dual-language subtitling generated by a relational database

two requirements: *AD contains text* + *Italian subtitle contains* + *English contains questions*. And you could also decide that instead of car adverts you want to listen to (and watch) something else – hence a query of the type *TV News contains…* etc. Flexible as this may seem, as your search skills increase you may well want to integrate the use of subtitling, translation and grammatical patterns with other strategies such as those that explore specific human activities or textual properties. Here a slightly different type of query can be applied. A search of the type: *AD contains text* + *SLOGAN contains YES* (or + *SONG contains YES* or + *HIDING contains YES*) will respectively find all the cases in the corpus exemplifying written and/or spoken slogans, songs and examples of hiding. And as your comprehension of the target language increases, you might also want to go beyond this, associating a linguistic approach to language learning with explorations of meanings made in other semiotic modalities – for example, hand and body movements that couple with language to make multimodal meanings in a way that even the casual observer will recognize as fundamental to a film's overall meaning: e.g. touching something or somebody, possible with a search of the type: *AD contains text* + *touches contains: YES*.

This brief illustration exemplifies how a multimodal concordancer can be used to achieve specific applicative functions (such as language learning) within a multimodal approach to text analysis. Indeed, at the time of writing MCA is still a prototype that is constantly being redesigned – for example, to make it suitable for the learning of minority European languages using the principle of query-generated screen overlays (subtitling, captioning and other more visually-oriented overlays). Other applications include the use of a multimodal concordancer within University courses to help students to understand the multimodal organization of texts, including, as Taylor explains in the following section, efforts undertaken by the Trieste *LINGUATEL* research group to guide students in their learning about screen translation (for a bibliography see Gottlieb).

Indeed, the next section provides a summary of the thinking that led to the original development of MCA and its constant redefinition, a matter discussed in more detail by Baldry in the subsequent section, which also describes MCA's technical specification in relation to research into texts as consisting of phases and transitions between phases, an approach ultimately concerned with defining the typical characteristics of specific multimodal genres.

2. MCA in Trieste

The University of Trieste *LINGUATEL* research unit, as part of a wider national research initiative in Italy sponsored by the Ministry, specialises in multimodal text analysis and the devising of strategies for the translation and subtitling of video text. An example of the work carried out by the unit provides the opportunity to describe how MCA can work in practice. Many types of dynamic text have so far been analysed by the Trieste group (feature films, TV soap operas, cartoons, advertisements, documentaries, news broadcasts, etc.) in particular by using the device of the multimodal transcription, originally devised by Thibault and Baldry (Baldry. 2000, Kress and van Leeuwen, 1996). The multimodal transcription technique consists of breaking a film down into single frames of, say, one second duration and minutely analysing their component parts (visual image, kinesic action, soundtrack, dialogue, etc.) thereby providing an approach that really gets to grips with the *multimodal* side of screen translation (see Fig. 2). It provides an ideal tool for analysing the multimodal text in its entirety and drawing the relevant conclusions in terms of how meaning can be successfully conveyed by the various semiotic modalities in operation, and thus how dispensable or indispensable the verbal element is in different sets of circumstances. From this premise it is possible to make informed choices regarding the translation strategies to adopt in subtitling a film.

One type of video text subjected to this multimodal approach was the television comedy series 'Blackadder'. Humour is notoriously difficult to translate, especially apparently British humour, as it involves a large number of interweaving factors: word play, register shifts, timing, characterisation – and creating the humorous effect through subtitles is doubly difficult. The episode examined here, from the Elizabethan era series, features a highly implausible plot involving Lord Blackadder and his scatter-brained assistants, the dreadful Baldrick and Lord Percy, who have inadvertently executed the wrong man, while temporarily in charge of the royal prison. The wife of the unfortunate victim, Lady Farrow, insists on seeing her husband, who she believes is still awaiting trial in the prison. Blackadder's scheme to extricate himself from this situation is to impersonate Lord Farrow at the meeting with his wife by wearing a bag over his head**.** Lord Percy has the job of explaining this to the unsuspecting lady**.**

1		Shot 1 CP: stationary/ HP: frontal/ VP: median/ D: MLS; VC: interior of the jail; Percy; Blackadder; Baldrick; Mr. Ploppy/ VS: the bag, exactly in the middle of the scene/ CO: artificial set; VF: distance: median; orientation: Blackadder's and Baldrick's gaze towards Percy **Kinesic Action**: Blackadder orders Percy out by shouting to him/ Tempo: M	{RG} [ ] Blackadder: (**)*Go on,* (NA)*go on*// Pause/ Volume: f/ Tempo: F	Sbrigati! Sbrigati!

Lo riconoscerete dal sacco in testa

Fig. 2: An example of a multimodal transcription

For reasons of space only two of the rows in the transcription of the subphase (the first and last 1-second frames) have been included. In the first row, Blackadder can be seen among his henchmen preparing to put the bag on his head. Lord Percy is nervously getting ready to meet Lady Farrow who is waiting outside (Row 5). Blending an interpersonal interpretation onto this ideational description, the viewer sees the participants from the same conspiratorial level. Indeed, the viewer has a better perspective than any of the characters in that he/she has an unhindered view of all of them as they are arrayed on the screen. Blackadder is recognised as the boss – he has central position and the others occupy the margin, to use Kress and van Leeuwen's terminology (1996: 206). From a textual point of view, the scene is the thematic element for the whole phase (Gregory, *in press*) covering the fateful meeting, and marks a cohesive element with the third sub-phase when Percy re-enters the room. The set is an obvious mock-up of a prison, the costumes instantly recognisable as Elizabethan period, from Percy's fancy ruff to the rags that Baldrick wears as a member of the lowest social order, the colours and lack of colour playing an important role. This already prepares the audience for the incongruous actions that are to follow, which are at the heart of all humour. The audience subconsciously knows that humour is based on this premise and generally makes every effort to make sense of the text somehow, however bizarre it may be. They are helped by their intertextual knowledge of similar texts they have previously been exposed to. Even a patchy and scholastic knowledge of Elizabethan England prepares the viewer for the setting, knowledge of past BBC comedies, the style of Rowan Atkinson, and indeed past Blackadder series, prepare him or her for the kind of parody that will take place. The foreign audience, however, may need a little more priming, especially pre-planning in the form of prior publicity, articles in other media, etc., but the basic mechanisms come into play just the same. Otherwise, how could we account for the massive popularity of Brazilian 'telenovelas' on Russian television?

To turn now to the question of the translation, the only thing that is said in this brief scene is Blackadder's impatient injunction to Percy – **Go on! Go on!** – and would thus not seem to tax the powers of the translator unduly. But conflicting pressures come to bear. In the interests of condensation, the obvious first step would be to remove the repetition, but this would overlook the importance of interpersonal elements; here the repeated order is designed to express Blackadder's contempt for Percy and intense irritation at Percy's constant incompetence. He almost snarls the words. So do we keep the repetition? At this point, the question of the audience arises. A minimum knowledge of the source language would equip any viewer with the necessary resources to interpret the text. And it is true that even those with no knowledge of the source language would still catch the aggressive intonation and the head movements expressing the feelings of the speaker. However, repetition of a word or short expression puts less pressure on the receptive capacities of a viewer than new material, and repeating the order would probably be the best option. This to-ing and fro-ing between competing solutions reflects the thought processes of the translator as various options are considered, a process well illustrated by Krings 'thinking aloud protocols' (Krings, 1987). But the problem still remains of what actual words to use. A literal translation into Italian would provide something like – **Avanti! Avanti!** – but if the interpersonal elements are to be integrated, namely the contempt and the irritation, then a version incorporating a fairly colloquial verb plus the second person singular intimate pronoun (expressing the superior to inferior relationship), might be preferred: **Sbrigati! Sbrigati!**

The time taken to discuss this first minimum utterance is an indication of how much thought is required to translate a film for subtitles, but also shows how the multimodal transcription enables the translator to focus his efforts. Proceeding in this vein, the analyst/translator/ adapter/subtitler (who may or may not be the same person) gets a very clear picture of how meaning is being

expressed and therefore to what extent s/he can intervene on the purely verbal element.

Analysing and subtitling large numbers of different kinds of texts, some of which purely for research purposes, others for student thesis preparation, others for language teaching modules, others still for genuine practical use, puts a large burden on computer storage facilities and databank management. Access to MCA allows the researcher/student to plug into a large selection of on-line filmed material which can be experimented with, in Trieste, without downloading material unless and until necessary. Secondly, in a reciprocal light, Trieste users can add to the stock of material on the MCA corpus which then becomes available to other members of the research team, the research community at large, and other selected participants.

This kind of symbiosis is already a reality within the *LINGUATEL* structure. In this way research into limitless genres and subgenres of video text can continue apace and at the same time feed back into the system material already analysed (even tagged) which can be used for other purposes. It is, of course, hoped to extend this service to all interested parties. The potentialities of the system have already far exceeded original expectations and are destined to produce ever more interesting avenues of use.

3. MCA in Pavia

3.1 Why we decided to build MCA

The multimodal transcription illustrated above and originally developed by Baldry in relation to the comparison of scenes from different medical texts (Baldry, 2000) and by Thibault in terms of a complete system for multimodal annotation of a bank advert (Thibault, 2000) has many limitations. Essentially a multimodal transcription is a static representation of something that is quintessentially dynamic, providing an *in vitro* frame-by-frame analysis of the component parts of a film. This is fine as far as it goes. But if we want to understand how films make meaning we need instead to develop instruments that examine texts in terms of an *in vivo* analysis treating them as if they were living objects which, as they unfold in time, present constantly changing patterns of semiotic selections. Dynamic texts need to be seen for what they are: a constant weaving and foregrounding of different constellations and integrations of meaning-making resources such as space, gesture, language, ambient sounds, music and gaze.

As Thibault (2000:320-321) points out, multimodal text analysis does not accept either in theory or in practice the notion that the meaning of the text can be divided into a number of separate semiotic 'channels' or 'codes'. The meaning of the text is the composite product/process of the ways in which different resources are co-deployed. A text can be segmented into a series of phases and transitions between phases. This will tell us how the selections of resources from different semiotic systems achieve a consistency of co-patterning. Phases, according to Thibault, are the enactment of the locally foregrounded selections of options which realise the meaning which is specific to a given phase of the text. Phases and subphases refer to salient local moments in the global development of the text as it unfolds in time. A given phase will be marked by a high level of metafunctional consistency or homogeneity among the selections from the various semiotic systems that comprise that particular phase in the text. Thibault also observes that the points of transition between phases have their own special features that play an important role in the ways in which observers or viewers recognise the shift from one phase to the next. Generally speaking, transition points are perceptually more salient in relation to the phases themselves. Thus, Thibault concludes, viewers of texts have no difficulty in perceiving particular textual phases thanks to their ability to recognise the transition points or boundaries between phases.

Of course, the multimodal transcription can be a useful starting point for an understanding of the ways in which resources such as gaze, gesture and language combine in typical phasal patterns. In the early stages of this work Baldry and Thibault developed a dynamic version of the static multimodal transcription, a forerunner of MCA, which allowed the user to generate the individual rows of a transcription through a query mechanism, and which facilitated understanding of how visual objects and their movements could be analysed in terms of Halliday's metafunctions (Halliday, 1994:38-144).

In an extension to their original conception Baldry and Thibault also devised a form of multimodal transcription that incorporated a multimodal tagging system based on Halliday's description of transitivity (Halliday, 1994: 101-144) but which also included the gestural semiotic (Baldry and Thibault: 2001:94-98). This kind of work can be particularly useful in understanding how (for example in a lecture) a speaker will typically use combinations of language, voice prosodics and gesture to express the point of view and/or circumstances of another person. All this helps us to understand how gesture and language combine to instantiate projection (Baldry and Thibault, 2000:96-98). This approach fits in with the notion of a specialised corpus highlighting specific kinds of textual phenomena such as projection, visual collocation, visual metaphor and so on within in multimodal approach to textuality.

But if we are to pursue our understanding of the codeployment of semiotic resources any further we need to understand how dynamic texts typically unfold in time and to ensure that this unfolding in time can be captured by *in vivo* rather than by *in vitro* multimodal analysis. In order to be able to identify typical patterns, the research process requires us to build corpora that can be analysed in terms of various textual phenomena, including in particular a study of the typical phasal organisation of a specific genre.

These then are the premises that led Baldry and Thibault to construct a corpus TV of car ads (currently 100) that a multimodal concordancer could help analyse. While sketching out some of the very preliminary results of this analysis (the corpus is still being constructed), we may describe the current organisation of MCA (the Beta test version released on 24.03.2002).

3.2 How it works

MCA is an XML-based multimodal concordancer whose user interface presents a series of rectangular green buttons (Fig. 3) which make up the *Projects Menu* and which represent the complete set of multimodal texts in the database.

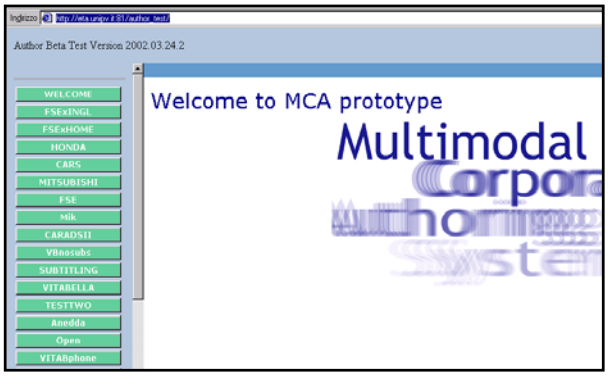

Fig. 3 Home page

When one is selected a specific project will open containing a video text. Using the scroll bar to browse through the *Projects Menu,* two light-blue buttons appear at the bottom of the list which respectively allow the user to create a *new* project in MCA or define *new* query-and-analysis parameters for use within the existing projects. Clearly, the system can be interpreted in one of two ways. While, on the one hand, it may be seen as an archive that can be consulted permitting detailed study of texts, on the other hand, MCA also represents a new area of distance work, given that users can enrich the relational database (which is the heart of MCA) with *their own* projects that are created and modified on-line and which the Server will immediately update and make available in Internet. When a particular MCA project is opened, a web page is loaded with a series of six light-blue buttons (grouped together on the left-hand side of the page) designed to 'handle' multimodal texts in ways described below.

Fig. 4: Analysis Inquiry and the Query Page

A user merely interested in viewing a film (such as the language learner posited in the *Introduction*) need only click on the last button, *Analysis Inquiry*, which will open up the *Query Page* and which when searched, using the *Parameters tool,* will return a film. In the example shown in Fig. 4, the query takes the form: *AD contains text 7*. This will automatically be opened and shown in *Windows Media Player* in the upper right-hand side of the web page. Clicking on the two leftmost *Media Player* buttons (Fig. 4), will, of course, stop and start the film. When we observe the open document, however, we quickly realise that construing MCA merely as a system for the reproduction of film texts would be reductive.

MCA in fact merges a relational database with streaming video technology, that allows specific sequences in a much longer film to be identified (and viewed) and to associate a description to each sequence. The basic idea is that the user can, in this way, consult a series of film sequences which share common characteristics. For example, a scholar concerned with an analysis of soap operas might want to find all the cases in which there is a dialogue between three, as opposed to two, speakers. Although in its current stage of development MCA is not able to show more than one film sequence at a time, the user can, as Fig. 5 indicates, nevertheless identify, with complete accuracy and certainty, all the cases sharing a particular feature, in the case in point all the Audi ads in the corpus.

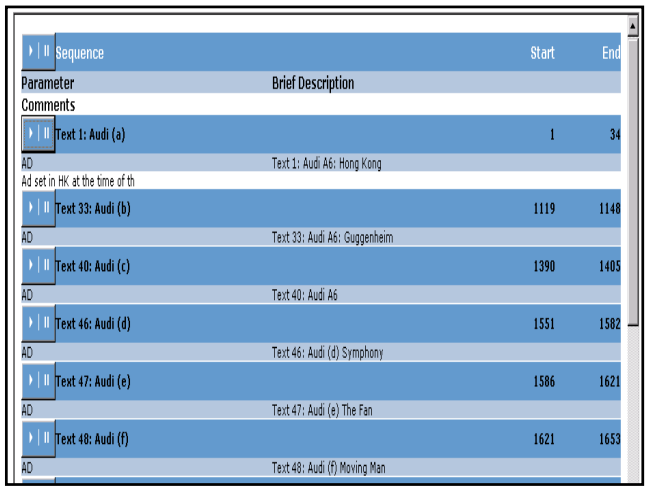

Fig. 5 Finding a subcorpus within the corpus

In this way, for example, the various sequences can be compared in such a way as to understand how body movements and gestures accompany these linguistic acts in characteristic patterns. To give one example (not shown here), we may care to analyse the way hand-and-arm movements are (as is always the case with gesture) crucially co-deployed with space in the construction of meaning. In a car ad for the New Mini, zombies appear from under the earth and prepare to lay their hands on a couple quietly kissing in a remote spot in their new car. The ad is constructed around the notion of space below and above ground (the zombies pop up from the world below) and inside and outside the car. A series of hand-arm movements are correlated to these notions creating the meaning, recurrent in contemporary European car ads, that the car is a place of safety. Indeed, the transition points in the advert coincide with the camera selecting parts of the car which divide the space in the Mini from the outside world (thereby reinforcing the message of safety and protection): the doors centrally locking from

inside, the front and rear windscreens. They also focus on a cohesive chain of hand movements: zombies outstretched hands (ready for attack), couple's hands raised upwards in fear and defence; driver's hands yawning; one zombie's hand replacing the windscreen wipers and patting the windscreen in a gesture of reassurance and leave-taking. All this is created in tandem with language which takes the form of an off-screen narrator (a voiceover) commenting on the zombies failed attack on the car.

In order for the user to be able to carry out such analyses and to make comparisons with other texts, preliminary operations (segmentation, indexing and tagging) need to be carried out. In particular, the user-author must:

- define a new project associating a film to MCA's descriptive tools (*Project Definition*)
- select the parameters used to tag and describe individual sequences (*Parameters Selection*)
- break the film up virtually into various sequences (*Video Indexing*)
- describe the characteristics of the individual sequences (*Sequence Analysis*) with a view to obtaining finely detailed information when queries are made.

When this has be done the final tool – *Analysis Inquiry* – can be used to produce the results shown in the various figures.

The user who wishes to create a new project can do so by clicking on the *New Project* button but can also modify an existing one (having selected it from MCA's home page). Creation and modification require completion (or redefinition) of the *Project Definition* menu. It is in this phase that the researcher associates a film (previously converted to the **.wmv* format) with the project. Input and output film are the same in MCA. In fact the film remains in its original form. All the work of segmentation, description tagging and retrieval is carried out within the relational database and associated tools.

When this first phase has been completed the parameters relevant to the research project need to be selected through the *Parameters Selection* menu. In the case that appropriate parameters are not available they can be added via a page accessible through the *Parameters Definition* menu. The list of parameters selected can be seen in *Sequence Analysis* page, through which a detailed description of the video text can be made. But before tagging and describing data, the film needs to be split up *virtually* into sequences. This operation is carried out in *Video Indexing*. The research and development cycle is completed with the use of *Analysis Inquiry,* from whose menu various queries and comparisons can be made.

4. Discussion

Although the system is relatively simple to use, nevertheless like any other software program, the MCA system is the result of specific design work which allows a limited degree of flexibility, on the one hand, but, on the other, allows the user to carry out investigations at a speed which would be hard to achieve by other means or which would be so demanding as not to be worth the candle. Thus while the system requires the use of Microsoft Internet Explorer browser and preferably release 5.5 or higher and a suitably updated release of Windows Media Player, on the other hand, the user is spared the constant need to wind backwards and forwards as is the case with video-cassettes or the wasteful dead-times associated with transferring, reproducing and downloading film.

Moreover, the user/author is able not only to play movie samples but also to add further annotations, providing he/she is authorised to do so (a system of authorisations and passwords is currently being added). Thus two or more researchers working in different locations can work on the description and/or tagging of the same corpus.

In one year's use many initial difficulties have been overcome, the system functioning reliably and responding to requirements for which it was not originally designed

Originally, conceived as an instrument to support research it has proved to be a useful means for teaching and on-line thesis preparation, the user base now including the following categories:

- the researcher who wishes to carry out his/her own work using MCA
- the teacher who needs to hold a language lesson supported by multimedia files
- the student who wishes to follow a self-access language learning course from his/her own home
- the thesis student who must carry out multimodal descriptions of texts
- the user who wishes to show the results of his/her research inserting them into a database.

For each of these user categories, specific needs have emerged which have required further work on the system so as to update it periodically to meet new demands. Feedback from users, who have required help in overcoming problems relating to minimum system requirements, has enabled us to perfect the film-coding technique, in such a way as to optimise the connection via modem and via LAN, avoiding, for example, lack of synchronisation between audio and image in the streaming video. A particular note needs to be made relating to the creation of new materials with subtitles, given the difficulties that users have encountered. For this reason the suggestion has been made that it would be appropriate to introduce a "text box" below the *Media Player* area in future MCA prototypes in which to introduce the subtitle corresponding to the sequence shown, which would be memorised in the database by means of a procedure that would extend the virtual approach adopted in MCA (i.e. subtitles would appear to be printed on the film, whereas in fact they are generated separately from the film).

Like any prototype MCA needs to be improved on and a fully-fledged second prototype is under production which, in addition to what has been outlined above, will introduce account-based security and privacy features respecting different user needs and user typologies more fully and introducing appropriate customisations. On the basis of the experience so far acquired, which has indicated a wider user base than at first expected, we can assume that other user categories, including institutional

users such as Language Centres and Libraries, will make use of MCA for the conversion/distribution of analogical or paper-based data, which may lead to the identification of new criteria for use of MCA. To date, most users have been closely associated only with Italian Universities, and mostly with the University of Pavia. Nevertheless, it has been exciting to follow the progress of graduating students who have used the system as an integral part of their graduation theses. We can therefore expect a growth in the number of graduating and postgraduate students who will use this system and are thus actively seeking inter-University ties and inter-University development projects that will help stimulate this goal.

5. Conclusion

Born in the text linguistics sector, MCA is an instrument for analysing dynamic multimodal texts, i.e. film and video texts which, as they unfold in time, display different and constantly varying constellations of sound, image, gesture, text and language (Baldry, 2000, Thibault 2000). Much of this work has already been reported elsewhere but this paper has described a new version of MCA as well as some of the results of one year's use of the tool. The growth in MCA's user base is evidence, apart from the growing interest in the description of multimodal texts, of the desire to learn about the potential and characteristics of this instrument, (including, of course, the need to understand how it works). Designed initially as a support for researchers dealing with the multimodal text analyses of texts, and specifically to provide them with the possibility of examining and comparing multiple contexts and texts in real time, it has proved a useful self-access distance language-learning and text analysis tool, since it provides students with the possibility of listening to, and watching, film clips, that are played and stopped at will. But the system has not yet benefited from critical comparison, one reason why we have decided to present it in various congresses. MCA has been built in virtual isolation vis-à-vis other systems and, in this respect, needs to grow considerably.

The Observer® Video-Pro: a Versatile Tool for the Collection and Analysis of Multimodal Behavioral Data

Niels Cadée, Erik Meyer, Hans Theuws & Lucas Noldus

Noldus Information Technology bv
P.O. Box 268, 6700 AG Wageningen, The Netherlands
n.cadee@noldus.nl, http://www.noldus.com

Abstract

The Observer is a professional tool for the collection, management, analysis and presentation of observational data. The user can record activities, postures, movements, positions, social interactions or any other aspect of behavior. The Observer can be used either for live scoring, or for scoring from analog or digital video material. With The Observer's generic configuration utility, detailed coding schemes can be designed for observing hand gestures, body postures, and facial expression. In the current version of the software, speech transcription is supported through free-format comments with time stamps. Improvements in the area of speech annotation are currently under way in the framework of the EU-funded NITE project. This includes more advanced coding schemes for speech annotation, as well as interfacing with other linguistic data collection and analysis tools via XML.

1. Introduction

The Observer (Noldus et al., 2000) has originally been developed as a tool to support observational studies in ethology. However, over the years it has become clear that the generic nature of the data collection and analysis functions of The Observer make it suitable for almost any observational study. The Observer is currently in use at thousands of universities, research institutes and industrial laboratories worldwide. Applications are found in a wide range of disciplines, including psychology, psychiatry, human factors and ergonomics, usability testing, industrial engineering, labor and time studies, sports research, consumer behavior and market research. Recently, we have noticed an increasing interest from researchers in the area of multimodality and speech annotation. We are in the process of extending our software to cater for the specific demands of researchers in this field, through our active collaboration in the EU-funded NITE project (Natural Interactivity Tools Engineering, http://nite.nis.sdu.dk/). Some research groups are already using The Observer to study, for example, turn taking in dialogues between two persons, verbal and non-verbal communication between mothers and toddlers, and for making a dictionary of everyday gestures.

2. Program features

The Observer can be used either for live scoring (Basic version), or scoring from analog or digital video material (Video-Pro version). The Observer can control a video recorder from the pc, and by use of a video overlay board, display the video image of a tape on the computer screen, within the program (Fig. 1). Digital video files can be played directly within The Observer. There is a direct coupling between time code in the data files with scored annotations and the video material. This allows for accurate scoring, even when playing the video at slow or fast speeds. Advanced search functions allow the user to find particular events or time stamps on the videotape or media file. A search for events is always based on elements from the coding scheme. A special highlights function allows the user to select specific episodes based on the scored events, and make analog or digital video clips for presentation purposes.

3. Program demonstration

During the workshop, The Observer 4.0, the latest release, will be demonstrated. Compared to previous editions, version 4 features improved usability, especially for design of the coding scheme. Data selection has been completely redesigned, and allows for the most complex filtering of annotation results. For example, one can define time intervals of variable length based on actual scored events, to answer questions like 'How often did Peter grin between the time when John entered the room, and the time when John left the room again?' Finally, The Observer 4.0 has an intuitive new layout that shows projects and their content in a tree view (Fig. 2).

4. Designing coding schemes

With The Observer's generic configuration utility, detailed coding schemes can be designed for observing hand gestures, body postures, and facial expression. Gaze can be scored manually, or recorded with additional eye-tracking equipment. The coding scheme is based on behavioral classes, which each contain a set of mutually exclusive behaviors. In a simple example, you can have one behavioral class with hand gestures, and another class with types of speech. Aggressive and normal speech could be two mutually exclusive behaviors in the speech class, while pointing and waving could both be in the hand gesture class. A pointing gesture in the hand gesture class can be scored at the same time as aggressive speech in the speech class, but it could also be scored during normal speech. The user can further detail the coding scheme by attaching one or two modifiers to the behaviors. These can indicate for example the intensity of a behavior, or the person or object the behavior is aimed at. For example, for a pointing gesture, you can also score the object that the person is pointing at.

5. Speech annotation

Speech and other audio signals can also be annotated with The Observer. The current form of speech transcription is as free-format comments with time stamps. We are working on improvement in the speech area through participation in the NITE project. We are currently looking into options for XML export, and for allowing more structure for speech annotation. The

Observer and prototypes of other software developed in this project will be shown in a demonstration session during the LREC conference.

6. Data analysis

The Observer has extensive features for data analysis. The user can filter the data with the data selection function, and for example select variable time intervals based on scored events. Data can be visually examined in tables and plots of events against time (Fig. 2). A range of elementary statistics can be calculated. Reliability analysis is another important feature, where users can check the consistency of several different people's annotations of the same video material. With lag sequential analysis, temporal relations and patterns can be discerned.

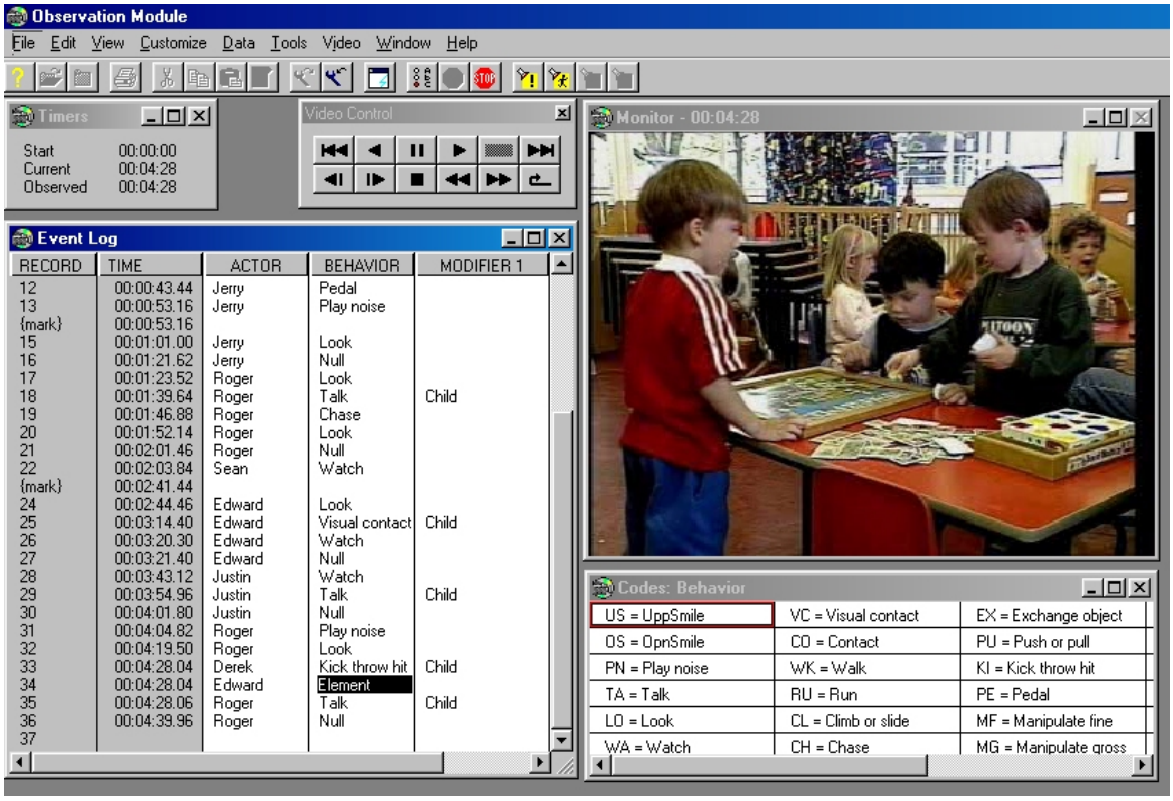

Figure 1: The Observation Module of The Observer. This example shows a project on children's playing behavior. The user can customize the size and position of the windows, and select which ones to display. In this case, the screen shows the codes for annotation, the event log with the data file with times and scored events, the video image, video controls, and timers.

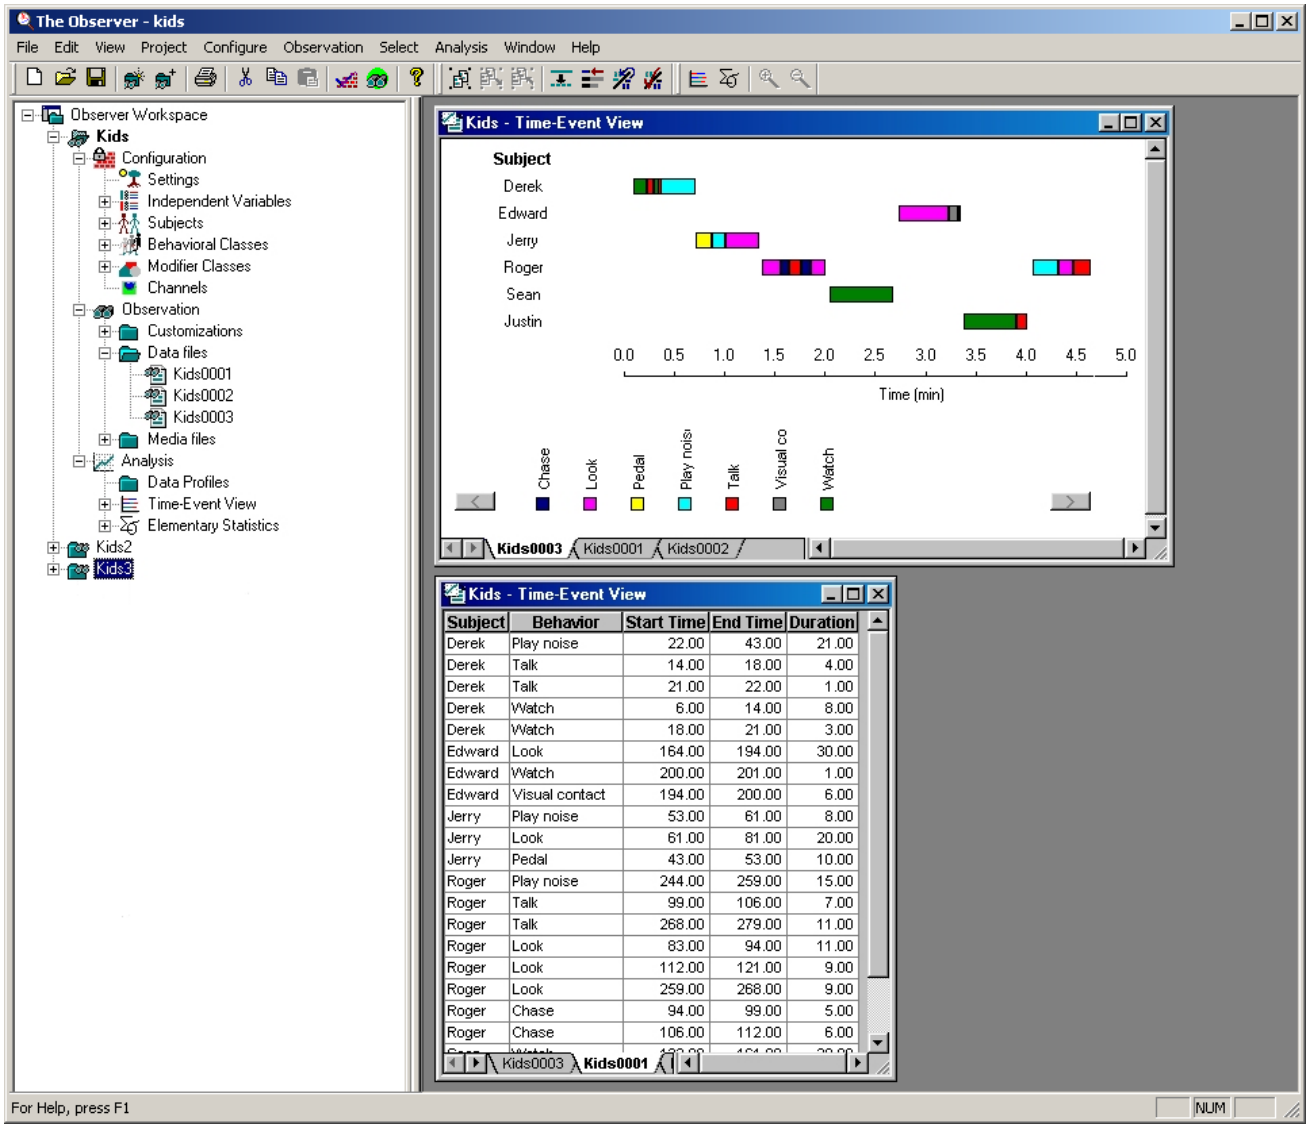

Figure 2: The Main Module of The Observer. In the Explorer view on the left side, a workspace with three projects is shown. One project (on children's playing behavior) is expanded to show its contents. The Configuration contains all settings of the coding scheme. On the right side of the screen, two types of analysis results are shown: a time-event plot and a time-event table.

Prosody Based Co-analysis of Deictic Gestures and Speech in Weather Narration Broadcast

Sanshzar Kettebekov, Mohammed Yeasin, Nils Krahnstoever, Rajeev Sharma

Abstract

Although speech and gesture recognition has been studied extensively all the successful attempts of combining them in the unified framework were semantically motivated, e.g., keyword co-occurrence. Such formulations inherited the complexity of natural language processing. This paper presents a statistical approach that uses physiological phenomenon of gesture and speech production process for improving accuracy of automatic segmentation of continuous deictic gestures. The prosodic features from the speech signal were co-analyzed with the visual signal to create a statistical model of co-occurrence with particular kinematical phases of gestures. Results indicated that the above co-analysis improves continuous gesture recognition. The efficacy of the proposed approach was demonstrated on a large database collected from the weather channel broadcast. This formulation opens new avenues for bottom-up frameworks of multimodal integration.

1. Introduction

In combination, gesture and speech constitute the most important modalities in human-to-human communication. People use large variety of gestures either to convey what cannot always be expressed using speech only or to add expressiveness to the communication. Motivated by this, there has been a considerable interest in incorporating both gestures and speech as the means for Human-Computer Interaction (HCI).

To date, speech and gesture recognition have been studied extensively but most of the attempts at combining them in an interface were in the form of a predefined signs and controlled syntax such as "*put <point> that <point> there*", e.g., (Bolt, 1980). Part of the reason for the slow progress in multimodal HCI is the lack of available sensing technology that would allow non-invasive acquisition of natural behavior. However, the availability of abundant processing power has contributed to making computer vision based continuous gesture recognition in real time to allow the inclusion of natural gesticulation in a multimodal interface (Kettebekov and Sharma, 2001, Pavlovic et al., 1997, Sharma et al., 2000).

State of the art in *continuous gesture recognition* is far from meeting the requirements of a multimodal HCI due to poor recognition rates. Co-analysis of visual gesture and speech signals provide an attractive prospect of improving continuous gesture recognition. However, lack of fundamental understanding of speech/gesture production mechanism restricted implementation of the multimodal integration at the semantic level, e.g. (Kettebekov and Sharma, 2001, Oviatt, 1996, Sharma et al., 2000). Previously, we showed somewhat significant improvement in co-verbal gesture recognition when those were co-analyzed with keywords (Sharma et al., 2000). However, the implications of using a top-down approach has augmented challenges with those of natural language and gesture interpretation and made automatic processing challenging.

The goal of the present work is to investigate co-occurrence of speech and gesture as applied to continuous gesture recognition from a bottom-up perspective. Instead of keywords, we employ a set of prosodic features from speech that correlate with deictic gestures. We address the general problem in multimodal HCI research, e.g., availability of valid data, by using narration sequences from the weather channel TV broadcast. The paper is organized as follows. First, a brief overview of the types of gestures that occur in the analysis domain is presented. The synchronization hierarchy of gestures and speech is also reviewed. In section 3 we discuss a computational framework for continuous gesture acquisition using a segmental approach. Section 4 presents a statistical method for correlating visual and speech signals. There, acoustically prominent segments are detected and aligned with segmented gesture phases. Finally, results are discussed within the framework for continuous gesture recognition.

2. Co-verbal Gesticulation for HCI

McNeill (1992) distinguishes four major types of gestures by their relationship to the speech. *Deictic* gestures are used to direct a listener's attention to a physical reference in course of a conversation. These gestures, mostly limited to the pointing, were found to be co-verbal, cf. (McNeill, 1992). From our previous studies, in the computerized map domain (***i*MAP,** see Figure 1) (Kettebekov and Sharma, 2000), over 93% of deictic gestures were observed to co-occur with spoken nouns, pronouns, and spatial adverbials.

Iconic and *metaphoric* gestures are associated with abstract ideas, mostly peculiar to subjective notions of an individual. *Beats* serve as gestural marks of speech pace. In the weather channel broadcast the last three categories roughly constitute 20% of all the gestures exhibited by the narrators. We limit our current study to the *deictic* gestures for a couple of reasons. First, they are they are more suitable for manipulation of a large display, which becomes more common for HCI applications. Second, this

type of gestures exhibits relatively close coupling with speech.

2.1. Gesture and Speech Production

The issue of how gestures and speech relate in time is critical for understanding the system that includes gesture and speech as part of a multimodal expression. McNeill (1992) distinguishes three levels of speech and gesture synchronization: semantic, phonological, and pragmatic. The pragmatic level synchrony is common for metaphoric and iconic gestures and therefore is beyond the scope of the present work.

Semantic synchrony rule states that speech and gestures cover the same idea unit supplying complementary information when they occur synchronously. The current state of HCI research provides partial evidence to this proposition. Previous co-occurrence analysis of weather narration (Sharma et al., 2000) revealed that approximately 85% of the time when any meaningful gestures are made, it is accompanied by a spoken keyword mostly temporally aligned during and after the gesture. Similar findings were shown in the pen-voice studies (Oviatt et al., 1997). The implication of the semantic level synchronization rule was successfully applied at the keyword level co-occurrence in the previous weather narration study (Sharma et al., 2000).

At the phonological level, Kendon (1990) found that different levels of movement hierarchy are functionally distinct in that they synchronize with different levels of prosodic structuring of the discourse in speech. For example, the peaking effort in a gesture was found to precede or end at the phonological peak syllable (Kendon, 1980). These findings imply a necessity for viewing a continuous hand movement as a sequence of kinematically different segments of gestures. This approach is reflected in the next section. Issue of using the phonological peak syllables is associated with the complexity of the nature of the tonal correlates, e.g., pitch of the voice. Pitch accent, which can be specified as low or high, is thought to reflect a phonological structure in addition to the tonal discourse, cf. (Beckman et al., 1992). We address this issue by proposing a set of correlate point features in the pitch contour that can be associated with the points on the velocity and acceleration contours of the moving hand (section 4).

3. Gesture Acquisition

Building human computer interfaces that can use gestures involves challenges that range from low-level signal processing to high-level interpretation. A wide variety of methods had been introduced to create gesture driven interfaces. With the advances in technology there has been a growing interest in using vision-based methods (Pavlovic et al., 1997). The advantage of these is in their non-invasive nature. The idea of a natural interface comes from striving to make HCI as close as communicating in ways we are accustomed to. Vision-based implementation therefore can be very useful for a natural interface.

One could expect that the meaning encoded in multimodal communication is somehow distributed across speech and gesture modalities. A number of recent implementations used predefined gesture syntax, e.g., (Oviatt, 1996). A user is confined to the predefined gestures for spatial browsing and information querying. As a result, a rigid syntax is artificially imposed. Therefore the intent of making interaction natural is defeated. However, with imprecise recognition of non-predefined gestures, it may be harder to argue for replacing more precise HCI devices, e.g., electronic pen with fixed predefined functions.

The key problem in building such interface, e.g., using statistical techniques, is the lack of existing *natural* multimodal data. Studies from human-to-human communication do not automatically transfer over to HCI due to artificially imposed paradigms. This controversy leads to a "chicken-and-egg" problem.

While the use of the weather narration domain as a bootstrapping analysis offers virtually unlimited bimodal data it can be assumed as a reasonable simplification of an HCI domain. In the series of the previous studies we employed the weather narration broadcast analysis (Sharma et al., 2000) to bootstrap ***i*MAP** framework (Figure 1) (Kettebekov and Sharma, 2001). It showed that the gesticulative acts used in both domain have similar kinematical structure as well as gesture and keyword co-occurrence patterns. However, the key aspect for choosing the weather domain for the current study is in a possibility of applying simple processing techniques for extraction of prosodic information from uninterrupted narration.

Figure 1. ***i*MAP** testbed in the context of a computerized map. The cursor is shown within the circle.

Over 60 minutes of the selected weather narration data was used in the analysis. The video sequences contained uninterrupted monologue of 1-2 minutes in length. The subject pool was presented by 5 men and 3 women.

3.1. Kinematics of Continuous Gestures

A continuous hand gesture consists of a series of qualitatively different kinematical phases such as movement to a position, hold, and transitional movement. We adopt Kendon's framework (Kendon, 1990) by organizing these into a hierarchical structure. He proposed a notion of gestural unit (*phrase*) that starts at the moment when a limb is lifted away from the body and ends when the limb moves back to the resting position. The *stroke* is distinguished by a peaking effort and it is thought to constitute the meaning of a gesture (Kendon, 1990). After extensive analysis of gestures in weather narration and *i*MAP (Kettebekov and Sharma, 2001, Sharma et al., 2000) we consider following strokes: *contour*, *point*, and *circle*.

Kita (1997) suggested that a *post-stroke hold* was a way to temporally extend a single movement stroke so that the *stroke* and *post-stroke hold* together will

synchronize with the co-expressive portion of the speech. It is thought that a *pre-stroke hold* is a period in which gesture waits for speech to establish cohesion so that the stroke co-occurs with the co-expressive portion of the speech. Therefore, in addition to our previous definitions we also include *hold* as a functional primitive.

3.2. Continuous Gesture Segmentation

Sixty minutes of weather domain gesture data for training and testing was collected from broadcast video using a semi-automatic gesture analysis tool (GAT) (see Figure 2). The tool provides a convenient user interface for rapid and consistent collection of positional data and a easily configurable set of pattern classification tools. GAT is integrated with PRAAT software for phonetics research (Boersma and Weenink, 2002) for speech processing and visualization.

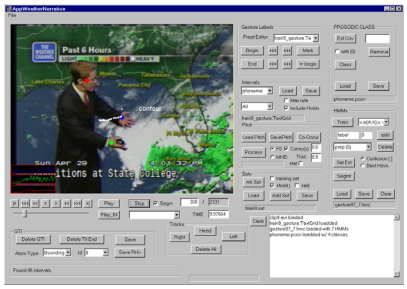

Figure 2. Gesture analysis tool (GAT) interface

The task of positional data ground truthing involves initialization the head and hand tracking algorithms (described in 2.3.1) at the beginning of each video sequence and in the events of self-occlusions of the hands.

3.2.1. Motion Tracking

The algorithm for visual tracking of the head and hands is based on motion and skin-color cues that are fused in a probabilistic framework. For each frame and each tracked body part, a number of candidate body part locations are generated within a window defined by the location of the body part in the previous frame and the current estimate of the predicted motion. The true trajectories of the body parts are defined as the most probable paths through time connecting candidate body part locations. The Viterbi algorithm is used to efficiently determine this path over time. This approach effectively models the hand and head regions as skin-colored moving blobs (Figure 3).

3.2.2. Kinematical Analysis

To model the gestures, both spatial and temporal characteristics of the hand gestures (phonemes) were considered. The time series patterns of gesture phases can be viewed as a combination of ballistic and guided motion of the hand reflected on the skewedness of the velocity profile. In the current study, a gesture phoneme is defined as a stochastic process of 2D positional and time differential parameters of the hand and head over a suitably defined time interval.

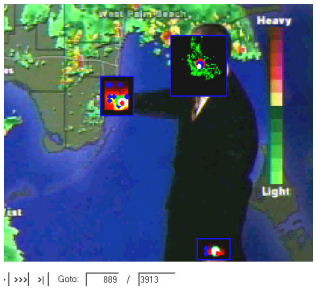

Figure 3. Semi-automatic ground truthing process employing a tracking algorithm;

A Hidden Markov Model (HMM) framework was employed for continuous gesture recognition, as described in (Sharma et al., 2000). The total of 446 phoneme examples extracted from the segmented training video footage were used for HMM training. The results of the continuous gesture recognition showed that only 74.2 % of 1876 were classified correctly. Further analysis indicated that phoneme pairs of preparation-pointing and contour-retraction constitute most of the substitution errors. This type of error, which can be attributed to the similarity of the velocity profiles, was accounted for the total of 33% of all the errors. The deletion[1] errors were mostly due a relatively small displacement of the hand during a pointing gesture. Those constituted approximately 58% of all the errors.

Although purpose of this work was not to introduce a robust algorithm with a high recognition rate there is an inherent limitation with the current acquisition method. I.e., 2D projected motion data can potentially introduce spurious variabilities that can have a detrimental effect on the recognition rate. The gesture model is based on the observed end-effector motion of the hands and the motion of the head projected into the camera plane and is only and indirect measurement of the true body

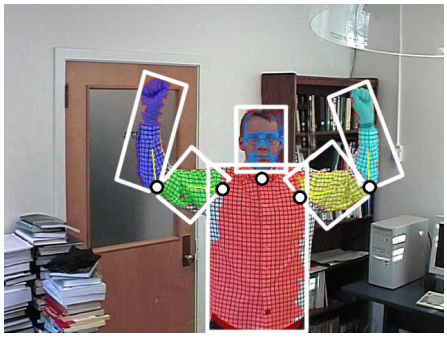

Figure 4. Model based tracking for future extraction of direct kinematical gesture parameters.

[1] Deletion type of errors occur when a gesture phoneme is recognized as part of another adjacent gesture.

kinematics. This observation model can hence introduces distortions and additional spurious variabilities that complicate the differentiation between gestures. Current work in progress, cf. (Krahnstoever et al., 2002), has the goal of visually extracting the true 3D kinematical parameters such as body pose and angles of the shoulder and arm joints (see Figure 4).

4. Prosody Based Co-analysis

Both psycholinguistic, e.g., (McNeill, 1992), and HCI, e.g., ***i*MAP** (Kettebekov and Sharma, 2000), studies suggest that deictic gestures do not exhibit one-to-one mapping of form to meaning. Previously, we showed that the semantic categories of strokes (derived through the set of keywords), not the gesture phonemes, correlate with the temporal alignment of keywords, cf. (Kettebekov and Sharma, 2000). This work distinguishes two types of gestures: referring to a static point on the map and to a moving object (i.e., moving precipitation front). Due to the homogeneity of the context and trained narrators in the weather domain we can statistically assume (mismatch <2%) that pointing gesture is the most likely to refer to the static and contour stroke to the moving objects. Therefore, for simplicity we will use *contour* and *point* definitions.

The purpose of the current analysis is to establish a framework by identifying correlate features in visual and acoustic signals. First we will separate acoustically prominent segments. A segment is defined as a voiced interval on the pitch contour that phonologically can vary from a single phone/foot[2] to intonational phrase units, see (Beckman, 1996) for details. Then we will analyze alignment of the prominent segment with the gesture phonemes. This framework was implemented in GAT.

4.1. Detecting Prosodically Prominent Segments

Pitch accent association in English underlines the discourse-related notion of focus of information. Fundamental frequency (F_0) is the correlate of pitch defined as the time between two successive glottis closures (Hess, 1983). We employed PRAAT software to extract F_0 contour, as described in (Boersma, 1993).

Prominent segments were defined as segments which were relatively accentuated (or perceived as such) from the rest of the monologue. We considered combination of the pitch accent and the pause before each voiced segment to detect abnormalities in spoken discourse. Maximum and minimum of F_0 contour represent features for high pitch and low pitch accents. Maximum gradient of the pitch slope was also considered. A statistical model of prosodic discourse for each narration sequence was created (Figure 5), see (Kettebekov et al., 2002) for details.

To find an appropriate level of threshold to detect prominent segments we employed a bootstrapping technique involving a perceptual study. A control sample set for every narrator was labeled by 3 naïve coders for auditory prominence. The coders had access only to the wave form of speech signal. The task was to identify at least one acoustically prominent sound within the window of 3 seconds. The moving window approach was considered to account for abnormally elongated pauses in the spoken discourse. Allowing 2% of misses, the threshold was experimentally set for each narrator (Figure 5). If a segment appeared to pass the threshold value it was considered for co-occurrence analysis with the associated gesture.

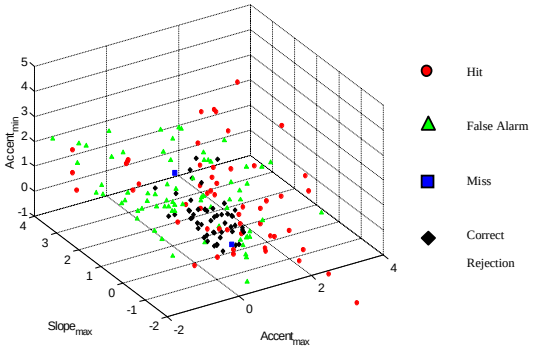

Figure 5. A sample distribution of auditory prominence for a female narrator with the decision boundary from the perceptual study.

4.2. Co-occurrence Models

A statistical model of the temporal alignment of active hand velocity and a set of features of the prominent pitch segments was created for every gesture phoneme class (Figure 6). The features on the pitch profile included max, min, beginning, and max of derivative of F_0, see (Kettebekov et al., 2002) for details. Present formulation

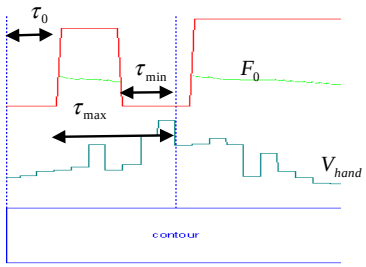

Figure 6. A set of features used for co-occurrence modeling of the hand velocity (V_{hand}) and a pitch (F_0) segment. Red contour represents prominence level of corresponding segments

accounts for the two levels of possible prosodic co-occurrence: discourse and phonological. The onset between a gesture and the beginning of a prominent segment is to model discourse cohesion (pauses). The onset of the peaks in the F_0 and peaks in the velocity profile of the hand addresses phonological level synchronization. All of 446 phonemes that have been used for training gesture phonemes were utilized for training of the co-occurrence models. Analysis of the resulted models indicated that there was no significant difference between *retraction* and *preparation* phases. Peaks of *contour* strokes tend closely to coincide with the peaks of the pitch

[2] Foot is a phonological unit that has a "heavy" syllable followed by a "light" syllable(s).

segments. *Pointing* appeared to be quite silent, however, most of the segments were aligned with the beginning of the *post-stroke hold* interval.

Figure 7 summarizes findings of the co-analysis framework. At the first level we separate co-verbally meaningful gestures (*strokes*) from *auxiliary* phonemes that included *preparation* and *retraction* phases. Also, we exclude strokes that are re-articulate previous gestures such as a stroke can be followed by the identical stroke where the second movement does not have associated speech segment. At the second level co-verbal strokes can be further classified according to their deixis, cf. (Kettebekov and Sharma, 2001). As it was noted before, in the context of the weather narration we can statistically consider those to be represented by *point* and *contour* phonemes without further definitions. *Preparation* and *retraction* phases were eventually collapsed into the same category and were not differentiated.

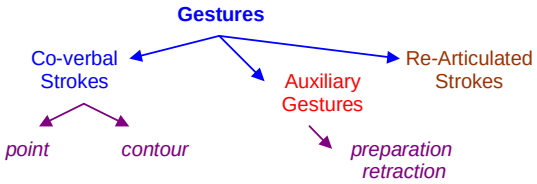

Figure 7. Prosodic co-analysis framework

The co-analysis models for co-verbal strokes were merged with the beginning of the post stroke-*hold* phases for classification purposes. Such redefinition of the co-verbal strokes for the purpose of co-analysis was motivated by the results associated with the *pointing* strokes and it was included into the computational framework.

4.3. Continuous Gesture Recognition with Co-occurrence Models

We employed Bayesian formulation to fuse the gesture framework and the co-occurrence models at the decision level, see (Kettebekov et al., 2002). The resulted segmentation showed significant improvement in the overall performance with the correct recognition of 81.8% (versus 72.4%). Subsequently, there was a significant reduction of deletion (8.6% versus 16.1%) and substitution errors (5.8% versus 9.2%). The deletion type of errors were minimized due to the inclusion of small point gestures, which are quite salient when correlated with prominent acoustic features. Figure 8 shows example of elimination of a deletion error after applying co-analysis. White trace on the figure illustrates visually negligible hand movement trajectory. Improvement of substitution errors can be attributed to the differentiation between the auxiliary gesture phases and the strokes in the co-occurrence analysis.

5. Conclusions

We presented an alternative approach for combining gesture and speech signals from the bottom-up perspective. Unlike commonly controlled gesture

a) b)

Figure 8. Example of deletion error using: a) visual-only signal resulted in *hold* gesture; b) with co-occurrence model *point* was recognized as a part of preceding *hold* (case a.);

recognition domains, we address this problem in the weather broadcast domain, which can be characterized by relatively unrestricted narration. Such formulation is more favorable for automated recognition of continuous deictic gestures then the semantic based (keyword co-occurrence). The current results demonstrate the concept of improving recognition of co-verbal gestures when combined with the prosodic features in speech. This is a first attempt which requires further improvement. The issues of portability to an HCI setting, e.g., ***i*MAP** framework, are currently under investigation.

Applicability of the current formulation for the other types of gestures is probably possible if the segmental approach is considered for the gesture acquisition. In a domain with more spontaneous behavior, e.g., in a dialogue (e.g., ***i*MAP**) (versus monologue as presented in the present work) the methodology of prosodically prominent feature extraction is more complex. It would require acquisition of an improved kinematical model (see section 3.2.2.) that considers additional visual cues such as turn of head (direction of the gaze), and etc.

Abstract

Representing the behaviour of multimodal interactive systems in a complete, concise and non-ambiguous way is still a challenge for formal description techniques. Indeed, multimodal interactive systems embed specific constraints that are either cumbersome or impossible to capture with classical formal description techniques. This is due to both the multiple facets of a multimodal system (in terms of supported modes) and the strong temporal constraints usually encountered in this kind of systems. This position paper presents a formal description technique dedicated to the engineering of interactive multimodal systems. The formal description technique is then used for the modelling and analysis of two fusion mechanisms. Lastly, benefits and limitations of the approach are discussed.

1. Introduction

Despite some efforts for providing toolkits for the construction of multimodal interactive systems (Bederson et al. 2000, Chatty 94), the actual engineering of multimodal interactive systems remains a cumbersome task usually carried out in a rather crafty process. Indeed, while the design (Coutaz & Nigay 1993, Nigay & Vernier 2000) and the evaluation (Coutaz et al. 1996) of multimodal interactive systems have been thoroughly studied, the process of going from a given design to an actual functional system has been the focus of very little research work.

An important aspect of this development process is the reuse of work done from a previous design to another application. Some work on toolkits (Bederson & al. 2000) and architectures (Nigay & Coutaz 95) address this problem at a very low level of abstraction thus making the solution bounded either to modalities or to development platforms.

We believe that the use of an adequate formal description technique can provide support for a more systematic development of multimodal interactive systems. Indeed, formal description techniques allows for describing a system in a complete and non-ambiguous way thus allowing for an easier understanding of problems between the various persons participating in the development process. Besides, formal description techniques allow designers to reason about the models by using analysis techniques. Classical results can be the detection of deadlock or presence or absence of terminating state. A set of properties for multimodal systems have been identified (Martin 1999, Coutaz et al. 1995) but their verification over an existing multimodal system is usually impossible to achieve. For instance it is impossible to guarantee that two modalities are redundant whatever state the system is in.

The paper is structured as follows. Next section is dedicated to related work dealing with specification of multimodal interactive systems. Section 3 is dedicated to the informal presentation of the ICO (Interactive Cooperative Objects) formalism. Section 4 presents extensions to ICO called the MICO formalism (Multimodal Interactive Cooperative Objects) which is dedicated to the formal description of multimodal interactive systems. This formalism is applied to two fusion mechanisms. The first one integrates voice and gesture while the second one features two handed interaction. Last section (section 5) presents the advantages and limitations of the approach as well as future and ongoing work.

2. Related work

Work in the field of multimodal can be sorted in four main categories. Of course the aim of this categorization is not to be exhaustive but to propose an organisation of previous work in this field.

- Understanding multimodal systems
  - (Coutaz & Nigay 1993) typology of multimodal systems, refined in (Bellik 1995)
  - (Coutaz et al. 1995), (Martin 1999) presenting properties of multimodal systems
- Software construction of multimodal systems
  - (Chatty 94, Bederson et al. 2000) propose toolkits for the construction of multimodal systems
  - (Nigay & Coutaz 95) proposes a generic software architecture for multimodal systems
- Analysis and use of novel modalities

- ✍ (Bolt 1980) presents the first use of voice and gesture as combined modalities.
- ✍ (Buxton & Myers, 1986) introduces two handed interaction.
- ✍ (Bolt & Herranz 92) introduces the use of the two handed interaction in virtual reality applications.
- ✍ (Vo & Wood 1996) presents Jeanie, a multimodal application, to test the use of eyes tracking and lips movements' recognition.

o Multimodal systems description.
- ✍ (Nigay & Coutaz 95) presents a Multimodal Air Traffic Information System (MATIS) using both voice and direct manipulation interaction.
- ✍ (Cohen et al. 1997) presents QuickSet a cooperative user interface to military systems using both voice and gesture.
- ✍ (Bier et al. 1993) presents a drawing systems featuring two handed interaction through a trackball and a mouse.

While formal description techniques have been defined and used for interactive systems since the early work from Parnas (Parnas 69), their extension and use for multimodal systems is still relatively rare. We can quote for instance work from (Duke & Harrison 1997) or (MacColl & Carrington 98) were they present how software engineering techniques such as Z and CSP can be used for the modelling of MATIS the multimodal air traffic information system developed byNigay (Nigay & Coutaz 1995).

We believe that multimodal interactive systems feature intrinsic characteristics that make formal description techniques used in software engineering not directly suitable for multimodal systems. First, multimodal interactive systems are, by definition, interactive and thus behave in an event-driven way, usually hard to capture and represent in state based descriptions such as Z. Second, the temporal constraints are at the core of these systems which are more often than not real time and highly concurrent. Indeed, users' actions may occur simultaneously on several input devices and the fusion mechanism must process those input in real-time. Formal description techniques with an interleaving semantics (such as CSP, CCS or LOTOS) are not capable of representing such truly concurrent behaviours. Lastly, the use of temporal windows in fusion mechanisms requires, from a formal description technique, the possibility to represent time in a quantitative way by expressing for instance that an event must be received within 100 milliseconds.

Petri nets is one of the few formal description techniques that allows for representing the behaviour of such systems. Indeed, they feature true-concurrency semantics, they are able to deal both with events and states and they provide several ways to represent quantitative time (Bastide & Palanque 1994).

For space reasons we do not present in detail the notation here but next section shows how these characteristics are used while modelling two fusion mechanisms.

3. Informal Description of ICOs

The Interactive Cooperative Objects (ICOs) formalism is a formal description technique dedicated to the specification of interactive systems (Bastide et al. 1998). It uses concepts borrowed from the object-oriented approach (dynamic instantiation, classification, encapsulaton, inheritance, client/server relationship) to describe the structural or static aspects of systems, and uses high-level Petri nets (Genrich 1991) to describe their dynamic or behavioural aspects.

ICOs are dedicated to the modelling and the implementation of event-driven interfaces, using several communicating objects to model the system, where both behaviour of objects and communication protocol between objects are described by Petri nets. The formalism made up with both the description technique for the communicating objects and the communication protocol is called the Cooperative Objects formalism (CO and its extension to CORBA COCE (Bastide et al. 2000)).

In the ICO formalism, an object is an entity featuring four components: a cooperative object with user services, a presentation part, and two functions (the activation function and the rendering function) that make the link between the cooperative object and the presentation part.

Cooperative Object (CO): a cooperative object models the behaviour of an ICO. It states how the object reacts to external stimuli according to its inner state. This behaviour, called the Object Control Structure (ObCS) is described by means of high-level Petri net. A CO offers two kinds of services to its environment. The first one, described with CORBA-IDL (OMG 1998), concerns the services (in the programming language terminology) offered to other objects in the environment. The second one, called user services, provides a description of the elementary actions offered to a user, but for which availability depends on the internal state of the cooperative object (this state is represented by the distribution and the value of the tokens (called marking) in the places of the ObCS).

Presentation part: the Presentation of an object states its external appearance. This Presentation is a structured set of widgets organized in a set of windows. Each widget may be a way to interact with the interactive system (user → system interaction) and/or a way to display information from this interactive system (system → user interaction).

Activation function: the user → system interaction (inputs) only takes place through widgets. Each user action on a widget may trigger one of the ICO's user services. The relation between user services and widgets is fully stated by

the activation function that associates to each couple (widget, user action) the user service to be triggered.

Rendering function: the system → user interaction (outputs) aims at presenting to the user the state changes that occurs in the system. The rendering function maintains the consistency between the internal state of the system and its external appearance by reflecting system states changes.

ICO are used to provide a formal description of the dynamic behaviour of an interactive application. An ICO specification fully describes the potential interactions that users may have with the application. The specification encompasses both the "input" aspects of the interaction (i.e. how user actions impact on the inner state of the application, and which actions are enabled at any given time) and its "output" aspects (i.e. when and how the application displays information relevant to the user).

An ICO specification is fully executable, which gives the possibility to prototype and test an application before it is fully implemented (Navarre et al. 2000). The specification can also be validated using analysis and proof tools developed within the Petri nets community and extended in order to take into account the specificities of the Petri net dialect used in the ICO formal description technique.

4. Fusion Mechanisms Modelling

This section presents how MICO formalism can be used for the modelling of two fusion mechanisms. As explained in previous section this formalism is able to capture all the elements that are embedded in fusion mechanisms.

4.1. Voice and Gesture Interaction

Our first example is Bolt's system (Bolt 80). Bolt was the first to have the idea to use voice and gesture recognition synergistically for multimodal input. This idea had been implemented in a drawing application, in which user can specify a command orally and give its arguments with either a precise oral description or with a deictic word (this, here, there, ...) and a designation gesture

In this system, five different commands are allowed: create, name, delete, make and move. Each command features a given number of arguments. As long as the command is incomplete, the system waits for the missing argument(s). When a deictic is uttered, user's gesture is taken in account.

As an input for the modelling of this system, we have taken the informal description that can be found in Bolt's papers. Of course, as this application has been presented in natural language and implemented, but not formally described, it is difficult to perfectly understand the functioning of the integration between deictic and gesture. We have supposed that the analysing of a deictic word is at the origin of the triggering of the gesture recognition. Similarly, fusion criteria between command and its potential arguments are not detailed. In the model, this has been represented by the use of typing constraints. Figure 2 and Figure 2 present the formal description of the system according to the assumption presented above. This model describes in a non-ambiguous way the behaviour of the fusion mechanism. In the model rectangles (called transitions) represent actions the system can perform while ellipses (called places) represent state variable of the system. Places can hold tokens and the distribution of tokens in the places represent the current state of the system. The Petri model used in the MICO formalism is called a high-level Petri net model as token can hold values.

Microphone	No	Utterance of a description	ProdDesc	No

Event production function:

Element name	Event produced
EndCmde	Event Comand_completed

Figure 2. A formal description of the fusion mechanism in Bolt's system(interaction part)

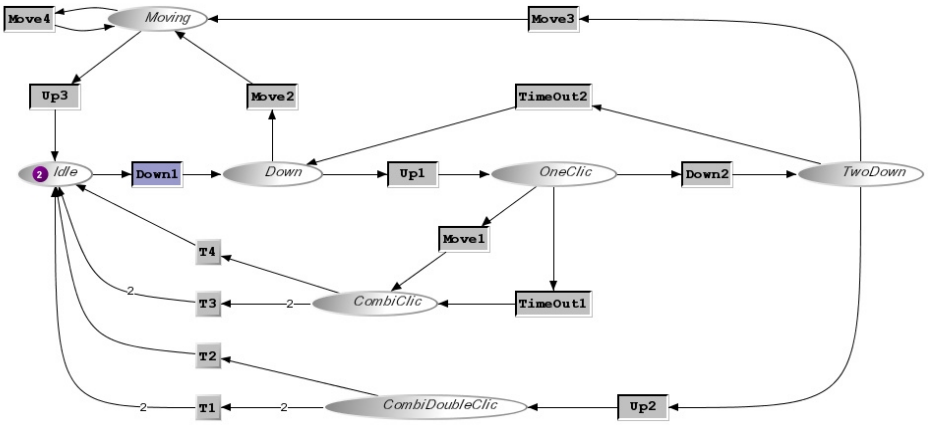
The initial state of the system presented in Figure 2 is thus the presence of 5 tokens in place *Model* and no token in the other places of the net. The values of these token are the description of the commands the system can interpret i.e. their number of arguments, the type of this arguments (object, position or name) and their name (create, name, delete, make or move). Places and transitions are related by arcs. A transition can be fired (i.e. an action performed) if and only if each input place of the transition holds at least one token. When a transition is fired, the token are remove from the input places and one token is deposited in each output place. The model in Figure 2 features two specific kinds of arcs. Tests arcs model the fact that a token is tested i.e. it is not removed or changed by the firing of the transition but its existence is necessary for the actual firing of the transition. Such an arc is represented between transition ProdDesc and place *Stop* meaning that in order for the system to process a description (transition ProdDesc) the system must be in the Stop state i.e. place *Stop* holds at least one token. Inhibitor arc model the zero test in a Petri net. For instance the arc between place *Stop* and transition ProdCommand is an inhibitor arc (the end of the arc is a black dot) meaning that this transition can only be fired if there is no token in place *Stop*. Relationship between transitions and events is done by means of dedicated transitions called synchronised transitions. A synchronized transition can only be fired if it is fireable (according to the current marking of the net) and the associated event is triggered (for instance after a corresponding user action on a dedicated input device). In Figure 2, “ProdCommand”, “ProdDei” and “ProdDesc” are synchronized with user events (utterance of a

command, deictic word or univocal description). As voice modality is dominant in this system, gestures are taken in account only if a deictic word is uttered. So there is no gesture event. Formal analysis of the Petri net of Figure 2 guarantees that whatever state the system is in, there is always at least one transition in the model that is fireable which means that the model is live. For space reasons we don't explain in details other properties that can be proven on the model and how the formal analysis is performed.

4.2. Two handed interaction

The models in Figure 4 and Figure 3 describe the interaction level events policy for two handed interaction. There is no assumption about the type of the devices except that they are graphical and produce the same set of low level events. It tells when and how those events are produced according to the user's actions on the devices. In this Petri net, the policy works like a transducer: each time a physical event is accepted, the Petri net fires a transition and creates higher level events.

For example, in the policy represented in Figure 4, the physical mouse-move (m) is transformed into a higher level mouse-move (M), e.g. the transition between places *One_Click* and *Idle* reacts to the event m by generating another event M plus an event click (C). However; all physical (low level) events are not immediately translated into interaction level events. For example, each event d (down) received while the system is in the initial state, is consumed without any production.



Type of places

Place Ilde < Int > = { 0, 1 }
Place Down < Int >
Place OneClic < Int >
Place TwoDown < Int >
Place CombiClic < Int >
Place CombiDoubleClic < Int >
Place Moving < Int >

Avail function :

Avail (MouseDown) = { Down1, Down2 } ;
Avail (MouseUp) = { Up1, Up2, Up3 } ;
Avail (MouseMove) = { Move1, Move2, Move3, Move4 } ;
Avail (Time) = { TimeOut1, TimeOut2 } ;

Figure 3. Formal model of a fusion mechanism for two handed interaction (behavioural part)

Activation function:

Media	Interaction object	Event	Service	Rendering method
Mouse button	All	Down	MouseDown	Internal
Mouse button	All	Up	MouseUp	Internal
Mouse	All	Move	MouseMove	Move_Mouse
		TimeOut	Time	Internal

Event production function:

Element name	Event produced
T1	Event CDC
T3	Event CC
Up2	Event DC
Move1	Events C and M
TimeOut1	Event C
TimeOut2	Event C
Move2	Event B
Move4	Event D
Up3	Event E
Move3	Events C and B

Figure 4. Formal model of a fusion mechanism for two handed interaction (interaction part)

We have already presented this example in (Accot et al. 1996) while presenting how transducer can be modelled using Petri nets. The model in Figure 4 presents a way to integrate information provided by two different mice. The system can react to the following set of events produced through users' actions on the physical devices: Button Down (d), Button Up (u), Mouse Move (m) and Time Out (t). If a precise sequence of event is performed on the mice, multimodal events are produced by the model. Such events are: "CombiDoubleClick" and "CombiClick" corresponding to the arrival, in the model, of tokens in place CombiClick and CombiDoubleClick.

5. Conclusion and future work

The MICO formalism is an extension of ICO formalism that is formalism dedicated to the design specification, verification and prototyping of interactive systems. Its formal underpinnings make it especially suitable for safety critical interactive systems. ICO formalism has been applied to various kinds of systems including business, Air Traffic Management and command and control applications. The continuously increasing complexity of the information manipulated by such systems calls for new interaction techniques increasing the bandwidth between the system and the user. Multimodal interaction techniques are considered as a promising way for tackling this problem. However, the lack of engineering techniques and processes for such systems makes them hard to design and to build and thus jeopardises their actual exploitation in the area of safety critical application.

This position paper has presented a formal description technique that can be used for the modelling and the analysis of multimodal interactive systems. This work is part of a new project on the evaluation and use of multimodal interaction techniques in the field of command and control real time systems.

Abstract

The Eye-bed prototype introduces new ergonomic language scenarios. This paper focuses on developing a demonstration eye gesture language for intelligent user interface and computer control. Controls are integrated with a user model containing a history of previous interactions with the interface. Context recognition enables the Eye-Bed environment to continually adapt to suit the user's inferred and demonstrated preferences. Staring, gazing, glancing, blinking, etc… are part of person-to-person visual communication. By creating a computer interface language composed of exaggerated eye gestures, we create a multi-modal interface that is easy to learn, use, and remember.

1. Introduction

Computer human interfaces have long been applied to everyday situations. These interfaces are often trapped in a user-directed model, relying on the user to know and use a language to directly specify what she wants from the computer. More recently computers are finding their way into everyday things. These days our appliances seem to need to have their computers booted before they work. Cars, phones, record players even house locks come to a grinding halt when their computers don't work. We have been programming our thermostats, watches, and videotape recorders for so long that it seems reasonable to spend hours learning to use an MP3 music player that fits in your hand. They are about to get simpler.

At the very least hospital beds have some control for comfort, height, angle, and temperature. The bed area has another control to call an assistant. Usually each bed has a control for a television. How should we position ourselves optimally to watch a movie from bed? Automation of communication and media in bed could be very useful. The Media-Bed scenario adds new rich command and control integration opportunities to the computer human interface (Shelley, R., 2001).

If one integrated environmental controls, educational materials, and entertainment media into a bed interface how would a user communicate with it? Imagine imagery projected on the ceiling over a bed. (Figure 2.) Consider functions presented spatially as an integrated ecological user interface. This would require a person to select things on the spatial interface. Spatial selection has many dexterity problems. Historically the control theory issues and other obstacles of the components of Fitts and Steering laws (Hinckley, K. et al, 1994) have paled in comparison to the difficulty of learning command languages. We consider new languages that are trivial to learn and require low cognitive overhead to use. Through mimicry and extension of the social communication people employ nonverbally, we explore the realm of reduced consciousness communication.

Graphical interfaces are wonderful in that they allow a user to recognise something they might not have been able to remember otherwise, like a place in a file hierarchy. If they want an item they simply point at it to select it. Still, graphical interfaces have long been cumbersome and frustrating. People control 3D interfaces with analogue devices that change the rate and angle of motion as though the ultimate way to interact with a computer would be some sort of hovering gravity-independent helicopter. It is hard to learn to fly a helicopter. Many novice users of 3D interfaces have the constant feeling of listing dangerously as they walk into walls and can't stop the scenes from rotating.

Figure 1: Multimedia Bed with Ceiling Projection

A provocative area of user input design has been eye control. It has seemed like one of the ultimate interface

approaches since the 1960s when the first rudimentary mechanical Perkinji trackers were demonstrated. Indeed psychologists and marketing people have used eye position to understand people's interests. (Yarbus, L. 1967). Unfortunately eye tracking utility has been stymied: the head moves; the eyes don't want to look at one thing; the tracking devices work in lab settings better than in an office; etc…. For the past 40 years, people have been improving eye-tracking technology using Electro-occulogram eye trackers, contact lenses, tracking infrared cameras and dual cameras to get to lightweight camera based systems. Dual camera systems like the Autostereoscopic user-computer interface (Pastoor, S., Skerjanc, R., 1997) and multiple multiplexed structured light source camera systems like the Blue Eyes™ system at IBM have become excellent tools (Flickner, 2001). Unfortunately, these "better eye tracking systems" have made it even more obvious that the eye is not simply looking for interesting things that it wants to effect.

The eye is not a cursor control device. The eye notices movement in the periphery and has to attend to it vigilantly searching for danger. The eye is a guard dog; it has a job to do. Using eyes and trackers to move a cursor precisely is like using a security officer in a bank to show people the bathroom. The officer could do it but not as well as a concierge; at the same time the officer would risk being remiss in the primary security duties.

2. Eye motion as language

Large areas of the brain are devoted to interpreting visual input and controlling the eye (Carpenter, M., 1976). The sensitivity of the eye itself makes it a strange choice for a pointing device. The eye, after all, seeks to understand anything in its view. The area centralis is some 3 degrees wide; anything in this visual area is well known to the mind. One of the most difficult issues with eye-tracking scenarios is that the eye-tracking computer demands "eye contact". This is the very thing people are most used to devoting to scanning for safety, acknowledging other people, and to expressing their feelings non-verbally (Clark, H., Wilkes-Gibbs, D., 1986).

Interest Tracker (Maglio et al, 2000) lets people use generalized directional gaze to select information content by demonstrated interest, much as a person does when meeting a new acquaintance. This stands in contrast to the standard eye-tracking interface in which a user is asked to stare at a specific thing until it is selected: the physical difficulty of doing so; the social inappropriateness; and the uncomfortable feeling of the interface is significant. In contrast if the user is asked to look at the general area of an item to be selected these interface obstacles are diminished.

More recent work, demonstrated "Magic Pointing" (Shumin, Z. 1999), an approach that uses eye gaze to make a non-linear jump or "warp" a cursor to where the eye is looking on a screen. Subsequent GUI control is done through the standard cursor control device. It is quite easy to use eye tracking to identify areas of interest. Of value to interface design is the fact that the eye is a course output device and a fine input device. The most important notion however is that Interest Tracker and Magic Pointing take advantage of the fact that the eye wants to look in the area of interest. The syntax that the action of looking at a work area changes the spatial position of the cursor is a powerful one. Using a dwell time of just 0.3 seconds was more than adequate to allow a user to distinguish things they wanted to select. It was also found to be much faster than a mouse can select the same area (Maglio et al., 2000) Interest Tracker, introduced above, is a system that shows another simple and productive use of gaze interpretation. It augments a person's natural gaze at an area of interest with additional information or content of a similar nature.

Invision (Li, M.; Selker, T., 2001), takes this one step further, based on evidence that shows that the paths that people's eyes follow demonstrate what they are thinking (Yarbus, 1967). When people rapidly transit from one place to another they are more likely to be making a selection of a familiar item. When people's eyes move slowly around the field-of-view they are taking in information, and making decisions, but not selections.

The pattern based Invision interface made two contributions to eye tracking. It demonstrated that eye tracking accuracy could in many cases be improved by interpreting eye movement as the endpoints of the trajectory (i.e. knowing where the eye had moved from and too helps to understand user intent and focus). In the second, and more interesting case, the relationships between objects that the eye gazes at and the order that they are gazed at become the language that drives the computer. The system showed a set of objects representing the various sponsors of the Media Lab. As a person traversed them with their eyes, it used the path to notice their interests. As a person's eye went back and forth, between two things, the objects they were looking at moved closer to one another. In this way, as a user shows interest in a group of items the interface literally brings these items together. This has been explored as an interface for a kitchen as well (opening the refrigerator, oven, cabinets and dishwasher). These pieces of research all focus our attention on the information that comes out of an eye.

2.1.1. Gaze vs. Stare Detection:

The Eye-ARe Project took this further. Eye-aRe is a simple system that consists of a glasses mounted infrared LED and photodiode that detect reflected infrared light from the eye's cornea and sclarea. (Selker et al., 2001) A small PIC can detect when a person is staring and when their eyes stay relatively fixed. It is not hard to separate simple eye gaze intent. This approach can separate out intended versus unintended selection events. Even without a camera, Eye-aRe has successfully been used to send business card information when a user stares at (or is engaged in conversation with) another person, to bring up information about a display when a person looks at it, and detect closed and opened eyes and individual blink signatures.

If the actions used to interact with a computer mimic the normal use of human eye gesture language, this synergy could assist user's learning and memory. Can such an eye gesture based language be the basis of an ecological interface? Can such a natural control language

be integrated without being difficult to learn or generating confusion? Can reasoning, learning, and representation of intelligence be employed to give users more control?

Complex social dynamics are traceable to eye motion (Clark, 1986). These can be used to enhance human computer communication. Eye motion demonstrates a social gesture language. These are significantly easier to record than eye position. With this thesis we will describe the ways that eye gestures and task modeling have been experimented with in the Eye-Bed to reduce reliance on direct manipulation in the interface.

Figure 2: Ecological display projected on Ceiling

3. Media-Bed & Eye-Bed

The bed is a place where the average person will spend approximately one third of their life. Once made of plant fiber and then synthetic materials, we have now made the bed digital. The Media-Bed and Eye-Bed (Figure 1.) are a response to the challenges of integrating environmental, educational, and entertainment controls in a universal interface. The Media-Bed and Eye-Bed could simplify the controls of a hospital bed while adding new features that integrate these domains [good morning america].

The Media-Bed and Eye-Bed are part of a growing body of language based interface development. (Selker, T.; Burleson, W., 2000) The thesis is that replacing explicit spatial selection with a language-based interaction may provide interfaces that are easy to learn, use, and remember. One novel control approach in this direction has been the use of eye tracking. The social language of the eye (i.e. "wink, wink…. Know what I mean" as said again and again in … Monty Python's Holy Grail) can be used as a natural easily understood language. In the Bed projects we overlay and map expected characterized ocular responses such as stare, gaze, wink, etc… with a language to communicate interface intentions between the user and the computer.

The Media-Bed and Eye-Bed are a computer systems that recognizes and remembers what a person is doing in bed to provide useful information and environmental modifications. They "listens" to many information channels to enhance the semantics of a language. The Eye-Bed extends language recognition of the Media-Bed to include eye-tracking semantics: blinking, winking, staring, and gazing. Both create a user model which includes time stamps, interface states, knowledge of the position and sound of the user, in additon to the traditional direct user input channel.

The Media-Bed and Eye-Bed are a place for us to experiment with new scenarios for using a computer in our live. They are also a place to experiment with new multi-modal input devices. For example, eye tracking in a bed has advantages. The person's head is supported and can be stabilized. This naturally reduces the difficulty of finding and tracking the eye position. The bed consists of an integrated multimedia personal computer and video projector. It runs a Macromedia Director movie projected onto the ceiling above a standard bed. This projection creates a virtual world that provides the user with a space for interaction and reactive input.

3.1. Prototype Scenario

A person is lying in bed. Many simple activities can be computer-facilitated making lying in bed more pleasurable and productive. A scene appears, projected on the ceiling above the user's head (Figure 2). It is a scene of rolling hills dotted with icons: an e-mail kiosk, a TV satellite dish, a juke box, a person reading in a lawn chair, a newspaper stand, the moon and stars, and the sun. Each of these icons can move the user into another part of the world depending on his needs and wishes at the time. We have experimented with different renditions of physical world imagery or so-called "ecological interfaces". Ecological interfaces have been shown to improve speed and accuracy of selection over two-dimensional interfaces when users are familiar with them (Ark et al. 1998).

Pointing and selecting it, the kiosk enlarges to fill the screen, bringing the user into another space. A smaller rendition of the rolling hills at the top of the screen points to the original main screen where the user came from. The user can similarly watch TV, read the newspaper or read an online book while lying on their back in bed. The display is projected upward to cover the ceiling above the bed. When reading something or watching TV or a movie, the user no longer has to prop themselves up with their arms or find a comfortable position to sit in. If the user has back or neck problems, this is especially important.

Once the user has finished reading e-mail selecting the hills at the top of the screen returns them to the initial selection screen. It's time to go to sleep, so the user moves to the moon and stars, a soothing song begins to play and a sunset that gradually darkens to reveal the night sky is projected. The bed can subtly and playfully encourage or persuade a person to go to sleep at an hour that they should by shifting to this mode as well. (Fogg, B., 1998) Selecting the moon presents the outlines of constellations. As the user explores the night sky, the names of the constellations and planets appear. Selecting a planet brings up its path and other information. This is an example of how the system can function in an educational and informational role as well. As the user falls a sleep (their eyes close and they move less), the bed recognizes the hour, and sets sunrise wake up music to accommodate the user's sleep patterns. The bed has learned how long it's occupant likes to sleep by

monitoring the use patterns of the alarm clock. Since the bed has access to the user's calendar, it knows the user will not miss any appointments by waking up at eleven o'clock. In the morning, the sun rises on the ceiling, accompanied by morning music. The room is gradually lit up by the sunlight, and the day's schedule is presented for review along with e-mail and newspaper customized to the user's interests and preferences. In this scenarios the user is able to enjoy the activities that they normally enjoy with the media selection assistance from the computer.

Selection of functions on the Media-Bed selection of items on the ceiling was originally accomplished with a Polhemous 6-degree of freedom system in a ball. The position of the ball controlled a ball-shaped cursor on the landscape imagery of the ceiling interface. The ball used a bed based coordinate system to control a cursor on the screen. It was tiresome to hold it in exactly the right position on the bed to activate the functions . The Gyromouse™ did not require the person's hand to go to a specific place in the air or on the bed to use spatial control. The TrackPoint™ in a custom built handle and a TrackPoint keyboard were much easier to use allowing hands to rest on the device. The next step in evaluating the Media Bed interface was to add an eye tracker. The newer Eye-Bed system uses the eye-tracker, positioned in a lamp mounted to the headboard, to control the system.

Through the construction of user model profiles, the Media-Bed and Eye-Bed can learn to suit the user's wishes by understanding what they are interested in seeing, doing, and listening to. The boom box and media presenting applications in the bed do this explicitly. A hiking boot icon when selected kicks the juke box or media player indicating to the user that the system will try to change what media to present. The system changes the current media and updates the model of what to try in the future. It uses artificial intelligence to record actions and reactions of the user to build a model of what kind of information and media will be useful in which situations.

The Eye-Bed version augments the positional syntax of a cursor on a GUI with a language of few simple eye gestures to make an even more interesting interaction scenario. This is done through a paradigm of *relaxed eye tracking*. The Eye-Bed version develops a contextual knowledge of the situation. It uses the "eyes shut" condition to know when a person is asleep or not wanting to see imagery anymore. "Eyes open" to tell the bed that a person need not hear the loud version of the alarm clock, "excessive blinking" or "nervous eyes" to change the station of the radio or TV, and "gazing" into a sparse ecological interface to select interface icons. The eye position itself and the way that a person is looking at something can determine what should be done. If the eye isn't wandering and there is only one nearby object of interest the selection is obvious. Using this multi-modal and contextually aware approach we have enhanced the user interface in the Media bed.

3.1.1. Nervous Eyes Want Change

Work with Eye-aRe and the work of many other researchers have shown that it is easy to recognize rapid blinking as a sign of dissatisfaction. In the Eye-Bed we integrate rapid blinking as the syntactic way to say you are not satisfied with the current interactions. For example, we used rapid blinking to change the channel on the radio and video, in a similar manner to the boot kicking the player. Since this action is similar to the natural way of communicating dissatisfaction, people are able to remember the action and accomplish it with ease.

3.1.2. Open Eyes

It is extremely easy to know when an eye is open or closed. Eyes open presumes the person is not asleep and is thus the syntax for telling the bed to activate wake-up imagery of a sunrise and turning off the loud alarm if the time is morning or if the user generally wakes up at that time of day. Likewise if a person is not in bed the wake up alarm is not needed. An eye projected on the ceiling shows the eye open and labels the status "open". This projected eye is part of the feedback to the user that the eye tracking is on and working.

3.1.3. Eyes Closed

Missing pupils is the syntax for putting the system into a sleep mode. Of course, a person need not watch TV or other things when they are asleep so it can fadeout these media. The Eye-Bed system puts up a black screen with "Zzzzzzz…" written across it when a person closes their eyes for several seconds.

3.1.4. Stare

Attention is a fundamental communication act. When a person looks at something intently we call it staring. In the Eye-Bed we use dwell time to activate a spatial icon. Eye-aRe demonstrates that staring at a toy dog is an obvious way to make it respond with a bark; staring at a TV is an obvious way to demonstrate interest in the TV show. Therefore staring in the Eye-Bed is used to select and activate media.

3.1.5. Gaze

When a person looks around we could say they are gazing. In the Eye-Bed the eye moving around without staying anywhere is interpreted as lack of focus on the bed interface. The system shows the interpretation on the ceiling display eye indicator.

The eye gesture syntax described in this section is small. The simple language of eye states has been enough to drive the entire Eye-Bed demonstration.

3.2. Discussion

Typical spatial interfaces use a spatial inclusion syntax. (Selker, T.; Appel, A, 1991). The control moves an indicator or cursor to within the boundaries of a spatial object or icon to associate syntax to it. The eye gesture language is an augmented visual language in which some eye gestures have global consequence while others act as parameters of a selection device just as mouse buttons on a mouse are parameters to the graphical object that the cursor associates it with. The Eye-Bed eye gesture language has made it possible for people to control the entire Media-Bed interface using only their eye gestures.

In using a gesture-based interface it usually becomes difficult to teach and use the gestures. This system's use

of natural eye gestures, which people do anyway, makes using the bed almost as natural as a social interaction. One goal of creating "natural interfaces" is to create interfaces that use the actions that people are familiar with and relate them to actions the system might expect of users. This can be achieved by copying the actions of people. Studying perceptual and physiological actions and capabilities of people is important as well. It has been shown that in many situations people treat computers as they do people (Reeves, B.; Nass, C., 1986). This paper and these uses of eye input demonstrate how the higher order behavioural and social psychological areas can be used as a motivating approach for interface design. By carefully studying these fields exciting taxonomies of natural behaviour can be found. Once found these can become a basis for more natural, social, and gesture-based interaction languages with the computer. Our goal is developing interaction languages that are amalgamations of typical human actions with appropriate computer augmentation to assistance people in what they want to do.

3.3. Status

3.3.1. Media Bed

The Media-Bed is a Macromedia Director program running on a computer. The Media-Bed with physical inputs has been demonstrated to hundreds of people at the MIT Media Lab; the opening of Media Lab Europe in Dublin, Ireland; and at the AAAI Fall 2000 workshop in Falmouth, MA. We are surprised at how relaxing it is to lie down to demonstrate the night time and wake up scenarios. Within days of it working people were approaching us to form marketing alliances. We have used the media Bed and its display as a place to work and find that it is quite relaxing.

3.3.2. User Model

All of the selection scenarios are enhanced by the creation of the user model. The simplest user model is that a person whose eyes are closed need not be shown imagery. Currently we consider a person whose eyes are closed to be asleep.

The user models in the radio and TV are the most sophisticated. These models notice what time of day it is, what has been playing and how long a user listens or watches it as a basis for appreciation. If a user likes the music then similar music continues to play. Of course we have found that some people don't like to hear the same music over and over again. Refining the heuristics for this is a current goal. The eye tracking approach has allowed us to simulate nervousness or detect actual nervousness as the way to tell the media generator that it should attempt to find other media to play. If a person is not paying any attention to anything near the media player and has not recently turned it on, these analyses of nervousness most likely are not about the media

3.3.3. Eye-Bed

An early version of the Eye-Bed was demonstrated on Good Morning April 10 2001 (Shelley, R. 2001). The Eye-Bed is the Media-Bed with another computer running the eye gesture recognition software. Mike Li wrote a Java version of the Eye-Bed software. It was replaced with a C version written by Jessica Scott that requires much less of the Ethernet communication for its interpretations. The New version has a much better ability to interpret eye gestures. Further, the new version includes the eye indicator on the ceiling bed display.

The Eye-Bed eye gesture based interface has been demonstrated dozens of times at the MIT Media Lab. The ability to control it with less than a minute of instruction amazes everyone. The impressive thing about Eye-Bed is that people enjoy using it and don't need much instruction. The system is so easy to use that we often have visitors demonstrate the eye-gesture based interface to one another. The real value of this interface is the ease with which we can recognize the gestures of eyes closed, open, gaze, stare, blink, and nervous blinking.

The current system has limitations. Text entry has not been satisfactorily resolved. There are good and bad times to use the system. So far the system is designed for a single user and does quite well at integrating the many controls of the previously discussed hospital bed. However the system does not make any accommodation for the social or sexual activities that take place in bed in fact at this point many users think that the current features are too intrusive. They are appalled at the thought of email intruding into their bedroom and literally "hanging over their heads".

3.4. Future Work

The interface is effective enough for us to sleep with it on and beneficial enough for us to enjoy it when we are awake. The goal of demonstrating the limits of time and fidelity of eye gesture are central to our future work. The integration and evaluation of new eye gestures and other physiologically natural gestures is central to the context aware stance of the research group that this work takes place in. Understanding what social cues are for and how to make them reliable within a graphical interface system continues to be exciting. We will extend the language that we have developed to include other forms of implicit communications such as facial gestures. The question as to whether a serious formal theory will aid in this endeavour stands before us.

Discussions in bed, on the phone, or in person will be augmented by pervasive access to information. The nature of this information will also rely upon user models. For example, a four-year old who wants to know what bears eat, is looking for a different answer than what a college biology major with the same question is looking for. We will continue to explore the integration of health monitoring and feedback systems. Sound sensing and acoustical feedback will be used to monitor sleep apnoea and snoring. The Media-Bed and Eye-Bed has moved into educational areas, starting with astronomy. We will soon move on to other contextually appropriate topics. Especially interesting is the context of looking up such as in auto mechanics, marine biology, meteorology, ornithology, and rainforest canopy sciences. This work will also be extended into the realms of fun, play, and creativity by implementing games and motivational activities.

4. Conclusion

The appropriate use of interface techniques should be the focus of the Computer Human Interface field. Unfortunately as industry develops new interface techniques and scenarios designers bring untested ideas into the market. In this paper we attempt to show that a well-understood language of a few eye gestures can simplify the use of the eyes as a control for user interfaces. We further use an ecological interface to simplify teaching control of the user interface. In doing so we create a system that is natural and ease for people to learn, use, and remember. The goal of developing improved user interactions will continue to require us to invent new scenarios and test where and how they can be applied.

Abstract

This paper describes a general framework for evaluating and comparing the performance of multimodal dialogue systems: PROMISE (**Pro**cedure for **M**ultimodal **I**nteractive **S**ystem **E**valuation). PROMISE is a possible extention to multimodality of the PARADISE framework ((Walker and al., 1998; Walker et al., 1997) used for the evaluation of spoken dialogue systems), where we aimed to solve the problems of scoring multimodal inputs and outputs, weighting the different recognition modalities and of how to deal with non-directed task definitions and the resulting, potentially uncompleted tasks by the users.
PROMISE is used in the end-to-end-evaluation of the SmartKom project - in which an intelligent computer-user interface that deals with various kinds of oral and physical input is being developed. The aim of SmartKom is to allow a natural form of communication within man-machine interaction.

1. Introduction

The aim of this paper is to give an extended framework on dialogue system evaluation for multimodal systems in the end-to-end evaluation of SmartKom.

In the SmartKom project, an intelligent computer-user interface is being developed which deals with various kinds of oral and physical input. The system allows and reacts to gestures as well as mimic and spoken dialogue. Potential benefits of SmartKom include the ease of use and the naturalness of the man-machine interaction which are due to multimodal input and output. However, a very critical obstacle to progress in this area is the lack of a general methodology for evaluating and comparing the performance of the three possible scenarios provided by SmartKom:

- SmartKom Home/Office allows to communicate and to operate machines at home (e.g. TV, workstation, radio),
- SmartKom Public provides public access to public services, and
- SmartKom Mobile

Because of the innovative character of the project, new methods for end-to-end evaluation had to be developed partly through transferring established criteria from the evaluation of spoken dialogue systems (PARADISE), and partly through the definition of new multimodal measures. These criteria have to deal with a fundamental property of multimodal dialogue systems, namely the high variability of the input and output modalities with which the system has to cope. As an example, the system can accept a task solution not only via three different input devices (mimic-camera, voice-recording, gesture-camera), but also many different long-term solution strategies. For example, in order to plan an evening watching TV, a subject using the system may start with a sender (or a time, or an actress, etc.), progress to give a time (or sender, or actress, etc.) and end choosing a single programme (or a series, or many programmes, or none, etc.). This inherent complexity and the tasks to be completed make it necessary to find an evaluation strategy which measures up to the possibilities of such a flexible system. Earlier evaluation strategies (PARADISE) had to deal with systems with only one input modality, used given solution strategies and thus were easily able to measure the success of a task. The advancements of SmartKom, though, cannot be adequately measured nor evaluated using an evaluation-strategy based on a monomodal system with pre-given solution strategies.
The following section gives an overview of standard problems of dialogue system evaluation which principly can be solved by the PARADISE framework (Walker and al., 1998; Walker et al., 1997). Section three describes how to define a task and extract the attribute value keys out of the description - solving a problem not uniquely belonging to multimodal dialogue evaluation. How we deal with incomplete tasks or tasks that get a very low task success measure due to incooperativity of the user, is described in section four. The scoring of multimodal inputs and outputs can be found in section four. Sections five to six give a detailed description of the status of multiple-to-one input facilities, i.e. the possibility to express the same user intention via multiple input as well as via different input modalities. Section seven defines the approach of PROMISE as a multimodal dialogue evaluation strategy which normalizes over dialogue strategy and dialogue systems. In the last section we sum up some ideas to be implemented in our framework.

2. Standard problems of dialogue system evaluation

Of course, multimodal dialogue evaluation has to deal with the same problems spoken dialogue system evaluation has to deal with, namely

- How can we abstract from the system itself, i.e. the different hardware and software components, in order to evaluate across dialogues and scenarios (see above)?

- How can we abstract from different dialogue strategies?

The PARADISE framework (for detailed description please refer to (Walker and al., 1998; Walker et al., 1997)) gives a useful and promising approach of how to compare different spoken dialogue strategies and different spoken dialogue systems via attribute value matrices (AVM), to compute the (normalized) task success measure (provided that a clearly defined task description is given to the user) define several (normalized) quality and quantity measures so-called cost functions , and to weigh their importance for the performance of the system via multiple linear regression dependent on the User Satisfaction value (cumulative function on the questionnaire completed by the subjects). This is not practicable, though, when dealing with a multimodal system like SmartKom**.**
Unfortunately, in dealing with multimodal systems we find a number of components which do not fit into the PARADISE approach, which are:

- The user is given a rather unprecise task definition, in order to enable a mostly natural interaction of user and system. Therefore there exist no static definitions of the "keys" (a PARADISE term) necessary to compute an AVM. Our solution is to extract different superordinate concepts depending on the task at hand. For example, when planning an evening watching TV, these superordinate concepts - we call them "information bits" - would contain movie title, genre, channel, timeslots, actors etc. Similar to a content-analysis, these "information bits" are carefully selected, categorized and weighted by hand before the tests start. This makes it possible for us to compute, normalize and compare across different tasks and scenarios.

- The number of information bits can vary within one completed task, but they must define a task unambiguously in order to finish it completely and successfully. For example, when a user asks to explicitly view a movie by name, assuming this movie is broadcasted at a set time and in only one channel, the number of information bits necessary to complete the task is one (the name of the movie). Whereas if a user doesn't know exactly what show he wants to watch, the number of information bits necessary to complete the task of planning an evening watching TV must be at least two (for example, time and channel).

In contrast to computing the task success via AVMs like PARADISE, in which case not completed tasks could implicitely influence the results, our information-bit-approach ensures that task success can only be calculated if the task has been completed.

3. How to deal with a bad performance due to user incooperativity?

One of the main problems of dialogue systems is an incooperative user. We consider only those users to be truly incooperative, who fall out of the role or purposely misuse the system. As an example, a user reading a book to the system or using his mobile phone will be classified as an "incooperative" user. These, of course, are not unique to multimodal system evaluation, but can occur in other situations as well. On a first cue, it is impossible to incorporate incooperative users in an evaluation without lowering task success and thus the system performance. To avoid this, there exist the following approaches:

- Only dialogues with cooperative users are evaluated using empirical methods

- Only dialogues which terminate with finished tasks are evaluated.

Both approaches will be used in conjunction, so that a clearly defined set of data can be evaluated. When deciding to follow the first idea, uncooperative users as defined above, are of course interesting for other than purely empirical reasons. Evaluating the data generated by these incooperative users, in the above sense, in order to improve the system for future development, though, is not part of our aim to judge the quality of the present state of the system SmartKom.

4. How to score multimodal inputs or outputs?

In contrast to interactive unimodal spoken dialogue systems, which are based on many component technologies like speech recognition, text-to-speech, natural language understanding, natural language generation and database query languages, multimodal dialogue systems consist of several such technologies which are functionally similar to each other and therefore could interfere with each other. To make this clear, just imagine the similar functions of ASR and Gesture Recognition: while interacting with a multimodal man-machine interactive system like SmartKom users have the possibility to say what information they want to have and to simultaneously give the same, an additional, or a more specific input by an "interactional gesture" (Steininger et al., 2001). There are several possible problem solving strategies for the system namely:

- First match: the information which was recognized first is taken for further system processing, regardless of the recognition method. This would of course not help in multimodal processing.

- "Mean" match: the system takes the information which is common to both of the recognition modules. This could be called multimodal verification.

- Additional match: take all the information given by several recognizers for further system processing. This would be the best solution, if we assume all recognizers to be highly accurate, which leads us to the next problem:

5. How to weight the several multimodal components of recognition systems?

How can we estimate the accuracy of different recognizers? For example, in talking about speech recognition,

we have to deal with a very complicated pattern match, whereas gesture recognition has a limited set of recognizable gestures which can be found in a given coordinate plane.

It should be clear, that

- the gesture recognizer will be more accurate than the ASR system but
- the ASR system must get a higher weight than the gesture recognition when evaluating the system, since the complexity of the gesture recognition is much lower than the complexity of the ASR sytem.
- Apart from the problems of how to weight the different multimodal system components in an end-to-end evaluation of a multimodal system, there is also the problem of synchrony:
- Are multimodal inputs synchronous or linear within the evaluation? Are inputs from different modalities synchronous, i.e. are they describing the same user intention, although they may not be synchronous in time? Or does the system have to cope with different inputs?

6. PROMISE - A Procedure for Multimodal Interactive System Evaluation

In the last sections we have identified the most characteristic problems which show the need for an extended framework for multimodal dialogue system evaluation. We already gave some examples of possible problem solving strategies. Within this section we will specify these ideas and present the current version of PROMISE. Given the normalized performance function of PARADISE

$$\text{performance} = \alpha\,\mathcal{N}(\kappa) \;-\; \sum_{i=1}^{n} \omega_i\,\mathcal{N}(c_i)$$

with α the weight for task success[1] κ, the assumed Gaussian cost functions [2] c_i weighted by ω_i, and $\mathcal{N}$ z-score normalization function. Weights are defined via a linear multiple regression over κ respectively the costs and the cumulative sum of the user satisfaction scores (see usability questionnaire (Walker and al., 1998)). PROMISE now splits this function in two parts in the way that the formula is reduced to normalized cost functions first. Instead of a multiple linear regression between the free cost variables and the dependent user satisfaction score, PROMISE searches correlations via Pearson correlation between User-Satisfaction - Cost pairs. This means that objective measurable costs will be addressed in the questionnaire to be answered by each user.

Tables 1 and 2 give an overview of the costs we defined in SmartKom, some of them equivalent to the PARADISE costs, some of them extended to deal with multimodality or to weed out user incooperativity.

[1] defined as the successful completion of a duty

[2] either mean or cumulative sum of one cost category (quantity and quality measures); differing from system to system

Quality measures	
system-cooperativity	measure of accepting misleading input
semantics	no.of multiple input possible misunderstandings of input/output semantical correctness of input/output
helps	no. of offered help for the actual interaction situation
recognition	speech facial expression gestures
transaction success	no. of completed sub-tasks
diagnostic error messages	percentage of error prompts
dialogue complexity	task complexity (needed information bits for one task) input complexity (used information bits) dialogue manager complexity (presentation of results)
ways of interaction	gestures/graphics vs.speech n-way communication (several modalities possible at the same time?)
synchrony	graphical and speech output
user/system turns	mixed initiative dialogue management incremental compatibility

Table 1: Quality measures for the SmartKom evaluation

Apart from measuring the quality of dialogue systems in general, like dialogue management (system directed, user directed or mixed initiative), elapsed time of input and output, task completion, mean response time, word count and turn count, we defined measures referring to the problems in section four and five above. Multiple inputs and outputs are scored via the "semantics" cost, to be precised the number of multiple input and the possible misunderstandings of input/output (due to multimodality).

The multimodal components of recognition systems are partly weighted via Pearson correlation using the corresponding user satisfaction scores for the recognition costs defined above. Comparing the accuracies of the different recognition systems for defining a cross-recognizer weight, we calculate "ways of interaction" and "helps". The latter defines the quality and quantity of dynamic help offered by the system in situations where the emotional status of the user changes.

[3] (Oppermann et al., 2001)

Quantity measures	
barge-in	no. of user and system overlap by means of backchanelling, negation of output, further information
cancels	planned system interrupts due to barge-in
off-talk [3]	no. of non-system directed user utterances
elapsed time	duration of input of the facial expression duration of gestural input duration of speech input duration of ASR duration of gesture recognition mean system response time mean user response time task completion duration of the dialogue
rejections	error frequency of input which require a repetition by the user
timeout	error rate of output error rate of input
user/system turns	no. of turns no. of spoken words no. of produced gestures percentage of appropriate/ inappropriate system directive diagnostic utterances percentage of explicit recovery answers

Table 2: Quantity measures for the SmartKom evaluation

The second step is to define another way to calculate the task success.

In PARADISE a set of defined static "keys" was used to measure task success via an attribute value matrix. Since "information bits" (see section two) are used, it makes no sense to calculate an AVM. As described above, these information bits can vary from situation to situation. A successful task is given, if the task was completed according to the necessary number of information bits. A task fails, if it has not been successfully completed. Therefore, we define task success in PROMISE as follows:

$\tau_j = +1$: task success; $\tau_j = -1$: task failure; where j is the index of the corresponding tests.

For each test the corresponding user satisfaction values are Pearson correlated with τ_j.

The system performance results in the following formula:

$$\text{performance} = \alpha\bar{\tau} \; - \; \sum_{i=1}^{n} \omega_i \mathcal{N}(c_i)$$

with α being the Pearson correlation between τ_j(task success) and the corresponding user satisfaction values,
$\bar{\tau}$ the mean value of all τ_j with j index of tests,
n the number of different cost functions,
c_i the assumed Gaussian cost functions - consistently either mean or cumulative sum of one cost category i (measured over all tests)
weighted by ω_i - the Pearson correlation between cost function c_i and defined associated user satisfaction values, and the z-score normalization function $\mathcal{N}(c_i) = \frac{c_i - \bar{c_i}}{\sigma_{c_i}}$, where σ_{c_i} as variance of c_i.

7. Conclusion and future work

Our aim was to roughly define an extended evaluation framework for a multimodal dialogue system evaluation which can deal with multimodal dialogue processing. However, there are still some unresolved or solely unsatisfactorily solved problems dealing with the timing of input in multimodal systems. We are currently specifying different approaches in order to satisfactorily solve the remaining problems which we hope to present at the LREC post-conference workshop on "Multimodal Resources and Multimodal Systems Evaluation" in June.

8. Acknowledgements

Abstract

This paper reports on a recent initiative undertaken under the language technology programme of the Nordic Research Training Academy (NORFA) to create a network of Nordic research institutes working with multimodal interfaces. In the paper we present the objectives of the network and give an overview of multimodal research and resources in the Nordic countries.

Keywords : multimodal integration, cognitive and usability studies, multimodal dialogue, multimodal research and resources in the Nordic countries

1. Motivation and objectives

In the Nordic countries as elsewhere, both the research and the industrial communities are showing a growing interest in multimodal interfaces. Therefore, there is a need to channel the efforts of individual organisations and countries in joint activities to establish a common research agenda and to define relevant standards and generic methodologies. The aim of the Nordic Network for MultiModal Interfaces (MUMIN) under the NORFA programme, is to stimulate Nordic research in this area and increase its visibility in the international research community. MUMIN, which was established in January 2002 and has funds for two years of activity, has the following goals:

? encouraging joint activities in building generic models and architectures as well as defining standards for the integration and development of multimodal interaction;

? encouraging investigations on the use of multimodality in various practical applications;

? providing a forum for sharing resources and results, and by encouraging network participants to make their research results available via the network's web site;

? organising PhD courses and research workshops on issues related to multimodal interaction;

? creating a network of contacts and a pool of shared knowledge that can be taken advantage of for the definition of collaborative research projects and for product development.

It will also be an important objective of the network to support investigation of the use of multimodal interaction in non-expert environments, and the accessibility of disabled people to IT technology. The network will thus contribute to the Nordic countries' social objectives and help them advance in their vision of building democratic and equal societies for everyone. This also conforms to the EU objectives of creating a user-friendly information society, with accessibility of IT benefits and services for all citizens.

A whole range of research issues, some of which have already received attention from the institutes engaged in the network, are relevant to this overall objective, and constitute topics of interest around which the network's activities will be organised.

2. Multimodal integration

A central issue is that of multimodal integration, which will be approached from different perspectives. A promising approach put forward by several researchers is that of using techniques known from NLP. A similar distinction to that made in NLP between grammar rules and parsing algorithms can be made between a multimodal grammar and an algorithm for applying the grammar to input from multiple modalities. By upholding this separation of process and data, the process of merging inputs from different modalities can be made more general, as the representation becomes media-independent. Furthermore, defining algorithms for modality integration independent of the specific

modalities used in a particular application, increases the chances that components of the system can be extended and reused. For example in the Danish research project Staging, Center for Sprogteknologi (CST) has developed a multimodal dialogue interface to a virtual environment (Paggio *et al*. 2000) where speech, keyboard and gestural inputs are merged by a feature-based parser. Relevant to this issue is also the work carried out by the Speech and Multimedia Communication (SMC) group from Center for PersonKommunikation, Aalborg, which also has extensive research and teaching experience in the area of multimodality, complemented with expertise in speech and image processing (Larsen & Brøndsted 2001).

Another promising approach to modality integration represented in MUMIN is the use of different machine learning techniques, in particular neural networks. As has been the case with many other application domains, also for multimodal integration hybrid systems mixing rule-based approaches with machine learning algorithms, may well provide the most interesting results. Although rule-based methods in general work reasonably well, it is a well-known problem that an explicit specification of the steps, i.e. rules that are required to control the processing of the input, is a difficult task, and when the domain becomes more complex, the rules become more complex too. Often the correlation between input and output is difficult to specify. This is the case e.g. with multimodal interfaces, and thus approaches which are both robust and able to adapt to new inputs are needed. Expertise in this domain is brought to the network by the Media Lab at the University of Art and Design in Helsinki (UIAH), and especially its Soft-Computing Interfaces Group which is devoted to designing adaptive interfaces and developing tools for human-machine interaction, relying on nature-like emergent knowledge that arises from subsymbolic, unsupervised processes of self-organizing nature (see e.g. Jokinen *et al*. 2001).

In a similar way as the rule-based integration of modalities can be enhanced using machine learning techniques, results obtained through pure probabilistic analysis methods may well be boosted by the addition of symbolic rules. An example relevant to multimodal interfaces are the algorithms for character and word prediction used in connection with eye-tracking, where the system tries to guess what the user is "typing with the eye". Although the performance of the probabilistic approaches implemented in current systems is promising, language technology techniques seem to constitute a valuable add-on. This is an issue that the IT University of Copenhagen is working on.

3. Neurocognitive basis and usability studies

To fully exploit multimodality in various interfaces, it is important to know how the neurocognitive mechanisms support multimodal and multisensory integration. In comparison to that devoted to single sensory systems, there has been very little research on the integration mechanisms of information received via different senses. However, the research group of Cognitive Science and Technology at the Helsinki University of Technology is using various methods to uncover the neurocognitive principles of multisensory integration with the purpose of developing mathematical models of this integration. The group is also developing a Finnish artificial person – a talking and gesturing audiovisual head model – which will serve as a well-controlled stimulus for neurocognitive studies (Sams *et al*. 1998).

A related issue is that of the impact of multimodality on the users. Relevant questions are which input and output modalities should be used for which task, which are the best combinations, and how different modalities are used by or for users with different degrees of expertise. There are in general two ways to use multimodal input: to react directly to the user's intentional input and to observe the user's unconscious use of certain modalities (e.g. eye-gaze). The former method is based on direct control and has been used in earlier conversational interface prototypes. Observing the user and understanding their intentions and mental states has not been extensively studied, and would add valuable information to the design of multimodal systems. The Computer Human Interaction group at the University of Tampere (TAUCHI) will bring to the network its extensive expertise in the design and use of innovative user interfaces and in usability testing, as well as the agent-based development platform Jaspis (Turunen and Hakulinen 2000). The Natural Interactive Systems Laboratory (NISLab) at the University of Southern Denmark, has also made pioneering contributions to the theoretical understanding of unimodal input/output modalities, and of the multiple conditions which determine the usability of individual modalities and their combinations (Bernsen 2001).

4. Multimodality and dialogue

A third issue, which encompasses a great deal of research work carried out by several of the network members, is that of multimodal dialogue. In this respect, it is interesting to note that the growing interest in multimodal interaction is opening a new perspective to Nordic research on dialogues, which is already acknowledged internationally. Several institutes in the Nordic countries have in fact contributed substantially to dialogue research, and developed dialogue models as well as implemented dialogue systems.

The Department of Linguistics at the University of Göteborg has extensive experience in corpus collection and dialogue management. They have developed tools for spoken language analysis and coding which can be applied to the collection and analysis of multimodal dialogues, thus providing empirical basis and insight for research on multimodal interaction: how different modalities are used in human-human communication (Allwood, 2001). NISLab has a strong background in dialogue management, dialogue systems evaluation, and spoken dialogue corpus coding from a number of EU projects. NISLab is currently addressing best practice in the development and evaluation of natural interactivity systems and components; surveying data resources, coding schemes and coding tools for natural interactivity;

and building a general-purpose coding tool for natural interactive communicative behaviour. The natural language processing research group (NLPLab) at the University of Linköping has for almost two decades conducted research on dialogue systems and now has a platform for the development of multimodal dialogue systems for various applications to be developed further towards an open source code repository (Degerstedt & Jönsson, 2001). Current focus is on integrating dialogue systems with intelligent document processing techniques in order to develop multimodal dialogue systems that can retrieve information from unstructured documents, where the request requires that the user, in a dialogue with the system, specifies their information needs (Merkel & Jönsson, 2001). Finally, the Centre for Speech Technology at the Royal Institute of Technology in Stockholm (KTH) has developed several multimodal dialogue systems with the motivation of studying speech technology as part of complete systems and the interaction between the different modules that are included in such systems. Their first system, Waxholm, was a multimodal system exploring an animated agent (Carlsson & Granström, 1996). Current work and interests involve research on multimodal output using animations and also to some extent multimodal input using both speech and pointing (Gustafson *et al*. 2000).

5. Participating groups

The groups participating in MUMIN are shown in Table 1 below. Currently, three Nordic countries are represented, but the network is interested in welcoming participants from other Nordic countries, as well as in cooperation with non-Nordic countries.

Denmark	Finland	Sweden
Center for Sprogteknologi, Copenhagen	University of Art and Design Helsinki , Media Lab, Helsinki	Linköpings Universitet, Institutionen för datavetenskap, Linköping
Syddansk Universitet , NISLab , Odense	University of Tampere, Department of Computer and Information Sciences, Tampere Unit for Computer-Human Interaction (TAUCHI), Tammerfors	KTH, CTT, Centre for Speech Technology, Stockholm
Aalborg Universitet , Center for PersonKommunikation, Aalborg	Helsinki University of Technology , Laboratory of Computational Engineering, HUT Espoo	Göteborgs Universitet, Institutionen för lingvistik, Göteborg
IT-Højskolen, Eye Gaze Research Team, Copenhagen		

Table 1: The groups participating in MUMIN

6. Conclusion

The MUMIN network is expected to play an important strategic role in the establishment of a common research agenda for Nordic researchers working with multimodal interfaces, but also to relate its activities to those of the international community, and to contribute to the general progress in the area. Therefore, it is highly relevant for MUMIN to participate in this workshop, and to provide a Nordic contribution to the discussion of a multimodal roadmap.

ISCA SALTMIL SIG: “Speech and Language Technology for Minority Languages”

The Workshop Programme

Saturday, 1st June 2002

14:30	Registration, and preparation of posters	
Oral Session: Portability Issues in Human Language Technologies		
14:50	Workshop Welcome and Introduction	Bojan Petek, University of Ljubljana, Slovenia
14:55	Multilingual Time Maps: Portable Phonotactic Models for Speech Technology	Julie Carson-Berndsen, University College Dublin, Ireland
15:20	Units for Automatic Language Independent Speech Processing	Jan Černocký, Brno University of Technology, Czech Republic
15:45	Some Issues in Speech Recognizer Portability	Lori Lamel, LIMSI-CNRS, France
16:10	Seven Dimensions of Portability for Language Documentation and Description	Steven Bird* and Gary Simons**, * Linguistic Data Consortium, University of Pennsylvania, USA ** SIL International, USA
16:35	Break	
Oral Session: HLT and the Coverage of Languages		
17:00	Challenges and Opportunities in Portability of Human Language Technologies	Bojan Petek, University of Ljubljana, Slovenia
17:25	The Atlantis Observatory: Resources Available on the Internet to Serve Speakers and Learners of Minority Languages	Salvador Climent*, Miquel Strubell*, Marta Torres*, and Glyn Williams** *Universitat Oberta de Catalunya, Spain **Foundation for European Research, Wales, Great Britain
17:50	Towards the Definition of a Basic Toolkit for HLT	Kepa Sarasola, University of the Basque Country, Spain
Poster Session		
18:15	Poster Session (see next page)	
20:00	End	

(continued next page)

(continued)

Poster Session	
Ubiquitous Multilingual Corpus Management in Computational Fieldwork	Dafydd Gibbon, Universität Bielefeld, Germany
A Theory of Portability	Hyo-Kyung Lee, University of Illinois at Urbana-Champaign, USA
A Requirement Analysis for an Open Set of Human Language Technology Tasks	Fredrik Olsson, Swedish Institute of Computer Science, Sweden
Taking Advantage of Spanish Speech Resources to Improve Catalan Acoustic HMMs	Jaume Padrell and José B. Mariño, Universitat Politècnica de Catalunya, Spain
Portability Issues of Text Alignment Techniques	António Ribeiro, Gabriel Lopes and João Mexia, Universidade Nova de Lisboa, Portugal
SPE Based Selection of Context Dependent Units for Speech Recognition	Matjaž Rodman*, Bojan Petek* and Tom Brøndsted** *University of Ljubljana, Slovenia **Center for PersonKommunikation (CPK), Aalborg University, Denmark
VIPTerm: The Virtual Terminology Information Point for the Dutch Language. A Supranational Project on Terminology Documentation and Resources.	Frieda Steurs, Lessius Hogeschool, Belgium

Multilingual Time Maps: Portable Phonotactic Models for Speech Technology

Julie Carson-Berndsen

Department of Computer Science

Abstract

This paper addresses the notion of portability of human language technologies with respect to a computational model of phonology known as the *Time Map model*, focusing specifically on generic techniques for acquiring, representing and evaluating specific phonological information used by the model in multilingual speech technology applications. *Multilingual time maps* are multilevel finite state transducers which define various types of information with respect to their phonotactic context. A development environment for *multilingual time maps* is presented and an illustration of how such a multilevel finite state transducer can be constructed for a new language is given.

1. Introduction*

The extent to which human language technologies can be adapted for use in other application domains has become obvious in recent years with speech interfaces to a wide variety of information systems becoming more and more commonplace. However, the extent to which such technologies can be adapted to other languages, in particular minority languages, remains to be seen. Furthermore, little emphasis has been placed on developing generic technologies which can be applied not only to "new" languages but which can be employed in other task domains. While it is often considered practical to have a speech recognition system for a language if one is about to embark on developing a speech synthesis system for that language - the recognition can support data annotation - the fact that the linguistic knowledge which is being represented for the one task domain could be relevant for the other is largely ignored. In order to address the issue of portability adequately, linguistic representations must be integrated more explicitly into human language technologies. While a hidden Markov model can be trained as a speech recognizer perhaps for any language given a large data set, there is no potential for exploiting the commonalities of human languages or for using the same knowledge in the synthesis task domain.

This paper addresses the notion of portability with respect to a computational model of phonology known as the *Time Map model* focusing specifically on generic techniques for acquiring, representing and evaluating different types of phonological information used by the model in multilingual speech technology applications. Ubiquitous language technology concerns the development of language technologies for different purposes on different platforms so that they can be made available to everybody at all times rather than to a select group for specific purposes. Much of the further development of the *Time Map model* is aimed towards providing fine-grained representations for speech recognition and synthesis and developing computational models which will contribute to achieving this long-term goal. The techniques presented in this paper make way for the extension of current speech technology to languages which have received little attention thus far by modeling linguistic information at various levels of granularity.

In the context of this paper, portability refers to extending the functionality of a system to cater for another language. It does not cover issues such as re-applying the technology to new content domains (e.g. adapting an English spoken language interface for a football results information system to an English information system for accommodation in London). The model described below is not restricted to a specific application domain and therefore the main concern is adapting the system to another language. This involves parameterization of the system so that the language-specific components can be substituted in a "plug and play" fashion.

In the next section, the *Time Map model* is sketched briefly with particular attention to the language-specific knowledge components. Section 3 discusses how the model has been parameterized to allow extension to other languages by defining the notion of *multilingual time maps* specifying information at different levels of granularity and a development environment, *PhonoDeSK*, for acquiring and evaluating such *time maps* is presented. Section 4 describes an example illustrating the role which can be played by *PhonoDeSK* in the context of portability of human language technologies and section 5 concludes with some comments on future work.

2. Time Map Model

The *Time Map model* was proposed as a computational linguistic model for speech recognition by Carson-Berndsen (1998, 2000) and has been tested within a speech recognition architecture for German. More recently, the model has been extended to English and has been provided with an interface which allows users to define and evaluate phonotactic descriptions for other languages and sublanguages (Carson-Berndsen & Walsh, 2000). In extending the model to cater for

* This research was part funded by the HEA under the MMRP programme.

English, particular emphasis was placed on parameterizing the model so that knowledge components for other languages could readily be substituted.

The original motivation for the design of the *Time Map model* was to address specific problems in the area of speech recognition below the level of the word. In particular, the problem of out-of-vocabulary items, also termed the "new word" problem, is addressed explicitly in the model. This is done by including *complete* phonotactic descriptions of a language which describe not only those forms specified in some corpus lexicon, but also all potential forms which adhere to the phonotactic constraints imposed by the language. Another specific problem addressed by this approach is the modelling of coarticulation phenomena. This is done by assuming a non-segmental approach to the description and interpretation of speech utterances which avoids having to segment an utterance into non-overlapping units at any level of representation.

The *Time Map model* has two main language-specific components: the *phonotactic automaton* and the *time map lexicon*. These components each assume a particular representation of speech utterances in terms of a multilinear representation of features similar to an autosegmental score.

2.1. Multilinear Representations

Speech utterances are defined in the model in terms of a multilinear representation of tiers of features which are associated with signal time. The notion of tiers of features is not new in the area of phonology (cf. for example Goldsmith, 1990). However, recently there has been a significant upsurge in phonetic feature extraction and classification, and automatic transcription using the type of features proposed in our model (e.g. Chang, Greenberg & Wester (2001), Ali et al., (1999)). An example multilinear event representation using the Chang, Greenberg & Wester (2001) features is depicted in figure 1.

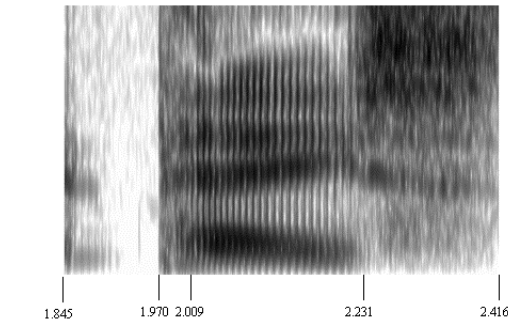

Figure 1: Multilinear representation of the word *pace*

As can be seen from figure 1, each feature in a multilinear event representation is associated with a specific tier (on the vertical axis) and with a specific time interval in terms of milliseconds (on the horizontal axis). The features do not all start and end simultaneously. An overlap of properties (coarticulation) exists in any time interval; for example, the feature *rd-* begins before the *voc* feature indicating that the lips have been spread during the plosive (*stp*) anticipating the following nonround vowel.

A multilinear event representation of a speech utterance is in fact highly constrained. It is not the case, that any combination of features can occur in any order. The allowable combinations of features are dictated partly by the phonological structure of the language, as defined by the phonotactics, and partly by predictable phonetic variation, which often results from limitations associated with human speech production.

2.2. Phonotactic Automata

The primary knowledge component of the *Time Map model* is a complete set of phonotactic constraints for a language which is represented in terms of a finite state automaton. A *phonotactic automaton* describes all permissible sound combinations of a language within the domain of a syllable. It can be phoneme-based (just specifying phonemes), feature-based (generalizing over phonemes) or event-based (specifying constraints on temporal relations between the features). A subsection of a phonotactic automaton depicting CC- clusters in English syllable onsets can be seen in figure 2.

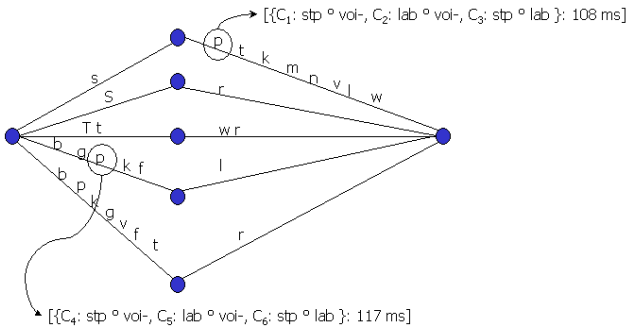

Figure 2: Subsection of a phonotactic automaton

The arcs in an event-based phonotactic automaton define a set of constraints on overlap relations which hold between features in a particular phonotactic context (i.e. the structural position within the syllable domain).[1] In the phonotactic automaton of figure 2, the constraint *C_1: stp ° voi-*, for example, states that the feature *stp* (a plosive) on the manner tier should overlap the feature *voi-* (voiceless) on the phonation tier. The millisecond values refer to the average durations for the sounds in this particular phonotactic context which have been calculated from a large corpus.

[1] The monadic symbols written on the arcs in figure 2 are purely mnemonic for the feature overlap constraints they represent; the ° symbol represents the overlap relation.

2.3. Time Map Lexicon

The *time map lexicon* defines fully specified multilinear event representation of each syllable in the corpus (or each lexicalised syllable in the language) together with their phonemic and orthographic forms. The *time map lexicon* is used online by the model to distinguish between actual and potential syllables and used offline for evaluation purposes with respect to a particular corpus.

The *time map lexicon* is compiled from a generic lexicon model (Carson-Berndsen, 1999). Generic lexical information is represented in DATR, a simple language designed specifically for lexical knowledge representation that allows the definition of nonmonotonic inheritance networks with path/value equations (cf. Evans & Gazdar, 1996). Varying degrees of granularity (syllables, tiers in a multilinear representation, consonants, vowels etc.) are specified as templates in DATR. For each language (see figure 3) specific word, syllable and segment inventories are defined which contain information such as frequency and average duration. Specific entries inherit regularities and sub-regularities from the templates while exceptions are specified in the entries themselves. Either individual or cascades of finite state transducers are then applied to generate individual lexicons for speech applications in an application specific format (cf. Cahill, Carson-Berndsen & Gazdar, 2000).

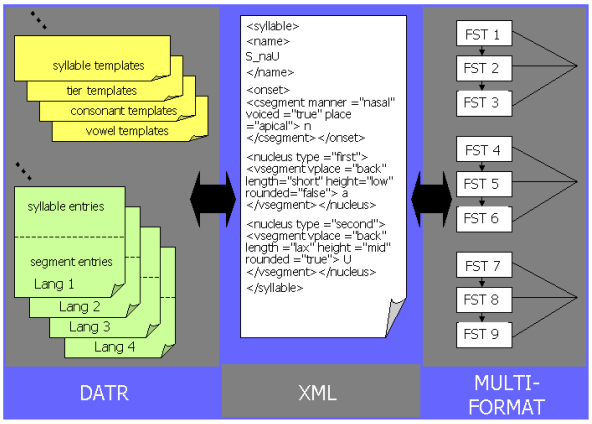

Figure 3: Generic lexicon architecture

2.4. Speech Recognition with the Time Map Model

In the context of speech recognition, input to the model is a multilinear representation of a speech utterance in terms of absolute time events, i.e. features with start and end points which are extracted from the speech signal. Phonological parsing in the *Time Map model* is guided by the *phonotactic automaton* which provides top-down constraints on the interpretation of the multilinear representation, specifying which overlap and precedence relations are expected by the phonotactics. If the constraints are satisfied, the parser moves on to the next state in the automaton. Each time a final state of the automaton is reached, a well-formed syllable has been found. This well-formed syllable may be underspecified, however, since some of the constraints in the phonotactic automaton may have been relaxed. It is then compared with a fully specified multilinear representation in the *time map lexicon* which allows the system to distinguish between actual (lexicalised) and potential syllables. The architecture of the model in the context of speech recognition is depicted in figure 4.

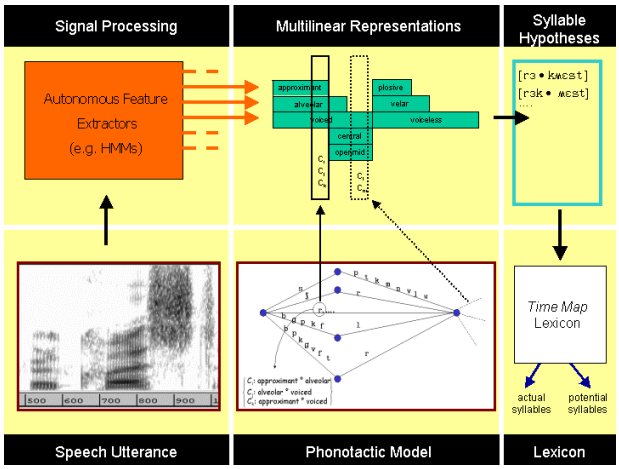

Figure 4: *Time Map* speech recognition architecture

Speech synthesis based on the *Time Map model* is also currently under investigation (see Bohan et al., 2001). This involves generating multilinear representations from a lexical representation of an utterance using a cascade of finite state transducers mapping from phonemes to allophones to event representations. The aim of this research is to investigate the application of the *Time Map model* in the synthesis domain and to a language with a significantly different phonology, namely Irish. The methodology used to port the model to Irish is discussed in section 4 below.

3. Multilingual Time Maps

The *Time Map model* has been parameterized to allow the language-specific components to be substituted by components describing other languages. There are two issues involved in this process. The first issue concerns how to represent the language-specific information in a uniform way so that it can be used immediately by the model and also be made available for use with other technologies. The second issue concerns the acquisition of the language-specific components. In what follows, both of these issues are discussed in turn with respect to the *phonotactic automaton* and the *time map lexicon*. The language-specific configuration of the model is defined by a *multilingual time map*. The *time map* defines mappings between different types of information and constraints on overlap relations between features. It is termed *multilingual* because on the one hand, it provides a framework for developing the language-specific knowledge components for the *Time Map model* either by using knowledge of a related language already available to the system to predict the relevant structures of a "new" language or by learning these directly. On the other hand, it has a uniform structure which allows for cross-language comparisons and the generation of *time maps* which cover a number of languages.

3.1. Representation

A *multilingual time map* comprises language-specific information at various levels of granularity represented as a multilevel finite state transducer. The advantage of this representation is that it is declarative, bidirectional and efficient to process. The multilevel finite state transducer can be viewed as an extension of the phonotactic automaton to include (at least) the following levels:

1. Graphemes
2. Phonemes
3. Allophones
4. Features
5. Constraints on Overlap Relations
6. Average Duration
7. Frequency
8. Probability

Each arc specifies information on all of these levels (although some of this information may not be available in all cases but can be readily updated at any time). For example, figure 5 depicts a single arc of a *multilingual time map* for English.

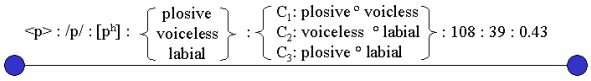

Figure 5: Arc in a *multilingual time map*

The first level is the grapheme level, the second is the phoneme level, the third is the allophone level (i.e. *p* is aspirated in this phonotactic context). The fourth level is the feature level specifying the features for this phoneme (which can be selected from a number of different possible feature sets). The fifth level specifies the constraints on the overlap relations between the features; the sixth level specifies the average duration of the [p] in this phonotactic context. The seventh level specifies the frequency of this sound in this phonotactic context and the eighth level specifies the probability of the arc.

A generic transducer interpreter[2] is used to extract the levels required for different purposes from the *multilingual time map*. To construct the phonotactic automaton for a speech recognition application of the *Time Map model*, for example, the generic transducer interpreter takes level 2 as input and outputs level 5 and level 6 from the transducer. Note that it is also possible to map between other levels in the transducer to obtain other types of information (e.g. input graphemes and output phonemes; input phonemes and output allophones etc.).

3.2. Acquisition

The real challenge for the portability of the *Time Map* model lies in acquisition of the *multilingual time maps* (i.e. not just to be able to use them to generate the *phonotactic automaton* and the *time map lexicon* for a particular language, but to be able to construct them efficiently). *PhonoDeSK* (see figure 6) is a suite of tools which has been designed specifically for acquiring and evaluating *multilingual time maps* (see Ashby, Carson-Berndsen & Joue, (2001 for an initial specification). These tools are used by *PhonoDeSK agents*[3] which collaborate with each other in order to define an optimal phonological description of the language.

PhonoDeSK foresees three strategies for structured data acquisition; user-driven, data-driven and data-driven with user prompting. That is to say, *multilingual time maps* can either be produced manually by a trained linguist or can be learned from a data set with or without user intervention. *PhonoDeSK* is web-based and can thus be accessed anywhere at any time. The user is also viewed as an agent in the context of *PhonoDeSK* – the *verification agent*.

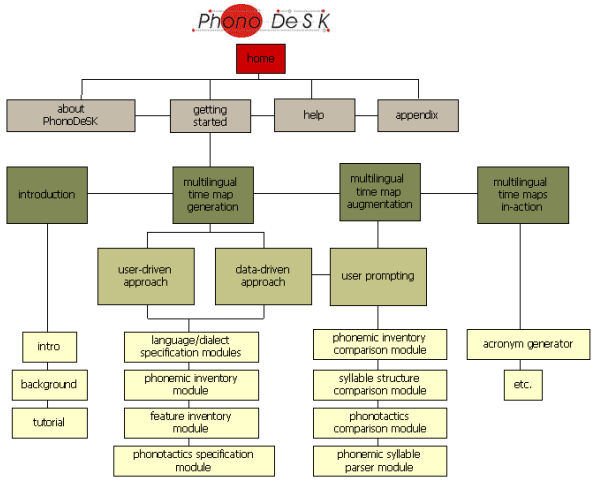

Figure 6*: PhonoDeSK*

When constructing a *multilingual time map* for a "new" language, a number of inventories are created by an *inventory agent:*

1. Phoneme Inventory
2. Allophone Inventory
3. Feature Inventory
4. Syllable Inventory

In each case, any available resources may be used directly. For example, a phonemically labeled data set can be used to extract the phoneme inventory and, together with a *learning age*nt for phonotactic automata, PAL (Kelly, 2001), to predict the syllable inventory. Using an existing *multilingual time map* for a related language, predictions may be made which can be accepted or rejected by a native speaker (*verification agent*) of the language. The acceptances/rejections are then incorporated into the learning procedure. If no resources whatsoever are available for the "new" language then much more manual input is required by the user. The first pass *multilingual time map*

[2] This has been implemented by Robert Kelly, University College Dublin.

[3] The notion of agent will not be discussed further in this paper. Further details on the agent approach assumed here can be found at http://said.ucd.ie.

constructed using *PhonoDeSK* will be, in general, underspecified on some of the transducer levels.

This section has discussed *multilingual time maps*, how they are represented and how they can be acquired for new languages. The next section illustrates how a *multilingual time map* can be constructed using *PhonoDeSK agents,* taking Irish as an example.

4. An Example

In this section, an example of a *multilingual time map* is presented which has been constructed from an initial corpus of tri-syllabic Irish words. This is work in progress and therefore as stated above not all levels in the *time map* are fully specified at present. In *PhonoDeSK*, a *phonotactic agent* and a *lexicon agent* collaborate with each other and with other learning and generalization agents to construct a *multilingual time map* which can be used with the *Time Map model* for speech recognition and synthesis.

4.1. Observation

The corpus was recorded and labeled phonetically including syllable boundaries and a distinction between stressed and unstressed syllables was made. The phoneme inventory and the feature inventory were specified manually by an expert on Irish phonology (a human *verification agent* for Irish). The corpus was input to the *learning agent*. The first pass produced a deterministic phonotactic automaton which included average durations for each sound in each phonotactic context, frequency of each sound in each phonotactic context with respect to the corpus and a probability of each arc. The initial *multilingual time map* for Irish specifies levels 2 to 8.

Since this initial *multilingual time map* specifies all the forms in the corpus, it automatically contains all the forms which should be included in the *time map lexicon*. Here a distinction is being made between a corpus lexicon and a complete lexicon of the Irish language. The *lexicon agent* uses all the information which is available in the *multilingual time map* to define new syllable and segment entries together with syllable, tier, consonant and vowel templates in the DATR-based lexicon.

4.2. From Observation to Generalization

The initial *multilingual time map* is input to a *generalization agent* which extends and optimizes the *time map*. The *generalization agent* interacts with 4 other agents until an optimal description is reached.

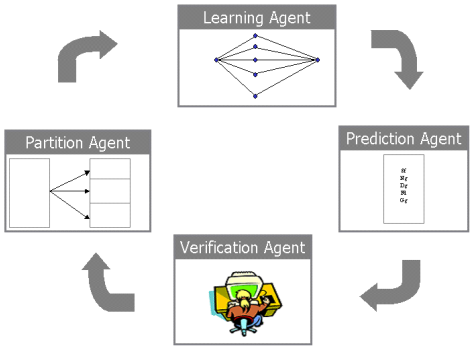

Figure 7: Generalisation cycle

For the purposes of generalization over substructures, the data is partitioned into initial consonant cluster (onset), vowel and final consonant cluster (rhyme) and further into CC- onsets; CCC-onsets etc. A phonotactic automaton for each of the partitions is learned separately by the *learning agent*. An example for the resulting structure for stressed syllable CC- onsets in Irish is depicted in figure 8, whereby only level 2 (phonemes) is specified. Note that Irish has both palatalized (represented in this figure by uppercase) and plain consonants.

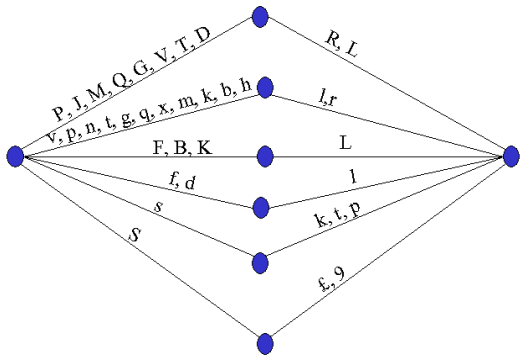

Figure 8: Learned CC- onset of Irish syllable

This onset automaton has been learned purely on the basis of the data set. It does not claim to cover all CC-onsets of Irish, only those represented in the data. In order to extend this to a complete onset description, (idiosyncratic) gaps must be identified in the representation which could also be permissible onsets of the language. There are two methods for identifying idiosyncratic gaps in the automaton. The first involves examining general distributional properties evident in the automaton. To the eye, one possible gap is obvious: there is a path representing the combinations [fl] and [dl] and [f] and [d] stand out as being the only plain consonants followed by [l] but not followed by [r] in the onset. The *prediction agent* identifies such gaps and the combinations [fr] and [dr] are presented to native speakers of the language (*verification agents*) to verify whether these are permissible combinations or not. The arcs in the *multilingual time map* are then generalized with respect to the feature level (level 4) in order to determine the commonalities between the phonemes in a particular phonotactic context. The *prediction agent* requests a *phonoclass agent* to group phonemes into natural classes (based on the intersection of the their features). Using the complete phoneme and feature inventories, the *prediction agent* presents other phonemes which are part of the natural class but are not found in that phonotactic position to the *verification agent*.

This is performed until all partitions of the data have been generalized or until the verification agent decides that the *multilingual time map* is optimal[4].

[4] In this context, optimal means deemed suitable for use in some application.

4.3. Alternative Routes

The description of the *multilingual time map* construction using *PhonoDeSK* has assumed thus far that phonemically labeled data is available as a starting point for learning. Clearly, this will not always be the case and there are two alternative routes which can be taken. Firstly, it may be possible to predict using the *multilingual time map* of a related language, what phonotactic combinations are permissible in the new language. These can be input directly to the *prediction agent* and the forms can be accepted or rejected by the *verification agent*. Secondly it is also possible for the user to specify the canonical form of the syllable and the phoneme inventory of the "new" language and this will be used by the *prediction agent* to elicit permissible combinations from the *verification agent*.

There are a number of additional tools available in *PhonoDeSK* which support the *verification agent* in constructing a new *multilingual time map* from an existing *time map*: for example, all possible forms represented by the *time map* can be generated; two descriptions may be compared directly with each other at the phoneme and syllable level (cf. Ashby, Carson-Berndsen & Joue, 2001); a single parse or all possible parses of a given phonemic representation can be generated and presented to the user for verification. The *verification agent* thus provides important information for preferences which are used in turn to update the probability of a particular parse.

The level which remains to be included in the *multilingual time map* after generalization of the phonotactics is complete is the grapheme level (level 1). This task is performed by the *lexicon agent*. The phonemic forms are presented to the *verification agent* to elicit a correct orthographic form for the lexicon, possibly using the *prediction agent* to suggest mappings based on the original corpus. Once the orthographic forms are available in the lexicon, the *phonotactic agent* requests the *learning agent* to learn the grapheme-phoneme mapping of the words in the corpus. This can later be used to estimate a grapheme-phoneme mapping for new forms.

5. Conclusion

This paper has presented the concept of a *multilingual time map* which has evolved out of a desire for portability of a computational phonological model for use in various human language technology tasks. The development environment, *PhonoDeSK*, has been designed specifically for acquiring, representing and applying phonological information at various levels of granularity. It combines finite state techniques with automatic and manual data acquisition through the use of agents which collaborate to instantiate the various levels of the *multilingual time map*. The *multilingual time maps* have been designed specifically for use with the *Time Map model* but they also represent an important step on the road to the realisation of ubiquitous language technology in general, by providing a framework which allows portability to new languages. However, the information represented in the *multilingual time maps* can be used directly by other technologies for structural fine tuning. Future work is concerned with extending *PhonoDeSK* agents and with applying the technology to other languages.

Units for Automatic Language Independent Speech Processing

Jan Černocký

Brno University of Technology, Faculty of Information Technology
Božetěchova 2, 61266 Brno, Czech Republic
cernocky@fit.vutbr.cz

Abstract

Many current systems for automatic speech processing rely on sub-word units defined using phonetic knowledge. Our paper presents an alternative to this approach – determination of speech units using ALISP (Automatic Language Independent Speech Processing) techniques. Such units were experimentally tested in a very low bit rate phonetic vocoder, where mean bit rates of hundreds bps for unit encoding were achieved. Improvements of the proposed coder and some links to "classical" approaches of speech synthesis are discussed. Based on the results of comparison of an ALISP segmentation with a phonetic alignment, we comment on the potential use of automatically derived units in speech recognition, speaker verification and language identification.

1. Introduction

The International Phonetic Association (IPA) sets up as one of its objectives the definition of a symbolic representation of speech for any of the speakers of any language in the world: the International Phonetic Alphabet[1]. However, despite efforts devoted to this topic, some substantial problems persist in the adequacy of this alphabet for spoken speech.

Recent advances in ALISP (Automatic Language Independent Speech Processing) (Chollet et al., 1999) led us to the idea of defining such a set of units *automatically*, without an a-priori knowledge; to let it emerge uniquely from the speech data. For this purpose, a number of tools which proved their efficiency in automatic speech processing (coding, recognition, synthesis, language identification, speaker verification) have been developed: temporal decomposition (TD), non-supervised clustering, Hidden Markov Models (HMM) and others. Basic information about these tools with references are given in Section 2.

On contrary to IPA, where it is difficult to find an objective criterion, the set of units can be evaluated using *very low bit rate (VLBR) speech coding* at about 200 bps (Černocký et al., 1998). At these rates, a symbolic representation of the incoming speech is required. If the decoded speech is intelligible, one must admit that the symbolic representation is capable of capturing the significant acoustic-phonetic structure of the message. Moreover, the coding rate in bps and dictionary size give an idea of *efficiency* of the description while the quality of decoded speech is related to its *precision*. Section 3. gives an overview of our VLBR coding experiments in three languages and their results. It also contains a description of recent advances in VLBR coding using ALISP units.

However, the domain with the greatest need of optimized and automatically derivable units is the large vocabulary continuous speech recognition (LVCSR) based in current systems on phones or their derivatives (context-dependent phones, syllables). Section 4. presents a comparison of two alignments of data: phonetic and ALISP in terms of a confusion matrix. It also contains some reflections on encoding of target vocabulary using data-driven units.

Section 5. contains conclusions and some comments on the use of ALISP units in other domains (speaker verification and language identification).

[1] http://www.arts.gla.ac.uk/IPA/ipa.html

2. ALISP tools

Classical speech processing suffers from the need of large phonetically labeled, or at least orthographically annotated corpora. This is making the current algorithms unpractical when used in a condition for which a database does not exist, or is very costly (rare language, environmental noise, channel, application domain). The main goal in ALISP processing is to find data-driven units with as little supervision as possible. We will see, that for coding, the process can be fully automated. Steps that should be taken to use such units in recognition are discussed in section 4. The expected result of unit creation is:

- a set of units (that can be compared to a set of phonemes).
- labeling of the training data using those units.
- models of units to detect them automatically in unseen data.

The tools used to find units are:

The *temporal decomposition (TD)* is a representative of algorithms able to detect quasi-stationary parts in the parametric representation of speech. This method, introduced by Atal (Atal, 1983) and refined by Bimbot (Bimbot, 1990), approximates the trajectories of parameters $x_i(n)$ by a sum of m *targets* a_{ik} weighted by *interpolation functions* (IF):

$$\hat{x}_i(n) = \sum_{k=1}^{m} a_{ik}\phi_k(n), \quad \text{for} \quad i = 1, \ldots, P, \qquad (1)$$

where P is the dimension of the parameter vectors. Equation 1 can be written:

$$\underset{(P \times N)}{\hat{\mathbf{X}}} = \underset{(P \times m)}{\mathbf{A}} \; \underset{(m \times N),}{\mathbf{\Phi}} \qquad (2)$$

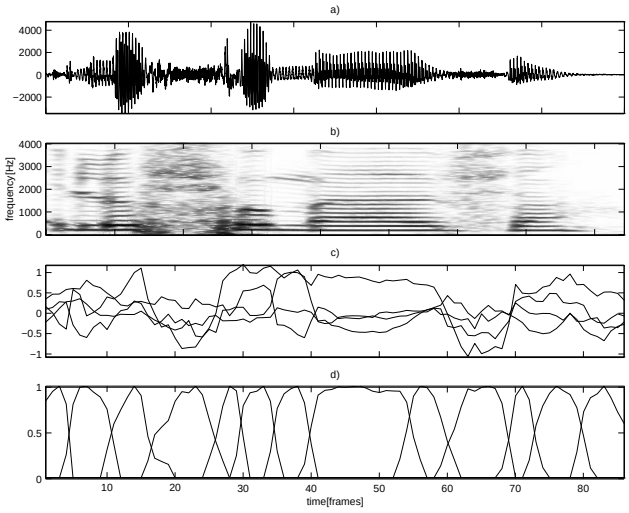

Figure 1: Illustration of temporal decomposition of French word “le chômage”: a) signal. b) spectrogram. c) trajectories of first 4 LPCC parameters. d) TD interpolation functions.

where the lower line indicates matrix dimensions. The initial interpolation functions are found using local Singular Value Decomposition with adaptive windowing, followed by post-processing (smoothing, decorrelation and normalization). Target vectors are then computed by: $\mathbf{A} = \mathbf{X}\mathbf{\Phi}^{\#}$, where $\mathbf{\Phi}^{\#}$ denotes the pseudo-inverse of IFs matrix. IFs and targets are locally refined in iterations minimizing the distance of $\mathbf{X}$ and $\hat{\mathbf{X}}$. Intersections of interpolation functions permit to define speech segments. An example of TD can be seen in Fig. 1. Critically speaking, any of automatic segmentation procedures, based for example on spectral variation function (SVF), could be used. We chose TD because the algorithm and software were readily available in the lab.

Unsupervised clustering assigns segments to classes. Vector quantization (VQ) is used for automatic determination of classes: class centroids are minimizing the overall distortion on the training set. The VQ codebook $\mathbf{Y} = \{\mathbf{y}_1, \ldots, \mathbf{y}_L\}$ is trained by K-means algorithm with binary splitting. Training is performed using vectors positioned in gravity centers of TD interpolation functions, while the *quantization* takes into account entire segments using cumulated distances between all vectors of a segment and a code-vector. TD with VQ produce a phone-like segmentation of speech.

Hidden Markov models (HMM) can be used to model the units. HMM parameters are *initialized* using context-free and context-dependent Baum-Welch training (Young et al., 1996) with TD+VQ transcriptions, and *refined* in successive steps of corpus segmentation (using HMMs) and model parameters re-estimation. The speech represented by observation vector string can then be aligned with models by standard likelihood maximization. At this point, we obtain the three desired outputs of the unit determination algorithm: units, their models and training data alignments. The units can be used in further processing.

3. Very low bit rate coding

The VLBR coding using ALISP units has been the first verification of our approach. It turned out however, that after some modifications to improve the output speech quality (discussed later in this section), it can have potential applications.

The coder performs the *recognition* of input unseen speech into ALISP units, that we call *coding units*. For the *synthesis* in the decoder, however, another type of units called *synthesis units* can be defined – units can be for example designed in such a way that the synthesis units spans a speech segment between two spectrally stable parts, so that the concatenation becomes easier. Finally, the decoder must dispose of a certain number of *representatives* of each synthesis unit. The coder must send the index of best-matching representative (DTW-distance was used as distortion measure) and information on the prosody: timing and pitch and energy contours.

The *decoder* receives the information on coding units and derives the information on synthesis units, then it retrieves the representative from its memory. The synthesis modifies the prosody of the representative and produces output speech.

3.1. Basic coding tests

This approach was first tested in speaker-dependent experiments on American English (Černocký, 1998), French (Černocký et al., 1998) and Czech (Černocký et al., 1999). The speech parameterization was done by a set of LPC-cepstral coefficients on 20 ms frames with 10 ms frame-shift. Temporal decomposition was set to produce 15–17 targets per second in average (corresponding to average phoneme rate). The VQ codebook had 64 code-vectors that were trained using the original vectors (not TD-targets) located in gravity centers of TD interpolation functions. After initial labeling using the TD+VQ tandem, first “generation” of HMMs (3 emitting states, no state-skip, single-Gaussian) was trained. The training corpus was aligned with those models, and 5 iterations of retraining-alignment were run.

In the coding, synthesis units corresponded to the coding ones, and for each, 8 longest representatives were searched in the training data. The number of bits per unit was therefore $\log_2 64$ (unit) $+ \log_2 8$ (representative) $= 9$. This led to the average bit rate for unit encoding of 100–200 bps. The prosody was not coded in those experiments, and the physical synthesis in the decoder was done by a rudimentary LPC synthesizer.

Intelligible speech was obtained for the three languages – low speech quality was attributed mainly to rudimentary LPC synthesis rather than the units themselves. Those experiments justified our approach – they proved that a “phonetic-like” speech coder can be trained without ever seeing any transcriptions of the speech data.

3.2. Harmonic Noise Model synthesis

In basic structure of the coder, LPC synthesis has been used to produce the output speech. It was found to be highly responsible for the low quality of the resulting speech (that can be proved by a copy LPC analysis-synthesis). Therefore, the Harmonic-Noise Model (HNM) which brings

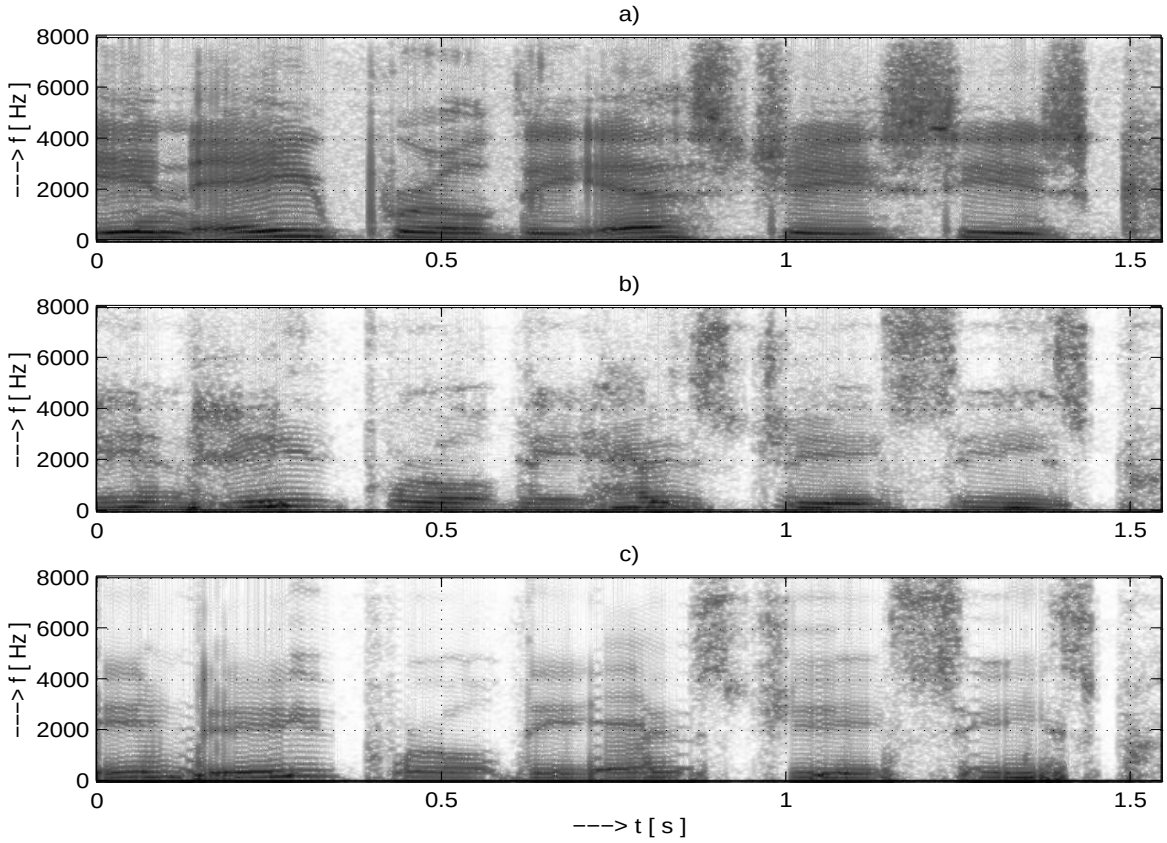

Figure 2: Spectrograms. a) original speech signal. b) coded speech synthesized by HNM. c) coded speech synthesized by LPC.

much higher quality of the synthesized speech, is applied. The principle of HNM is in detail described in (Oudot, 1996; Stylianou, 1996). The HNM is built on following representation of signal $x(n)$:

$$x(n) = \underbrace{\sum_{k=1}^{P} \alpha_k \cos(2\pi f_k n - \phi_k)}_{\text{Harmonics}} + \underbrace{b(n)}_{\text{Noise}}, \qquad (3)$$

where P is the number of harmonics, α_k are the amplitudes, f_k the multiples of pitch and ϕ_k phases of harmonic part. $b(n)$ expresses components of noise.

Eq. 3. describes both parts of HNM. The first part "Harmonics" decomposes the speech signal into a sum of sinusoids. In fact, a combination of harmonically related and non-harmonically related sinusoids can also be used. "Noise" in Eq. 3 represents non-harmonic part of speech signal. The parameters for the noise and harmonic part are estimated separately. The fundamental frequency estimation is isolated from the estimation of amplitudes and phases and the interdependence of the parameters in neighboring frames is alleviated through the hypothesis of the quasi-stationary signal. Thus, the first step of the analysis process consists of estimating the fundamental frequency for the voiced frames. In our work, a classical method based on normalized cross correlation function (NCCF) (Talkin, 1995) has been applied.

The estimation of amplitudes and phases of the harmonics is done using the method of least mean squares (Charbit and Paulsson, 2000). The noise of *voiced frames* is obtained by subtracting the previously computed harmonics from the input signal. Its spectrum is modeled by LPC auto-recursive filter of 12^{th} order. In *unvoiced frames*, only parameters of the noise model are estimated. Auto-recursive filter of 12^{th} order is used, as above. In synthesis, the source signal is represented by white noise filtered by the estimated LPC filter.

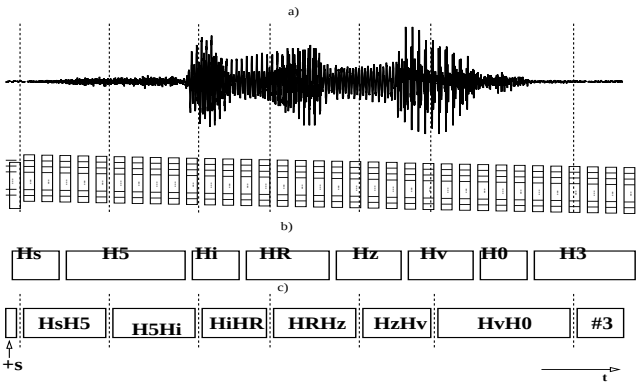

Figure 3: Example of re-segmentation according to middle frames of original units. Minimal length of new units is 4 frames: a) speech signal with its splitting into the frames. b) original segmentation recognized by HMMs. c) new re-segmentation.

Spectral envelope is needed to perform pitch modifica-

tion in the synthesized speech. The log of spectral envelope is computed from the estimated amplitudes of the harmonics using real-cepstrum coefficients (Charbit and Paulsson, 2000).

The results (Motlíček et al., 2001) have demonstrated, that the replacement LPC synthesis by HNM version is highly responsible for great improvement of quality of resulting speech, as can be seen in Fig. 2, where spectrograms from the same part of speech signal are compared[2].

3.3. Synthesis units

The units initialized by the temporal decomposition are inherently unstable at their boundaries (remember, that the center of TD-units tends to be stable). Such units are therefore not very suitable for synthesis as they do not have good concatenation properties. We have therefore tested two approaches to make *synthesis units* units closer to diphone-based or corpus-based speech synthesis.

First, *selection of longer synthesis units* based on the original coding ones was tested (Motlíček et al., 2001). This approach is illustrated in Fig. 3. These long units can be constructed by aggregation of short ALISP coding units with re-segmentation in spectrally stable parts of the extremity units. The synthesizer is similar to a diphone one. The results were however not satisfactory, some concatenation noise was still audible and due to the limitation of the training corpus, some synthesis units were missing and difficult to replace.

Therefore, a different method called *short synthesis units with dynamic selection* was developed (Baudoin et al., 2002). Here, for each ALISP class, a large number of representatives is extracted from the training corpus. These synthesis representatives are determined in order to fulfill criteria of good representation of a given segment to be coded and criteria of good concatenation of successive segments.

For each coding unit H_j, we define sub-classes called H_iH_j containing all the speech segments of class H_j that were preceded by a segment belonging to the class H_i in the training corpus. It is possible to keep as synthesis representatives all the segments of the training corpus organized in classes and sub-classes as described above or to limit the size of each sub-class to some maximal value K.

During coding, if a segment is recognized as belonging to class H_j and is preceded by a segment in class H_i, the representative is searched in the subclass H_iH_j of class H_j. The selection of the best representative in the sub-class is done on the distance D_C of good representation of the segment. The D_C distance is based on a spectral comparison by DTW between the segment to code and the potential synthesis representatives. The distance D_C can also include a distance on prosody parameters.

We have verified that this approach provides superior speech quality than the "short" coding units or re-segmented longer ones.

3.4. Toward speaker independent ALISP coder

First results of speaker-independent (SI) coding on large French database BREF have been reported in (Baudoin et al., 2002). Coding units were trained on 33 male speakers from this corpus, and the corresponding representatives were selected from all available speakers in similar fashion to speaker-dependent coding presented in section 3.1. The resulting speech was intelligible, though with lower quality than the speaker-dependent counterpart. This confirmed the possibility to use the ALISP scheme also in SI environment.

Two problems are crucial for the SI operation: speaker clustering or speaker adaptation in the coder and voice modification in the decoder. For the first problem, the TSD article (Baudoin et al., 2002) presents speaker-independent coding with VQ-based speaker clustering. Here, the reference speakers are *pre-clustered*, in order to select the closest speaker or the closest subset of speakers for HMM refinements and/or adaptation of synthesis units. A VQ-based inter-speaker distance using the unsupervised hierarchical VQ algorithm was used (Furui, 1989). The basic assumption is that training speech material from the processed speaker is available during a short training phase for running the VQ adaptation process. The inter-speaker distance is defined as the cumulated distance between centroids of the non-aligned code-books, using the correspondence resulting from the aligned code-books obtained through the adaptation process. This distance is used in the off-line pre-training phase for clustering the reference speakers, and during the on-line training phase for selecting the closest cluster to the user. From the distance matrix, subclasses are extracted using a simplified split-based clustering method.

The proposed concept has been validated on the BREF corpus (phonetically balanced sentences), 16 LPCC coefficients and 64 classes were used. Illustration of the clustering process is given for the largest class, (left panel of Fig. 4), a typical class (middle panel) and an isolated speaker (right panel) in terms of relative distance to the other speakers. One could note the similar positioning of speakers belonging to the same cluster.

The obtained results in terms of speaker clustering using a small amount of data are encouraging. In our future works, we will study a speaker-independent VLBR structure derived from this concept, by adding HMM adaptation at the encoder, and voice conversion techniques at the decoder.

4. ALISP units in recognition

4.1. ALISP–phonetic correspondence

To investigate the potential usability of ALISP units in speech recognition, we performed several experiments on the comparisons of ALISP and phonetic alignments (Černocký et al., 2001).

Such alignments were available with the Boston University corpus of American English (a database that we used for the initial VLBR coding experiments). They were obtained at BU using a segmental HMM recognizer constrained by possible pronunciations of utterances (Ostendorf et al., 1995). The measure of correspondence was the relative overlap r of ALISP unit with a phoneme (see Fig. 5 for illustration). The results are summarized in *confusion*

[2] http://www.fee.vutbr.cz/∼motlicek/speech_hnm.html contains examples of speech after coding/decoding.

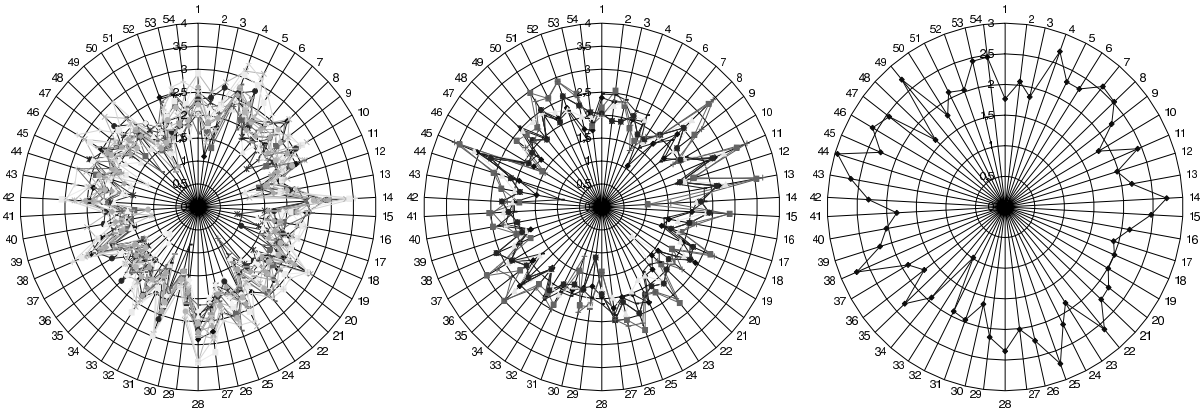

Figure 4: Left panel: Relative distance of speakers from the largest cluster. Middle panel: Relative distance of speakers from a typical cluster (indexes 6, 14, 21, 29, 31, 43). Right panel: Relative distance of speakers from an isolated speaker (index 33).

matrix $\mathbf{X}$ ($n_p \times n_a$), whose elements are defined:

$$x_{i,j} = \frac{\sum_{k=1}^{c(p_i)} r(p_{i_k}, a_j)}{c(p_i)}. \quad (4)$$

n_p and n_a are respectively the sizes of phoneme and ALISP unit dictionaries, p_i is the i-th phoneme, a_j is the j-th ALISP unit, $c(p_i)$ is the count of p_i in the corpus and $r(p_{i_k}, a_j)$ is the relative overlapping of k-th occurrence of p_i with ALISP unit a_j. The columns of $\mathbf{X}$ are rearranged to let the matrix have a quasi-diagonal form. As for the phoneme set, on contrary to BU alignments, where stressed vowels are differentiated from unstressed ones, we used the original TIMIT set. The ALISP set had 64 units. The resulting matrix is given in Fig. 6.

This matrix shows, that the correspondence between ALISP units and phonemes is consistent, but not unique. We can for example see, that the ALISP unit `a` corresponds to closures, but also to the pause. The unit `$` has a strong correlation with `SH` but it is also linked to its voices counterpart `ZH` and to affricates `JH` et `CH`, which are acoustically very closed.

4.2. Using ALISP units in recognition

Although the above mentioned experiments showed a correlation of phonemes and ALISP units, an ALISP recognition system should probably not be based on direct phoneme–ALISP mapping. Stochastic mapping of *sequences* of phonemes to *sequences* of ALISP units would be one solution. This approach was studied in (Deligne, 1996): likelihood maximization is applied to joint segmentation of two streams of observations, where the first can be the phonetic labeling and the second the sequence of automatically derived units. When the testing data are processed, the method finds the segmentation together with optimal "transcription" into sequences of phonemes. The observations can be either symbolic (in this case, the method is "discrete") or vectorial (here, not only statistics of sequences, but also emission PDFs come into mind).

Another option is the *composition* of ALISP units into word and phone models, proposed in (Fukada et al., 1996). Here, the basic units are first derived in an unsupervised manner. Then, phonetic transcription is compared to ALISP segmentation and composite models are constructed for the *words* of the corpus. In case the data do not contain sufficient number of examples of a word, the method can "back-up" to *phoneme models* composed in similar manner as the word ones.

Third solution was proposed for triphone models, but it would generalize well also with ALISP units. This approach does not require phonetic transcriptions but a large database with word boundaries. ALISP labels are generated for this DB and the ALISP-pronunciation dictionary is created. It is however necessary to develop an expert system for the transcription of unseen words in terms of ALISP units.

5. Conclusions

The algorithm of unit search produces set of consistent units but is far from optimal. As for the feature extraction, we have for example not investigated the perceptually motivated features used by Hermansky and his group (Hermansky, 1997). The distance used in VQ could be replaced by the Kullback-Leibler one, that has shown superior performances in selection of units for synthesis (Stylianou and Syrdal, 2001). The training of unit models could be done completely without initialization of time boundaries (currently temporal decomposition) and of labels (VQ) by using an Ergodic Hidden Markov model (EHMM) for both tasks simultaneously. Finally, it is necessary to think about "shaping" the units for the target application.

The first part of the paper demonstrates that *speech coding*, at transmission rate lower than 400 bps, can be achieved using automatically derived units. The drawback of our proposal is the size of the memory required both in coder and decoder and the delay introduced by the maximal duration of the segments (several hundreds msec). There are many applications which could tolerate both a large memory (let say 200 Mbytes) and the delay. Among such applications are the multimedia mobile terminal of the future (including the electronic book), the secured mobile phone, the compression of conferences (including distance education), etc. More work is necessary on voice transformation so that only typical voices will be kept in memory.

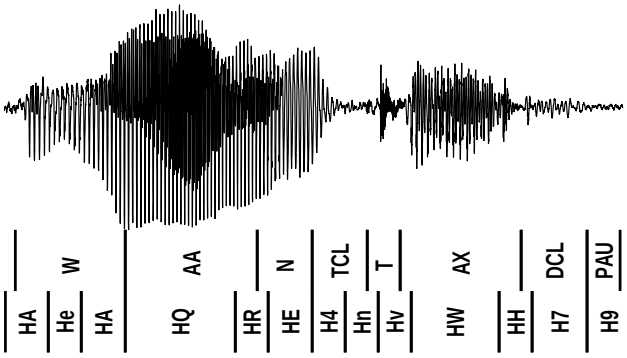

Figure 5: Illustration of comparison of ALISP and phonetic segmentations: word "wanted" from female speaker of Boston University corpus.

Characterization of a voice based on limited data and use of this characterization to transform another voice is an interesting research topic.

As for the *recognition*, we can conclude that building of ALISP-based recognizer will not be a straightforward task. The invested efforts should however be generously recompensed by the limitation of human efforts needed to create or modify such a recognizer. If we obtain an efficient scheme, and in the same time we succeed in limiting the human labor (annotations, pronunciation dictionaries, etc.), it will be a great step toward the *real automating* of speech processing, and it will also open the way to its easier implementation in different languages.

ALISP unit use should not be limited to coding or recognition. In (Petrovska-Delacrétaz et al., 2000), we have reported results of a speaker-verification system with pre-segmentation in ALISP units before actual scoring. The performance of our system on 1999 NIST data was not optimal, but we believe that pre-segmentation of speech into classes and determination of their speaker-characterization performances can aid the verification system. Results obtained from class-specific models can be then combined using appropriate weighting factors before taking the decision.

The last proposed application domain is the *language identification*. Most current language identification (LI) systems are based on the approach of extracting the phonotactic language specific information. The phonotactics is related to the modeling of the statistical dependencies inherent in the phonetic chains. Unfortunately, transcribed databases should be available to train the required phonetic recognizer, and the transcription step is a major bottleneck for the adaptation of systems to new languages or services (as it is for the other domains). We propose to replace the widely used phonetic-based recognizers by an ALISP-based recognizer, and to extract from the automatically segmented speech units the necessary information for solving the problem of language identification. The advantage of the proposed method is its portability to new languages, for which we do not have annotated databases.

6. Acknowledgments

Several colleagues have contributed to this article. Fréderic Bimbot (IRISA Rennes, France) contributed the `td95` package used for the temporal decomposition. Geneviève Baudoin (ESIEE Paris) supervised initial stages of the work and with Fadi El Chami (Université Libanaise Tripoli and ESIEE), she is the author of dynamic unit selection for the synthesis. Petr Motlíček (VUT Brno) worked on the creation of long synthesis units and HNM synthesis. François Capman (Thales Communications) is the author of VQ-based speaker clustering. Dijana Petrovska-Delacrétaz (University of Fribourg, Switzerland) did the speaker-independent experiments and is working on ALISP units deployment in speaker verification. Maurice Charbit and his students (ENST Paris) contributed to the HNM synthesis. Vladimír Šebesta and Richard Menšík (VUT Brno) helped with the visualization of confusion matrices. Finally, thanks to Gérard Chollet (ESNT Paris) for having been at the original ALISP idea and for many constructive comments and supervision.

This research has been supported by Grant Agency of Czech Republic under project No. 102/02/0124 and by the RNRT (Réseau National de Recherche en Télécommunications) project SYMPATEX.

Some Issues in Speech Recognizer Portability

Lori Lamel

Spoken Language Processing Group,
LIMSI-CNRS, France
lamel@limsi.fr

Abstract

Speech recognition technology has greatly evolved over the last decade. However, one of the remaining challenges is reducing the development cost. Most recognition systems are tuned to a particular task and porting the system to a new task (or language) requires substantial investment of time and money, as well as human expertise. Todays state-of-the-art systems rely on the availability of large amounts of manually transcribed data for acoustic model training and large normalized text corpora for language model training. Obtaining such data is both time-consuming and expensive, requiring trained human annotators with substantial amounts of supervision. This paper addresses some of the main issues in porting a recognizer to another task or language, and highlights some some recent research activities aimed a reducing the porting cost and at developing generic core speech recognition technology.

1. Introduction

Speech recognition tasks can be categorized by several dimensions: the number of speakers known to the system, the vocabulary size, the speaking style, and the acoustic conditions. Concerning speakers, the most restrictive is when only one speaker can use the system and the speaker is required to enroll with the system in order to be recognized (speaker-dependent). The system may be able to recognize speech from several speakers, but still requires enrollment data (multiple speaker) or the system can recognize the speech from nominally any speaker without any training data (speaker-independent).

A decade ago the most common recognition tasks were either small vocabulary isolated word or phrases or speaker dependent dictation, whereas today speech recognizers are able to transcribe unrestricted continuous speech from broadcast data in multiple languages with acceptable performance. The increased capabilities of todays recognizers is in part due to the improved accuracy (and increased complexity) of the models, which are closely related to the availability of large spoken and text corpora for training, and the wide availability of faster and cheaper computational means which have enabled the development and implementation of better training and decoding algorithms. Despite the extent of progress over the recent years, recognition accuracy is still quite sensitive to the environmental conditions and speaking style: channel quality, speaker characteristics, and background noise have a large impact on the acoustic component of the speech recognizer, whereas the speaking style and discourse domain largely influence the linguistic component. In addition, most systems are both task and language dependent, and bringing up a system for a different task or language is costly and requires human expertise.

Only for small vocabulary, speaker-dependent isolated word or phrase speech recognizers, such as name dialing on mobile telephones, portability is not really an issue. With such devices, all of the names must be entered by the user according to the specific protocol - such systems typically use whole word patterns and do not care who the speaker or what the language is. For almost all more complex tasks, portability is a major concern. Some speech technology companies have been addressing the language localization problem for many years, and some research sites have also been investigating speech recognition in multiple languages (4; 13; 14; 21; 35; 37) as well as speech recognition using multi-lingual components (19; 33). Multi-lingual speech processing has been the subject of several special sessions at conferences and workshops (see for example, (1; 2; 3; 20)). The EC CORETEX project (http://coretex.itc.it) is investigating methods to improve basic speech recognition technology, including fast system development, as well as the development of systems with high genericity and adaptability. Fast system development refers to both language support, i.e., the capability of porting technology to different languages at a reasonable cost; and task portability, i.e. the capability to easily adapt a technology to a new task by exploiting limited amounts of domain-specific knowledge. Genericity and adaptability refer to the capacity of the technology to work properly on a wide range of tasks and to dynamically keep models up to date using contemporary data. The more robust the initial generic system is, the less there is a need for adaptation.

In the next section an overview of todays most widely used speech recognition technology is given. Following subsections address several approaches to reducing the cost of porting, such as improving model genericity, and reducing the need for annotated training data. An attempt is made to give an idea of the amount of data and effort required to port to a different language or task.

2. Speech Recognition Overview

Speech recognition is concerned with converting the speech waveform into a sequence of words. Today's most performant approaches are based on a statistical modelization of the speech signal (16; 31; 32; 38). The basic modeling techniques have been successfully applied to a number of languages and for a wide range of applications.

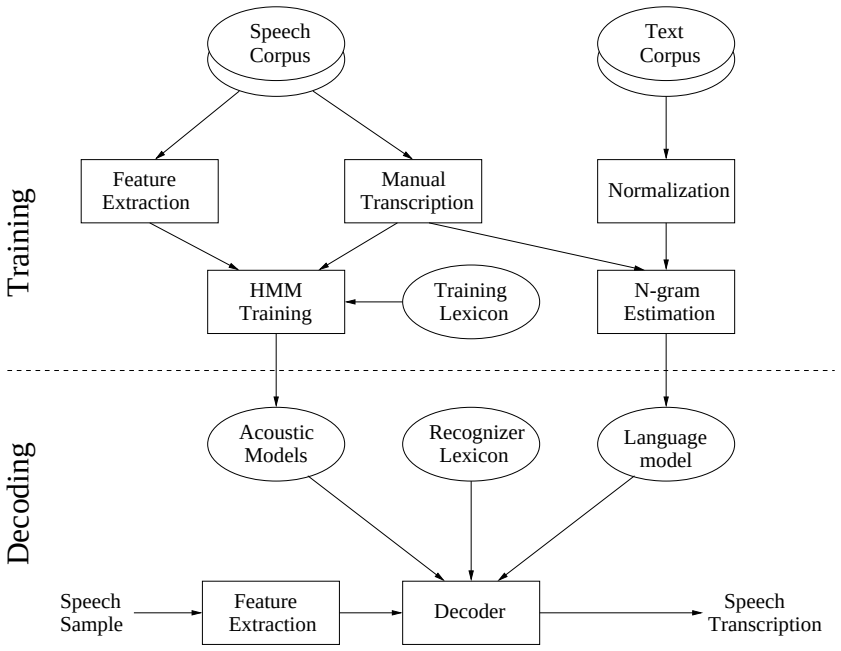

Figure 1: System diagram of a generic speech recognizer based using statistical models, including training and decoding processes.

The main components of a speech recognition system are shown in Figure 1. The elements shown are the main knowledge sources (speech and textual training materials and the pronunciation lexicon), the feature analysis (or parameterization), the acoustic and language models which are estimated in a training phase, and the decoder. The training and decoding algorithms are largely task and language independent, the main language dependencies are in the knowledge sources (the training corpora).

The first step of the acoustic feature analysis is digitization, in which the continuous speech signal is converted into discrete samples. Acoustic feature extraction is then carried out on a windowed portion of speech [1], with the goal of reducing model complexity while trying to maintain the linguistic information relevant for speech recognition. Most recognition systems use short-time cepstral features based either on a Fourier transform or a linear prediction model. Cepstral parameters are popular because they are a compact representation, and are less correlated than direct spectral components. Cepstral mean removal (subtraction of the mean from all input frames) is commonly used to reduce the dependency on the acoustic recording conditions, and delta parameters (obtained by taking the first and second differences of the parameters in successive frames) are often used to capture the dynamic nature of the speech signal. While the details of the feature analysis differs from system to system, most of the commonly used analyses can be expected to work reasonably well for most languages and tasks.

Most state-of-the-art systems make use of hidden Markov models (HMM) for acoustic modeling, which consists of modeling the probability density function of a sequence of acoustic feature vectors (32). These models are popular as they are performant and their parameters can be efficiently estimated using well established techniques. The Markov model is described by the number of states and the transitions probabilities between states. The most widely used acoustic units in continuous speech recognition systems are phone-based[2], and typically have a small number of left-to-right states in order to capture the spectral change across time. Since the number of states imposes a minimal time duration for the unit, some configurations allow certain states to be skipped. The probability of an observation (i.e. a speech vector) is assumed to be dependent only on the state, which is known as the 1st order Markov assumption.

Phone based models offer the advantage that recognition lexicons can be described using the elementary units of the given language, and thus benefit from many linguistic studies. It is of course possible to perform speech recognition without using a phonemic lexicon, either by use of "word models" (a commonly used approach for isolated word recognition) or a different mapping such as the fenones (7). Compared with larger units, small subword units reduce the number of parameters, and more importantly can be associated with back-off mechanisms to model rare or unseen, contexts, and facilitate porting to new vocabularies. Fenones offer the additional advantage of automatic training which is of interest for language porting, but lack the ability to include *a priori* linguistic models.

A given HMM can represent a phone without consideration of its neighbors (context-independent or mono-

[1] An inherent assumption is that due to physical constraints on the rate at which the articulators can move, the signal can be considered quasi-stationary for short periods (on the order of 10ms to 20ms).

[2] Phones usually correspond to phonemes, but may also correspond to allophones such as flaps or glottal stop.

phone model) or a phone in a particular context (context-dependent model). The context may or may not include the position of the phone within the word (word-position dependent), and word-internal and cross-word contexts may or may not be merged. Different approaches can be used to select the contextual units based on frequency or using clustering techniques, or decision trees, and different types of contexts have been investigated. The model states are often clustered so as to reduce the model size, resulting in what are referred to as "tied-state" models.

Acoustic model training consists of estimating the parameters of each HMM. For continuous density Gaussian mixture HMMs, this requires estimating the means and covariance matrices, the mixture weights and the transition probabilities. The most popular approaches make use of the Maximum Likelihood criterion, ensuring the best match between the model and the training data (assuming that the size of the training data is sufficient to provide robust estimates). Since the goal of training is to find the best model to account of the observed data, the performance of the recognizer is critically dependent upon the representativity of the training data. Speaker-independence is obtained by estimating the parameters of the acoustic models on large speech corpora containing data from a large speaker population. Since there are substantial differences in speech from male and female talkers arising from anatomical differences it is thus common practice to use separate models for male and female speech in order to improve recognition performance (requiring automatic gender identification).

2.1. Lexical and pronunciation modeling

The lexicon is the link between the acoustic-level representation and the word sequence output by the speech recognizer (34). Lexical design entails two main parts: definition and selection of the vocabulary items and representation of each pronunciation entry using the basic acoustic units of the recognizer. Recognition performance is obviously related to lexical coverage, and the accuracy of the acoustic models is linked to the consistency of the pronunciations associated with each lexical entry. Developing a consistent pronunciation lexicon requires substantial language specific knowledge from a native speaker of the language and usually entails manual modification even if grapheme-to-phoneme rules are reasonably good for the language of interest. The lexical units must be able to be automatically extracted from a text corpus or from speech transcriptions and for a given size lexicon should optimize the lexical coverage for the language and the application. Since on average, each out-of-vocabulary (OOV) word causes more than a single error (usually between 1.5 and 2 errors), it is important to judiciously select the recognition vocabulary. The recognition word list is to some extent dependent on the conventions used in the source text (punctuation markers, compound words, acronyms, case sensitivity, ...) and the specific language. The lexical units can be chosen to explicitly model observed pronunciation variants, for example, using compound words to represent word sequences subject to severe reductions such as "dunno" for "don't know". The vocabulary is usually comprised of a simple list of lexical items as observed in the text. Attempts have been made to use other units, for example, to use a list of root forms (stems) augmented by derivation, declension, composition rules. However, while more powerful in terms of language coverage, such representations are more difficult to integrate in present state-of-the-art recognizer technology.

These pronunciations may be taken from existing pronunciation dictionaries, created manually or generated by an automatic grapheme-phoneme conversion software. Alternate pronunciations are sometimes used to explicitly represent variants that cannot be easily modeled by the acoustic units, as is the case for homographs (words spelled the same, but pronounced differently) which reflect different parts of speech (verb or noun) such as *excuse*, *record*, *produce*. While pronunciation modeling is widely acknowledged to be a challenge to the research community, there is a lack of agreement as to what pronunciation variants should be modeled and how to do so. Adding a large number of pronunciation variants to a recognition lexicon without accounting for their frequency of occurrence can reduce the system performance. An automatic alignment system is able to serve as an analysis tool which can be used to quantify the occurrence of events in large speech corpora and to investigate their dependence on lexical frequency (5).

2.2. Language modeling

Language models (LMs) are used in speech recognition to estimate the probability of word sequences. Grammatical constraints can be described using a context-free grammars (for small to medium size vocabulary tasks these are usually manually elaborated) or can be modeled stochastically, as is common for LVCSR. The most popular statistical methods are *n*-gram models, which attempt to capture the syntactic and semantic constraints by estimating the frequencies of sequences of *n* words. The assumption is made that the probability of a given word string $(w_1, w_2, ..., w_k)$ can be approximated by $\prod_{i=1}^{k} \Pr(w_i | w_{i-n+1}, ..., w_{i-2}, w_{i-1})$, therefore reducing the word history to the preceding $n-1$ words. A back-off mechanism is generally used to smooth the estimates of the probabilities of rare *n*-grams by relying on a lower order *n*-gram when there is insufficient training data, and to provide a means of modeling unobserved word sequences (17).

Given a large text corpus it may seem relatively straightforward to construct *n*-gram language models. Most of the steps are pretty standard and make use of tools that count word and word sequence occurrences. The main differences arise in the choice of the vocabulary and in the definition of words, such as the treatment of compound words or acronyms, and the choice of the back-off strategy. There is, however, a significant amount of effort needed to process the texts before they can be used.

One of the main motivations for text normalization is to reduce lexical variability so as to increase the coverage for a fixed vocabulary size. The normalization decisions are generally language-specific. Much of speech recognition research for American English has been supported by ARPA and has been based on text materials which were

processed to remove upper/lower case distinction and compounds. Thus, for instance, no lexical distinction is made between *Gates, gates* or *Green, green*. However with increased interest in going beyond transcription to information extraction tasks (such as finding named entities or locating events in the audio signal) such distinctions are important. In our work at LIMSI for other languages (French, German, Portuguese) capitalization of proper names is distinctive with different lexical items for the French words *Pierre, pierre* or *Roman, roman*.

The main conditioning steps are text mark-up and conversion. Text mark-up consists of tagging the texts (article, paragraph and sentence markers) and garbage bracketing (which includes not only corrupted text materials, but all text material unsuitable for sentence-based language modeling, such as tables and lists). Numerical expressions are typically expanded to approximate the spoken form ($150 $\rightarrow$ one hundred and fifty dollars). Further semi-automatic processing is necessary to correct frequent errors inherent in the texts (such as obvious mispellings *milllion, officals*) or arising from processing with the distributed text processing tools. Some normalizations can be considered as "decompounding" rules in they modify the word boundaries and the total number of words. These concern the processing of ambiguous punctuation markers (such as hyphen and apostrophe), the processing of digit strings, and treatment of abbreviations and acronyms (ABCD $\rightarrow$ A. B. C. D.). Another example is the treatment of numbers in German, where decompounding can be used in order to increase lexical coverage. The date 1991 which in standard German is written as *neunzehnhunderteinundneunzig* can be represented by word sequence *neunzehn hundert ein und neunzig*. Generally speaking, the choice is a compromise between producing an output close to correct standard written form of the language and lexical coverage, with the final choice of normalization being largely application-driven.

In practice, the selection of words is done so as to minimize the system's OOV rate by including the most useful words. By useful we mean that the words are expected as an input to the recognizer, but also that the LM can be trained given the available text corpora. There is the sometimes conflicting need for sufficient amounts of text data to estimate LM parameters and assuring that the data is representative of the task. It is also common that different types of LM training material are available in differing quantities. One easy way to combine training material from different sources is to train a language model per source and to interpolate them, where the interpolation weights are estimated on some development data.

2.3. Decoding

The aim of the decoder is to determine the word sequence with the highest likelihood given the lexicon and the acoustic and language models. Since it is often prohibitive to exhaustively search for the best solution, techniques have been developed to reduce the computational load by limiting the search to a small part of the search space. The most commonly used approach for small and medium vocabulary sizes is the one-pass frame-synchronous Viterbi beam search which uses a dynamic programming algorithm. This basic strategy has been extended to deal with large vocabularies by adding features such as dynamic decoding, multipass search and N-best rescoring. Multi-pass decoding strategies progressively add knowledge sources in the decoding process and allows the complexity of the individual decoding passes to be reduced. Information between passes is usually transmitted via word graphs, although some systems use N-best hypotheses (a list of the most likely word sequences with their respectives scores). One important advantage of multi-pass is the possibility to adapt the models between decoding passes. Acoustic model adaptation can be used to compensate mismatches between the training and testing conditions, such as due to differences in acoustic environment, to microphones and transmission channels, or to particular speaker characteristics. Attempts at language model adaptation have been less successful. However, multi-pass approaches are not well suited to real-time applications since no hypothesis can be returned until the entire utterance has been processed.

3. Language porting

Porting a recognizer to another language necessitates modification of some of the system parameters, i.e. those incorporating language-dependent knowledge sources such as the phone set, the recognition lexicon (alternate word pronunciations), and phonological rules and the language model. Different languages have different sets of units and different coarticulation influences amomg adjacent phonemes. This influences the way of choosing context-dependent models and of tying distributions. Other considerations are the acoustic confusability of the words in the language (such as homophone, monophone, and compound word rates) and the word coverage of a given size recognition vocabulary.

One important aspect in developing a transcription system for a different language is obtaining the necessary resources for training the acoustic and language models, and a pronunciation lexicon. The Linguistic Data Consortium (LDC http://www.ldc.upenn.edu) and the European Language Resources Association (ELRA http://www.elda.fr) have greatly aided the creation and distribution of language resources. The number and diversity of language resources has grown substantially over recent years. However, most of the resources are only available for the most interesting languages from the commercial or military perspectives.

There are two predominant approaches taken to bootstrapping the acoustic models for another language. The first is to use acoustic models from an existing recognizer and a pronunciation dictionary to segment manually annotated training data for the target language. If recognizers for several languages are available, the seed models can be selected by taking the closest model in one of the available language-specific sets. An alternative approach is to use a set of global acoustic models, that cover a wide number of phonemes (33). This approach offers the advantage of being able to use the multilingual acoustic models to provide additional training data, which is particularly interesting when only very limited amounts of data ($<$ 10 hours)

for the target language are available.

A general rule of thumb for the necessary resources for speaker independent, large vocabulary continuous speech recognizers is that the minimal data requirements are on the order of 10 hours transcribed audio data for training the acoustic models and several million words of texts (transcriptions of audio if available) for language modeling. Depending upon the application, these resources are more or less difficult to obtain. For example, unannotated data for broadcast news type tasks can be easily recorded via standard TV, satellite or cable and data of this type is becoming more easily accessible via the Internet. Related text materials are also available from a variety of on-line newspapers and new feeds. The manual effort required to transcribe broadcast news data is roughly 20-40 hours per hour of audio data, depending upon the desired precision (8).

Data for other applications can be much more difficult to obtain. In general, for spoken language dialog systems, training data needs to be obtained from users interacting with the system. Often times an initial corpus is recorded from a human-human service (should it exist) or using simulations (Wizard-of-OZ) or an initial prototype system. The different means offer different advantages. For example, WOz simulations help in making design decisions before the technology is implemented and allow alternative designs to be simulated quickly. However, the amount of data that can be collected with a WOz setup is limited by the need for a human wizard. Prototype systems offer the possibility of collection much larger corpora, albeit somewhat limited by the capacity of the current system. We have observed that the system's response generation has a large influence on the naturalness of the data collected with a prototype system.

Other application areas of growing interest are the transcription of conversational speech from telephone conversations and meetings, as well as voicemail. Several sources of multilingual corpora are available (for example, the CallHome and CallFriend corpora from LDC). This data is quite difficult to obtain and costly to annotate due to its very spontaneous nature (hesitations, interruptions, use of jargon). The manual effort involved is higher than that required for broadcast news transcription, and the transcriptions are less consistent and accurate.

The application-specific data is useful for accurate modeling at different levels (acoustic, lexical, syntactic and semantic). Acquiring sufficient amounts of text training data is more challenging than obtaining acoustic data. With 10k queries relatively robust acoustic models can be trained, but these queries contain only on the order of 100k words, which probably yield an incomplete coverage of the task (ie. they are not sufficient for word list development) and are insufficient for training *n*-gram language models.

At LIMSI broadcast news transcription systems have been developed for the American English, French, German, Mandarin, Spanish, Arabic and Portuguese languages. The Mandarin language was chosen because it is quite different from the other languages (tone and syllable-based), and Mandarin resources are available via the LDC as well as reference performance results from DARPA benchmark tests. To give an idea of the resources used in developing these systems, the training material are shown in Table 1. It can be seen that there is a wide disparity in the available language resources for a broadcast news transcription task: for American English, 200 hours of manually transcribed acoustic training were available from the LDC, compared with only about 20-50 hours for the other languages. Obtaining appropriate language model training data is even more difficult. While newspaper and newswire texts are becoming widely available in many languages, these texts are quite different than transcriptions of spoken language. Over 10k hours of commercial transcripts are available for American English (from PSMedia), and many TV stations provide closed captions. Such data are not available for most other languages, and in some countries it is illegal to sell transcripts. Not shown here, manually annotated broadcast news corpora are also available for the Italian (30 hours) and Czech (30 hours) languages via ELRA and LDC respectively, and some text sources can be found on the Internet.

Some of the system characteristics are shown in Table 2, along with indicative recognition performance rates for these languages. State-of-the-art systems can transcribe unrestricted American English broadcast news data with word error rates under 20%. Our transcription systems for French and German have comparable error rates for news broadcasts (6). The character error rate for Mandarin is also about 20% (10). Based on our experience, it appears that with appropriately trained models, recognizer performance is more dependent upon the type and source of data, than on the language. For example, documentaries are particularly challenging to transcribe, as the audio quality is often not very high, and there is a large proportion of voice over.

4. Reducing the porting cost

4.1. Improving Genericity

In the context of the EC CORETEX project, research is underway to improve the genercity of speech recognition technology, by improving the basic technolgoy and exploring rapid adaptation methods which start with the initial robust generic system and enhance performance on particular tasks. To this extent, cross task recognition experiments have been reported where models from one task are used as a starting point for other tasks (24; 9; 15; 26; 30; 11). In (26) broadcast news (BN) (28) acoustic and language models to decode the test data for three other tasks (TI-digits (27), ATIS (12) and WSJ (29)). For TI-digits and ATIS the word error rate increase was shown to be primarily due to a linguistic mismatch since using task-specific language models greatly reduces the error rate. For spontaneous WSJ dictation the BN models out-performed task-specific models trained on read speech data, which can be attributed to a better modelization of spontaneous speech effects (such as breath and filler words).

Methods to improve genericity of the models via multi-source training have been investigated. Multi-source training can be carried out in a variety of ways – by pooling data, by interpolating models or via single or multi-step model adaptation. The aim of multi-source training is to ob-

	Audio			*Text (words)*	
Language	*Radio-TV sources*	*Duration*	*Size*	*News*	*Com.Trans.*
English	ABC, CNN, CSPAN, NPR, PRI, VOA	200h	1.9M	790M	240M

Mandarin	VOA, CCTV, KAZN	20h	0.7M(c)	200M(c)	-
Portuguese	9 sources	3.5h	∼35k	70M	-
Spanish	Televisa, Univision, VOA	30h	0.33M	295M	-
Arabic	tv: Aljazeera, Syria; radio: Orient, Elsharq, ...	50h	0.32M	200M	-

Table 1: Approximate sizes of the transcribed audio data and text corpora used for estimating acoustic and language models. For the text data, newspaper texts (News) and commercial transcriptions (Com.Trans.) are distinguished in terms of the millions of words (or characters for Mandarin). The American English, Spanish and Mandarin data are distributed by the LDC. The German data come from the EC OLIVE project and the French data partially from OLIVE and from the DGA. The Portuguese data are part of the 5h, 11 source Pilot corpus used in the EC ALERT project (data from 2 sources 24Horas and JornalTarde were reserved for the test set). The Arabic data were produced by the Vecsys company in collaboration with the DGA.

	Lexicon			*Language Model*		*Test*	
Language	*#phon.*	*size (words)*	*coverage*	*N-gram*	*ppx*	*Duration*	*%Werr*
English	48	65k	99.4%	11M fg, 14M tg, 7M bg	140	3.0h	20
French	37	65k	98.8%	10M fg, 13M tg, 14M bg	98	3.0h	23
German	51	65k	96.5%	10M fg, 14M tg, 8M bg	213	2.0h	25(n)-35(d)
Mandarin	39	40k+5k(c)	99.7%	19M fg, 11M tg, 3M bg	190	1.5h	20
Spanish	27	65k	94.3%	8M fg, 7M tg, 2M bg	159	1.0h	20
Portuguese	39	65k	94.0%	9M tg, 3M bg	154	1.5h	40
Arabic	40	60k	90.5%	11M tg, 6M bg	160	5.7h	20

Table 2: Some language characteristics. Specified for each language are: the number of phones used to represent lexical pronunciations, the approximate vocabulary size in words (characters for Mandarin) and lexical coverage (of the test data), the language model size and the perplexity, the test data duration (in hours) and the word/character error rates. For Arabic the vocabulary and language model are vowelized, however the word error rate does not include vowel or gemination errors. For German, separate word error rates are given for broadcast news (n) and documentaries (d).

tain generic models which are comparable in performance to the respective task-dependent models for all tasks under consideration. Compared to the results obtained with task-dependent acoustic models, both data pooling and sequential adaptation schemes led to better performance for ATIS and WSJ read, with slight degradations for BN and TI-digits (25).

In (9) cross-task porting experiments are reported for porting from an Italian broadcast news speech recognition system to two spoken dialogue domains. Supervised adaptation was shown to recover about 60% of the WER gap between the broadcast news acoustic models and the task-specific acoustic models. Language model adaptation using just 30 minutes of transcriptions was found to reduce the gap in perplexity between the broadcast news and task-dependent language models by 90%. It was also observed that the out-of-vocabulary rates for the task-specific language models are 3 to 5 times higher than the best adapted models, due to the relatively limited amount of task-specific data and the wide coverage of the broadcast news domain.

Techniques for large-scale discriminative training of the acoustic models of speech recognition systems using the maximum mutual information estimation (MMIE) criterion in place of conventional maximum likelihood estimation (MLE) have studied and it has been demonstrated that MMIE-based systems can lead to sizable reductions in word error rate on the transcription of conversational telephone speech (30). Experiments on discriminative training for cross-task genericity have made use of recognition systems trained on the low-noise North American Business News corpus of read newspaper texts and tested on television and radio Broadcast News data. These experiments showed that MMIE-trained models could indeed provide improved cross-task performance (11).

4.2. Reducing the need for annotated training data

With today's technology, the adaptation of a recognition system to a new task or new language requires the availability of sufficient amount of transcribed training data. When changing to new domains, usually no exact transcriptions of acoustic data are available, and the generation of such transcribed data is an expensive process in terms of manpower and time. On the other hand, there often exist incomplete information such as approximate transcriptions, summaries or at least key words, which can be used to provide supervision in what can be referred to as "informed speech

Amount of training data		*Language Model*
Raw	*Usable*	News.Com.Cap
10min	10min	53.1
1.5h	1h	33.3
50h	33h	20.7
104h	67h	19.1
200h	123h	18.0

Table 3: Supervised acoustic model training: Word error rate (%) on the 1999 evaluation test data for various conditions using one set of gender-independent acoustic models trained on subsets of the HUB4 training data with detailed manual transcriptions. The language model is trained on the available text sources, without any detailed transcriptions of the acoustic training data. The raw data reflects the size of the audio data before partitioning, and the usable data the amount of data used in training the acoustic models.

recognition". Depending on the level of completeness, this information can be used to develop confidence measures with adapted or trigger language models or by approximate alignments to automatic transcriptions. Another approach is to use existing recognizer components (developed for other tasks or languages) to automatically transcribe task-specific training data. Although in the beginning the error rate on new data is likely to be rather high, this speech data can be used to re-train a recognition system. If carried out in an iterative manner, the speech data base for the new domain can be cumulatively extended over time *without* direct manual transcription. This approach has been investigated in (18; 22; 23; 36; 39).

In order to give an idea of the influence of the amount of training data on system performance, Table 3 shows the performance of a 10xRealTime American English BN system for different amounts of manually annotated training data. The language model News.Com.Cap is trained on large text corpora, and results from the interpolation of individual language models trained on newspaper and newswires tests (790M words), commercially produced transcripts and closed-captions predating the test epoch (240M words). The word error is seen to rapidly decrease initially, with only a relatively small improvement above 30 hours of usable data. However, there is substantial information available in the language models. Table 4 summarizes supervised training results using substantially less language model training material. The second entry is for a language model estimated only on the newpaper texts (790M words), whereas for the remaining two language models were estimated on only 30 M words of texts (the last 2 months of 1997) and 1.8 M words (texts from December 26-31, 1997). It can be seen that the language model training texts have a large influence on the system performance, and even 30 M words is relatively small for the broadcast news transcription task.

The basic idea of light supervision is to use a speech recognizer to automatically transcribe unannotated data, thus generating "approximate" labeled training data. By iteratively increasing the amount of training data, more accurate acoustic models are obtained, which can then be used to transcribe another set of unannotated data. The manual work is considerably reduced, not only in generating the annotated corpus but also during the training procedure, since it is no longer necessary to extend the pronunciation lexicon to cover all words and word fragments occurring in the training data. In (22) it was found that somewhat comparable acoustic models could be estimated on 400 hours automatically annotated data from the TDT-2 corpus and 150 hours of carefully annotated data.

	Raw Acoustic training data		
Language model	*200 hours*	*1.5 hours*	*10 min*
News.Com.Cap, 65k	18.0	33.3	53.1
News, 65k	20.9	36.1	55.6
30 M words, 60k	24.1	40.8	60.2
1.8 M words, 40k	28.8	46.9	65.3

Table 4: Supervised acoustic model training: Reference word error rates (%) on the 1999 evaluation test data with varying amounts of manually annotated acoustic training data and a language model trained on 1.8 M and 30 M words of news texts from 1997.

Raw Acoustic training data		*WER (%)*
bootstrap models	10 min manual	65.3
1 (6 shows)	4 h	54.1
2 (+12 shows)	12 h	47.7
3 (+23 shows)	27 h	43.7
4 (+44 shows)	53 h	41.4
5 (+60 shows)	103 h	39.2
6 (+58 shows)	135 h	37.4

Table 5: Unsupervised acoustic model training: Word error rate (%) on the 1999 evaluation test data with varying amounts of automatically transcribed acoustic training data and a language model trained on 1.8 M words of news texts from 1997.

The effects of reducing the amount of supervision are summarized in Table 5. The first observation that can be made, is that even using a recognizer with an initial word error of 65% the procedure is converging properly by training acoustic models on automatically labeled data. This is even more surprising since the only supervision is via a language model trained on a small amount of text data predating the raw acoustic audio data. As the amount of automatically transcribed acoustic data is successively doubled, there are consistent reductions in the word error rate. While these error rates are still quite high compared to supervised training, retranscribing the same data (36) can be expected to reduce the word error rate further. (Recall that even with supervised acoustic model training trained on 200 hours of raw data the word error rate is 28.8% with this language model.)

4.3. Unsupervised Cross-Task Adaptation

An incremental unsupervised adaptation scheme was investigated for cross-task adaptation from the broadcast news task to the ATIS task (26). In this system-in-loop adaptation scheme, a first subset of the training data is automatically transcribed using the generic system. The acoustic and linguistic models of the generic system are then adapted with these automatically annotated data and the resulting models are used to transcribe another portion of the training data. One obvious use of this scheme is for online model adaptation in a dialog system.

Using about one-third (15 hours) of the ATIS training corpus transcribed with a BN system to adapt both the acoustic and language models, the word error rate is reduced from 20.8% to 6.9%. Transcribing the remaining data, and readapting the models reduces the word error to 5.5% (which can be compared to 4.7% for a task-specific system). Contrastive experiments have shown that this gain is somewhat equally split between adaptation of the acoustic and language models.

4.4. Cross Language Portability

The same basic idea was used to develop BN acoustic models for the Portuguese language for which substantially less manually transcribed data are available. RTP and INESC, partners in the Alert project (http:alert.uni-duisburg.de) provided 5 hours of manually annotated data from 11 different news programs. Two of the programs (82 minutes) were reserved for testing purposes (JornalTarde_20_04_00 and 24Horas_19_07_00). The remaining 3.5 hours of data were used for acoustic model training. The language model texts were obtained from the following sources: the Portuguese Newswire Text Corpus distributed by LDC (23M words from 1994-1998); Correio da Manha (1.6M words), Expresso (1.9M words from 2000-2001), and Jornal de Noticias (46M words, from 1996-2001), The recognition lexicon contains 64488 words. The pronunciations are generated by grapheme-to-phoneme rules, and use 39 phones.

Initial acoustic model trained on the 3.5 hours of available data were used to transcribe 30 hours of Portuguese TV broadcasts. These acoustic models had a word error rate of 42.6%. By training on the 30 hours of data using the automatic transcripts the word error was reduced to 39.1%. This preliminary experiment supports the feasibility of lightly supervised and unsupervised acoustic model training.

5. Conclusions

This paper has discussed the main issues in speech recognizer development and portability across languages and tasks. Today's most performant systems make use of statistical models, and therefore require large corpora for acoustic and language model training. However, acquiring these resources is both time-consuming, costly, and may be beyond the economic interest for many languages. Research is underway to reduce the need for manually annotated training data, thus reducing the human investment needed for system development when porting to another task or language. By eliminating the need for manual transcription, automated training can be applied to essentially unlimited quantities of task-specific training data.

The pronunciation lexicon still requires substantial manual effort for languages without straightfoward letter-to-sound correspondences, and to handle foreign words and proper names. For languages or dialects without a written form, the challenge is even greater, since important language modeling data are simply unavailable. Even if a transliterated form can be used, it is likely to be impractical to transcribe sufficient quantities of data for language model training.

In summary, our experience is that although general technologies and development strategies appear to port from one language to another, to obtain optimal performance language specificities must be taken into account. Efforts underway to improve the genericity of speech recognizers, and to reduce training costs will certainly help to enable the development of language technologies for minority languages and less economically promising applications.

Acknowledgments

This work has been partially financed by the European Commission and the French Ministry of Defense. I would like to thank the members of the Spoken Language Processing group at LIMSI who have participated to the research reported here and from whom I have borrowed experimental results.

Seven Dimensions of Portability for Language Documentation and Description

Steven Bird* **and Gary Simons†**

Abstract

The process of documenting and describing the world's languages is undergoing radical transformation with the rapid uptake of new digital technologies for capture, storage, annotation and dissemination. However, uncritical adoption of new tools and technologies is leading to resources that are difficult to reuse and which are less portable than the conventional printed resources they replace. We begin by reviewing current uses of software tools and digital technologies for language documentation and description. This sheds light on how digital language documentation and description are created and managed, leading to an analysis of seven portability problems under the following headings: content, format, discovery, access, citation, preservation and rights. After characterizing each problem we provide a series of value statements, and this provides the framework for a broad range of best practice recommendations.

1. Introduction

It is now easy to collect vast quantities of language documentation and description and store it in digital form. It is getting easier to transcribe the material and link it to linguistic descriptions. Yet how can we ensure that such material can be re-used by others, both now and into the future? While today's linguists can access documentation that is over 100 years old, much digital language documentation and description is unusable within a decade of its creation.

The fragility of digital records is amply demonstrated. For example, the interactive video disks created by the BBC Domesday Project are inaccessible just 15 years after their creation.[1] In the same way, linguists who are quick to embrace new technologies and create digital materials in the absence of archival formats and practices soon find themselves in technological quicksand.

The uncritical uptake of new tools and technologies is encouraged by sponsors who favor projects that promise to publish their data on the web with a search interface. However, these projects depend on technologies with life cycle of 3-5 years, and the resources they create usually do not outlive the project any longer than this.

This paper considers portability in the broadest sense: across different software and hardware platforms; across different scholarly communities (e.g. field linguistics, language technology); across different purposes (e.g. research, teaching, development); and across time. Portability is frequently treated as an issue for software, but here we will focus on data. In particular, we address portability for language documentation and description, and interpret these terms following Himmelmann:

> The aim of a language documentation is to provide a comprehensive record of the linguistic practices characteristic of a given speech community. Linguistic practices and traditions are manifest in two ways: (1) the observable linguistic behavior, manifest in everyday interaction between members of the speech community, and (2) the native speakers' metalinguistic knowledge, manifest in their ability to provide interpretations and systematizations for linguistic units and events. This definition of the aim of a language documentation differs fundamentally from the aim of language descriptions: a language description aims at the record of A LANGUAGE, with "language" being understood as a system of abstract elements, constructions, and rules that constitute the invariant underlying structure of the utterances observable in a speech community. (Himmelmann, 1998, 166)

We adopt the cover term DATA to mean any information that documents or describes a language, such as a published monograph, a computer data file, or even a shoebox full of hand-written index cards. The information could range in content from unanalyzed sound recordings to fully transcribed and annotated texts to a complete descriptive grammar. Beyond data, we are be concerned with language resources more generally, including tools and advice. By TOOLS we mean computational resources that facilitate creating, viewing, querying, or otherwise using language data. Tools include software programs, along with the digital resources that they depend on such as fonts, stylesheets, and document type definitions. By ADVICE we mean any information about what data sources are reliable, what tools are appropriate in a given situation, and what practices to follow when creating new data (Bird and Simons, 2001).

This paper addresses seven dimensions of portability for digital language documentation and description, identifying problems, establishing core values, and proposing best practices. The paper begins with a survey of the tools and technologies (§2), leading to a discussion of the problems that arise with the resources created using these tools and technologies (§3). We identify seven kinds of portability problem, under the headings of content, format, discovery, access, citation, preservation and rights. Next we give statements about core values in digital language documentation and description, leading to a series of "value statements", or requirements for best practices (§4), and followed up with collection of best practice recommendations (§5). The structure of the paper is designed to build consensus. For instance, readers who take issue with a best practice recommendation in §5 are encouraged to review the corresponding statement of values in §4 and either suggest a different practice which better implements the values, or else take issue with the value statement (then back up to the corresponding problem statement in §3, and so forth).

2. Tools and Technologies for Language Documentation and Description

Language documentation projects are increasing in their reliance on new digital technologies and software tools. This section contains a comprehensive survey of the range of practice, covering general purpose software, specialized tools, and digital technologies. Reviewing the available tools gives us a snapshot of how digital language documentation and description is created and managed, and provides a backdrop for our analysis of data portability problems.

2.1. General purpose tools

The most widespread practice in language documentation involves the use of office software. This software is readily available, often pre-installed, and familiar. Word processors have often been used as the primary storage for large lexical database, including a Yoruba lexicon with 30,000 entries split across 20 files. Frequently cited benefits are the WYSIWYG editing, the find/replace function, the possibility of cut-and-paste to create sublexicons, and the ease of publishing. Of course, a large fraction of the linguist's time is spent on maintaining consistency across multiple copies of the same data. Word processors have also been used for interlinear text, with three main approaches: fixed width fonts with hard spacing, manual setting of tabstops, and tables.[2] All methods require manual linebreaking, and significant labor if line width or point size are changed. Another kind of office software is the spreadsheet, which is often used for wordlists. Language documentation created using office software is normally stored in a secret proprietary format that is unsupported within 5-10 years. While other export formats are supported, they may loose some of the structure. For instance, part of speech may be distinguished in a lexical entry through the use of a particular font, and this information may be lost when the data is exported. Also, the portability of export formats may be compromised, by being laden with presentational markup.

A second class of general purpose software is the hypertext processors. Perhaps the first well-known application to language documentation was the original Macintosh hypercard stacks of *Sounds of the World's Languages* (Ladefoged and Maddieson, 1996). While it was easy to create a complex web of navigable pages, nothing could overcome the limitations of a vendor-specific hypertext language. More recently, the HTML standard and universal, free browsers have encouraged the creation of large amounts of hypertext for a variety of documentation types. For instance, we have interlinear text with HTML tables (e.g. Austin's Jiwarli fieldwork[3]), interlinear text with HTML frames (e.g. Culley's presentation of Apache texts[4]), HTML markup for lexicons, with hyperlinks from glossed examples and a thesaurus (e.g. Austin and Nathan's Gamilaraay lexicon[5]), gifs for representing IPA transcriptions (e.g. Bird's description of tone in Dschang[6]), and Javascript for image annotations (e.g. Poser's annotated photographs of gravestones engraved with Déné syllabics[7]). In all these cases, HTML is used as the primary storage format, not simply as a view on an underlying database. The intertwining of content and format makes this kind of language documentation difficult to maintain and re-use.

The third category of general purpose software is database packages. In the simplest case, the creator shares the database with others by requiring them to purchase the same package, and by shipping them a full dump of the database (e.g. the StressTyp database, which requires users to buy a copy of "4th Dimension"[8]). A more popular approach is to put the database on a web-server, and create a forms-based web interface that allows remote users to search the database without installing any software (e.g. the Comparative Bantu Online Lexical Database[9] and the Maliseet-Passamaquoddy Dictionary.[10]) Recently, some sites have started allowing database updates via the web (e.g. the Berkeley Interlinear Text Collector[11] and the Rosetta Project's site for uploading texts, wordlists and descriptions[12]).

2.2. Specialized tools

Over the last two decades, several dozen tools have been developed having specialized support for language documentation and description. We list a representative sample here; more can be found on SIL's page on *Linguistic Computing Resources*,[13] on the *Linguistic Exploration* page,[14] and on the *Linguistic Annotation* page.[15]

Tools for linguistic data management include Shoebox[16] and the Fieldworks Data Notebook.[17] Speech analysis tools include Praat[18] and SpeechAnalyzer.[19] Many specialized signal annotation tools have been developed, including CLAN,[20] EMU,[21] TableTrans, InterTrans, TreeTrans.[22] There are many orthographic transcription tools, including Transcriber[23] and MultiTrans.[24] There are morphological analysis tools, such as the Xerox finite state toolkit.[25] There are a wealth of concordance tools. Finally, some integrated multi-function systems have been created, such as LinguaLinks Linguistics Workshop.[26]

In order to do their specialized linguistic processing, each of these tools depends on some model of linguistic information. Time-aligned transcriptions, interlinear texts, syntax trees, lexicons, and so forth, all require suitable data structures and file formats. Given that most of these tools have been developed in isolation, they typically employ incompatible models and formats. For example, data created with an interlinear text tool cannot be subsequently annotated with syntactic information without losing the interlinear annotations. When interfaces and formats are open and documented, it is occasionally possible to cobble the tools together in support of a more complex need. However, the result is a series of increasingly baroque and decreasingly portable approximations to the desired solution. Computational support for language documentation and description is in disarray.

2.3. Digital technologies

A variety of digital technologies are now used in language documentation thanks to sharply declining hardware costs. These include technologies for digital signal capture (audio, video, physiological) and signal storage (hard disk, CD-R, DVD-R, minidisc). Software technologies are also playing an influential role as new standards are agreed. The

most elementary and pervasive of these is the hyperlink, which makes it possible to connect linguistic descriptions to the underlying documentation (e.g. from an analytical transcription to a recording). Such links streamline the descriptive process; checking a transcription can be done with mouse clicks instead of digging out a tape or finding an informant. The ability to navigate from description to documentation also facilitates analysis and verification. Software technologies and standards have given rise to the internet which permits low-cost dissemination of language resources. Notably, it is portability problems with these tools and formats that prevents these basic digital technologies from having their full impact. The download instructions for the Sumerian lexicon[27] typify the problems (hyperlinks are underlined):

> Download the Sumerian Lexicon as an Adobe Acrobat PDF file. In order to minimize downloads of this large file, once you have it, please use your Acrobat Reader to save it and retrieve it to and from your own desktop.
>
> Download the Sumerian Lexicon as a Word for Windows 6.0 file in a self-extracting WinZip archive.
>
> Download the same contents in a non-executable zip file.
>
> Includes version 2 of the Sumerian True Type font for displaying transliterated Sumerian. Add the font to your installed Windows fonts at Start, Settings, Control Panel, Fonts. To add the Sumerian font to your installed Windows fonts, you select File and Add New Font. Afterwards, make sure that when you scroll down in the Fonts listbox, it lists the Sumerian font. When you open the SUMERIAN.DOC file, ensure that at File, Templates, or at Tools, Templates and Add-Ins, there is a valid path to the enclosed SUMERIAN.DOT template file. If you do not have Microsoft's Word for Windows, you can download a free Word for Windows viewer at Microsoft's Web Site.
>
> Download Macintosh utility UnZip2.0.1 to uncompress IBM ZIP files. To download and save this file, you should have Netscape set in Options, General Preferences, Helpers to handle hqx files as Save to Disk. Decode this compressed file using Stuffit Expander. Download Macintosh utility TTconverter to convert the IBM format SUMERIAN.TTF TrueType font to a System 7 TrueType font. Decode this compressed file using Stuffit. Microsoft Word for the Macintosh can read a Word for Windows 6.0 document file. There is no free Word for Macintosh viewer, however.

2.4. Digital Archives

Recently several digital archives of language documentation and description have sprung up, such as the Archive of the Indigenous Languages of Latin America,[28] and the Rosetta Project's Archive of 1000 Languages.[29] These exist alongside older archives which are in various stages of digitizing their holdings: the Archive of the Alaska Native Language Center,[30] the LACITO Linguistic Data Archive,[31] and the US National Anthropological Archives.[32] These archives and many others are surveyed on the *Language Archives* page.[33] Under the aegis of OLAC, the *Open Language Archives Community*,[34] the notion of language archive has been broadened to include archives of linguistic software, such as the Natural Language Software Registry[35]

These archives face many challenges, the most significant being the lack of funding. Other challenges may include: identifying, adapting and deploying digital archiving standards; setting up key operational functions such as offsite backup, migration to new digital formats and media over time, and the support of new access modes (e.g. search facilities) and delivery formats (e.g. streaming media); and obtaining the long-term support of a major institution to assure contributors and users that the materials will be available over the long term.

3. Seven Problems for Portability

With the rapid uptake of new digital technologies, many creators of language documentation and description are ignoring the question of portability, with the unfortunate consequence that the fruits of their labors are likely to be unusable within 5-10 years. In this section we discuss seven critical problems for the portability of this data.

3.1. Content

Many potential users of language data are interested in assimilating multiple descriptions of a single language to gain an understanding of the language which is as comprehensive as possible. Many users are interested in comparing the descriptions of different languages in order to apply insights from one analysis to another or to test a typological generalization. However, two descriptions may be difficult to compare or assimilate because they have used terminology differently, or because the documentation on which the descriptions are based is unavailable.

Language documentation and description of all types depends critically on technical vocabulary, and ambiguous terms compromise portability. For instance, the symbols used in phonetic transcription have variable interpretation depending on the descriptive tradition: "it is crucial to be aware of the background of the writer when interpreting an unexplained occurrence of [y]" (Pullum and Ladusaw, 1986, 168). In morphosyntax, the term "absolutive" can refer to one of the cases in an ergative language, or to the unpossessed form of a noun (in the Uto-Aztecan tradition) (Lewis et al., 2001, 151), and a correct interpretation of the term depends on an understanding of the linguistic context.

This terminological variability leads to problems for retrieval. Suppose that a linguist wanted to search the full-text content of a large collection of digital language data, in order to discover which other languages have relevant phenomena. Since there are no standard ontologies, the user will discover irrelevant documents (low precision) and will fail to discover relevant documents (low recall). In order to carry out a comprehensive search, the user must know all the ways in which a particular phenomena is described. Even once a set of descriptions are retrieved, it will generally not be possible to draw reliable comparisons between the descriptions of different languages.

The content of two descriptions may also be difficult to reconcile because it is not possible to verify them with respect to the language documentation that they cite. For example, when two descriptions of the same language provide different phonetic transcriptions of the same word, is this the result of a typographical error, a difference in transcription practice, or a genuine difference between two speech varieties? When two descriptions of different languages report that the segmental inventories of both languages contain a [k], what safe conclusions can be drawn about how similar the two sounds are? Since the underlying documentation is not available, such questions cannot be resolved, making it difficult to re-use the resources.

While the large-scale creation of digital language resources is a recent phenomenon, the language documentation community has been active since the 19th century, and much earlier in some instances. At

risk of oversimplifying, a widespread practice over this extended period has been to collect wordlists and texts and to write descriptive grammars. With the arrival of new digital technologies it is easy to transfer the whole endeavor from paper to computer, and from tape recorder to hard disk, and to carry on just as before. Thus, new technologies simply provide a better way to generate the old kinds of resources. Of course this is a wasted opportunity, since the new technologies can also be used to create digital multimedia recordings of rich linguistic events. Such rich recordings often capture items which turn out to be useful in later linguistic analysis, and have immense intrinsic value as a record of cultural heritage for future generations. However, managing digital technologies in less controlled situations leads to many technical and logistical issues, and there are no guidelines for integrating new technologies into new documentary practices.

3.2. Format

Language data frequently ends up in a secret proprietary format using a non-standard character encoding. To use such data one must often purchase commercial software then install it on the same hardware and under the same operating system used by the creator of the data.

Other formats, while readable outside the tool that created them, remain non-portable when they are not explicitly documented. For example, the interpretation of the field names in Shoebox format may not be documented, or the documentation may become separated from the data file, making it difficult to guess what the different fields signify.

The developers of linguistic tools must frequently parse presentational formats. For example, the occurrence of `<b>[n]</b>` in a lexical entry might indicate that this is an entry for a noun. More difficult cases involve subtle context-dependencies. This presentational markup obscures the structure and interpretation of the linguistic content. Conversely, in the absence of suitable browsing and rendering tools, end-users must attempt to parse formats that were designed to be read only by machines.

3.3. Discovery

Digital language data is often presented as a physical or digital artefact with no external description. Like a book without a cover page or a binary file called `dict.dat`, one is forced to expend considerable effort to discover the subject matter and the nature of the content. Organized collections – such as the archive of a university linguistics department – may provide some metadescription, but it is likely to use a parochial format and idiosyncratic descriptors. If they are provided, key descriptors like *subject language* and *linguistic type* are usually given in free text rather than a controlled vocabulary, reducing precision and recall. As a consequence, discovering relevant language resources is extremely difficult, and depends primarily on word-of-mouth and queries posted to electronic mailing lists. Thus, new resource creation efforts may proceed in ignorance of prior and concurrent efforts, wasting scarce human resources.

In some cases, one may obtain a resource only to discover upon closer inspection that it is in an incompatible format. This is the flip-side of the discovery problem. Not only do we need to know that a resource exists, but also that it is relevant. When resources are inadequately described, it is difficult (and often impossible) to find a relevant resource, a huge impediment to portability.

3.4. Access

In the past, primary documentation was usually not disseminated. To listen to a field recording it was often necessary to visit the laboratory of the person who collected the materials, or to make special arrangements for the materials to be copied and posted. Digital publication on the web has alleviated this problem, although projects usually refrain from full dissemination by limiting access via a restrictive search interface. This means that only selected portions of the documentation can be downloaded, and that all access must use categories predefined by the provider. Moreover, these web forms only have a lifespan of 3-5 years, relying on ad hoc CGI scripts which may cease working when the interpreter or webserver are upgraded. Lack of full access means that materials are not portable. More generally, people have often conflated digital publication with web publication, and publish high-bandwidth materials on the web which would be more usable if published on CD or DVD.

Many language resources have applications beyond those envisaged by their creators. For instance, the Switchboard database (Godfrey et al., 1992), collected for the development of speaker-independent automatic speech recognition, has since been used for studies of intonation and disfluency. Often this redeployment is prevented through the choice of formats. For instance, publishing conversation transcripts in the Hub-4 SGML format does not facilitate their reuse in, say, conversational analysis. In other cases, redeployment is prevented by the choice of media. For instance, an endangered language dictionary published only on the web will not be accessible to speakers of that language who live in a village without electricity.

One further problem for access deserves mention here. It sometimes happens that an ostensibly available resource turns out not to be available after all. One may discover the resource because its creator cited it in a manuscript or an annual research report. Commonly, a linguist wants to derive recognition for the labor that went into creating primary language documentation, but does not want to make the materials available to others until deriving maximum personal benefit. Two tactics are to cite unresolved, non-specific intellectual property rights issues, and to repeatedly promise but to never finally deliver. Despite its many guises, this problem has two distinguishing features: someone draws attention to a resource in order to derive credit for it – "parading their riches" as Mark Liberman (pers. comm.) has aptly described it – and then applies undocumented or inconsistent restrictions to prevent access. The result may be frustration that a needed resource is withheld, leading to wasted effort or a frozen project, or to suspicion that the resource is defective and so must be protected by a smoke screen.

3.5. Citation

Research publications are normally required to provide full bibliographic citation of the materials used in conducting the research. Citation standards are high for conventional resources (such as other publications), but are much lower for language resources which are usually incorrectly cited, or not cited at all. This makes it difficult to find out what resource was used in conducting the research and, in the reverse direction, it is impossible to use a citation index to discover all the ways in which a given resource has been applied.

Often a language resource is available on the web, and it is convenient to have the uniform resource locater (URL) since this may offer the most efficient way to obtain the resource. However, URLs can fail as a persistent citation in two ways: they may simply break, or they may cease to reference the same item. URLs break when the resource is moved or when some piece of the supporting infrastructure, such as a database server, ceases to work. Even if a URL does not break, the item it references may be mutable, changing over time. Language resources published on the web are usually not versioned, and a third-party description of some item may cease to be valid if that item is changed. Publishing a digital artefact, such as a CD, with a unique identifier, such as an ISBN, avoids this problem.

Citation goes beyond bibliographic citation of a complete item. We may want to cite some component of a resource, such as a specific narrative or lexical entry. However, the format may not support durable citations to internal components. For instance, if a lexical entry is cited by a URL which incorporates its lemma, and if the spelling of the lemma is altered, then the URL will not track the change. In sum, language documentation and description is not portable if the incoming and outgoing links to related materials are fragile.

3.6. Preservation

The digital technologies used in language documentation and description greatly enhance our ability to create data while simultaneously compromising our ability to preserve it. Relative to paper copy which can survive for hundreds of years, digitized materials are evanescent because they use some combination of binary formats with undocumented character encodings saved on non-archival media and physically stored with no ongoing administration for backups and migration to new media. Presentational markup with HTML and interactive content with Javascript and specialized browser plugins require future browsers to be backwards-compatible. Furthermore, primary documentation may be embodied in the interactive behavior of the resource (e.g. the gloss of the text under the mouse may show up in the browser status line, using the Javascript "mouseover" effect). Consequently, digital resources – especially dynamic or interactive ones – often have a short lifespan, and typically become unusable 3-5 years after they are actively maintained.

3.7. Rights

A variety of individuals and institutions may have intellectual property vested in a language resource, and there is a complex terrain of legal, ethical and policy issues (Liberman, 2000). In spite of this, most digital language data is disseminated without identifying the copyright holder and without any license delimiting the range of acceptable uses of the material. Often people collect or redistribute materials, or create derived works without securing the necessary permissions. While this is often benign (e.g. when the resources are used for research purposes only), the researcher risks legal action, or having to restrict publication, or even having to destroy primary materials. To avoid any risk one must avoid using materials whose property rights are in doubt. In this way, the lack of documented rights restrict the portability of the language resource.

Sometimes resources are not made available on the web for fear that they will get into the wrong hands or be misused. However, this confuses medium with rights. The web supports secure data exchange between authenticated parties (through data encryption) and copyright statements together with licenses can be used to restrict uses. More sophisticated models for managing digital rights are emerging (Iannella, 2001). The application of these techniques to language resources is unexplored, and we are left with an all-or-nothing situation, in which the existence of any restriction prevents access across the board.

3.8. Special challenges for little-studied languages

Many of the problems reported above also apply to little-studied languages, though some are greatly exacerbated in this context. The small amount of existing work on the language and the concomitant lack of established documentary practices and conventions may lead to especially diverse nomenclature. Inconsistencies within or between language descriptions may be harder to resolve because of the lack of significant documentation, the limited access to speakers of the language, and the limited understanding of dialect variation. Open questions in one area of description (e.g. the inventory of vowel phonemes) may multiply the indeterminacies in another (e.g. for transcribed texts). More fundamentally, existing documentation and description may be virtually impossible to discover and access, owing to its fragmentary nature.

The acuteness of these portability problems for little-studied languages can be highlighted by comparison with well-studied languages. In English, published dictionaries and grammars exist to suit all conceivable tastes, and it therefore matters little (relatively speaking) if none of these resources is especially portable. However, when there is only one dictionary for the language, it must be pressed into a great range of services, and significant benefits will come from maximizing portability.

This concludes our discussion of portability problems arising from the way new tools and technologies are being used in language documentation and description. The rest of this paper responds to these problems, by laying out the core values that lead to requirements for best practices (§4) and by providing best practice recommendations (§5).

4. Value Statements

Best practice recommendations amount to a decision about which of several possible options is best. The notion of best always involves a value judgment. Therefore, before making our recommendations, we articulate the values which motivate our choices. Our use of "we" is meant to include the reader and the wider language resources community who share these values.

4.1. Content

TERMINOLOGY. We value the ability of users to identify the substantive similarities and differences between two resources. Thus the best practice is one that makes it easy to associate the comparable parts of unrelated resources.

ACCOUNTABILITY. We value the ability of researchers to verify language descriptions. Thus the best practice is one that provides the documentation that lies behind the description.

RICHNESS. We value the documentation of little-studied languages. Thus the best practice is one that establishes a record that is sufficiently broad in scope and rich in detail that future generations can experience and study the language, even when no speakers remain.

4.2. Format

OPENNESS. We value the ability of any potential user to make use of a language resource without needing to obtain unique or proprietary software. Thus the best practice is one that puts data into a format that is not proprietary.

DOCUMENTATION. We value the ability of potential users of a language resource to understand its internal structure and organization. Thus the best practice is one that puts data into a format that is documented.

MACHINE-READABLE. We value the ability of users of a language resource to write programs to process the resource. Thus the best practice is one that puts the resource into a well-defined format which can be submitted to automatic validation.

HUMAN-READABLE. We value the ability of users of a language resource to browse the content of the resource. Thus the best practice is one that provides a human-digestible version of a resource.

4.3. Discovery

EXISTENCE. We value the ability of any potential user of a language resource to learn of its existence. Thus the best practice is one that makes it easy for anyone to discover that a resource exists.

RELEVANCE. We value the ability of potential users of a language resource to judge its relevance without first having to obtain a copy. Thus the best practice is one that makes it easy for anyone to judge the relevance of a resource based on its metadescription.

4.4. Access

COMPLETE. We value the ability of any potential user of a language resource to access the complete resource, not just a limited interface to the resource. Thus the best practice is one that makes it easy for anyone to obtain the entire resource.

UNIMPEDED. We value the ability of any potential user of a language resource to follow a well-defined procedure to obtain a copy of the resource. Thus the best practice is one in which all available resources have a clearly documented method by which they may be obtained.

UNIVERSAL. We value the ability of potential users to access a language resource from whatever location they are in. Thus the best practice is one that makes it possible for users to access some version of the resource regardless of physical location and access to computational infrastructure.

4.5. Citation

CREDIT. We value the ability of researchers to be properly credited for the language resources they create. Thus the best practice is one that makes it easy for authors to correctly cite the resources they use.

PROVENANCE. We value the ability of potential users of a language resource to know the provenance of the resources it is based on. Thus the best practice is one that permits resource users to navigate a path of citations back to the primary linguistic documentation.

PERSISTENCE. We value the ability of language resource creators to endow their work with a permanent digital identifier which resolves to an instance of the resource. Thus the best practice is one that associates resources with persistent digital identifiers.

IMMUTABILITY. We value the ability of potential users to cite a language resource without that resource changing and invalidating the citation. Thus the best practice is one that makes it easy for authors to freeze and version their resources.

COMPONENTS. We value the ability of potential users to cite the component parts of a language resource. Thus the best practice is one that ensures each sub-item of a resource has a durable identifier.

4.6. Preservation

LONG-TERM. We value access to language resources over the very long term. Thus the best practice is one which ensures that language resources will still be usable many generations into the future.

COMPLETE. We value the ability of future users of a language resource to access the complete resource as experienced by contemporary users. Thus the best practice is one which preserves fragile aspects of a resource (such as dynamic and interactive content) in a durable form.

4.7. Rights

DOCUMENTATION. We value the ability of potential users of a language resource to know the restrictions on permissible uses of the resource. Thus the best practice is one that ensures that potential users know exactly what they are able to do with any available resource.

RESEARCH. We value the ability of potential users of a language resource to use it in personal scholarship and academic publication. Thus the best practice is one that ensures that the terms of use on resources do not hinder individual study and academic research.

5. Best Practice Recommendations

This section recommends best practices in support of the values set out in §4. We believe that the task of identifying and adopting best practices rests with the community, and we believe that OLAC, the *Open Language Archives Community*, provides the necessary infrastructure for identifying community-agreed best practices. Here, however, we shall attempt to give some broad guidelines to be fleshed out in more detail later, by ourselves and also, we hope, by other members of the language resources community.

5.1. Content

TERMINOLOGY. Map linguistic terminology and descriptive markup elements to a common ontology of linguistic terms. This applies to the obvious candidates such as morphosyntactic abbreviations and structural markup, but also to less obvious cases such as the phonological description of the symbols used in transcription. (NB vocabularies can be versioned and archived in an OLAC archive; archived descriptions cite their vocabularies using the `Relation` element.)

ACCOUNTABILITY. Provide the full documentation on which language descriptions are based. For example, where a narrative is transcribed, provide the primary recording (without segmenting it into multiple sound clips). Create time-aligned transcriptions to facilitate verification.

RICHNESS. Make rich records of rich interactions, especially in the case of endangered languages or genres. Document the "multimedia linguistic field methods" that were used. Provide theoretically neutral descriptions of a wide range of linguistic phenomena.

5.2. Format

OPENNESS. Store all language documentation and description in an open format. Prefer formats supported by multiple third-party software tools. NB some proprietary formats are open, e.g. Adobe Portable Document Format (PDF) and MPEG-1 Audio Layer 3 (MP3).

DOCUMENTATION. Provide all language documentation and description in a self-describing format (preferably XML). Provide detailed documentation of the structure and organization of the format. Encode the characters with Unicode. Try to avoid Private Use Area characters, but if they are used document them fully. Document any 8-bit character encodings. (OLAC will be providing detailed guidelines for documenting non-standard character encodings.)

MACHINE-READABLE. Use open standards such as XML and Unicode, along with Document Type Definitions (DTDs), XML Schemas and/or other definitions of well-formedness which can be verified automatically. Archive the format definition, giving each version its own unique identifier. When archiving data in a given format, reference the archived definition of that format. Avoid freeform editors for structured information (e.g. prefer Excel or Shoebox over Word for storing lexicons).

HUMAN-READABLE. Provide one or more human readable version of the material, using presentational markup (e.g. HTML) and/or other convenient formats. Proprietary formats are acceptable for delivery as long as the primary documentation is stored in a non-proprietary format.

N.B. Format is a critical area for the definition of best practices. We propose that recommendations in this area be organized by type (e.g. audio, image, text), possibly following the inventory of types identified in the Dublin Core metadata set.[36]

5.3. Discovery

EXISTENCE. List all language resources with an OLAC data provider. Any resource presented in HTML on the web should contain metadata with keywords and description for use by conventional search engines.

RELEVANCE. Follow the OLAC recommendations on best practice for metadescription, especially concerning language identification and linguistic data type. This will ensure the highest possibility of discovery by interested users in the OLAC union catalog hosted by Linguist.[37]

5.4. Access

COMPLETE. Publish complete primary documentation. Publish the documentation itself, and not just an interface to it, such as a web search form.

UNIMPEDED. Document all access methods and restrictions along with other metadescription. Document charges and expected delivery time.

UNIVERSAL. Make all resources accessible by any interested user. Publish digital resources using appropriate delivery media, e.g. web for small resources, and CD/DVD for large resources. Where appropriate, publish corresponding print versions, e.g. for the dictionary of a little-studied language.

5.5. Citation

CREDIT, PROVENANCE. Furnish complete bibliographic data for all language resources created. Provide complete citations for all language resources used. Document the relationship between resources in the metadescription (NB in the OLAC context, use the `Relation` element).

PERSISTENCE. Ensure that resources have a persistent identifier, such as an ISBN or a persistent URL (e.g. a Digital Object Identifier[38]). Ensure that at least one persistent identifier resolves to an instance of the resource or to detailed information about how to obtain the resource.

IMMUTABILITY. Provide fixed versions of a resource, either by publishing it on a read-only medium, and/or submitting it to an archive which ensures immutability. Distinguish multiple versions with a version number or date, and assign a distinct identifier to each version.

COMPONENTS. Provide a formal means by which the components of a resource may be uniquely identified. Take special care to avoid the possibility of ambiguity, such as arises when lemmas are used to identify lexical entries, and where multiple entries can have the same lemma.

5.6. Preservation

LONG-TERM. Commit all documentation and description to a digital archive which can credibly promise long-term preservation and access. Ensure that the archive

satisfies the key requirements of a well-founded digital archive (e.g. implements digital archiving standards, provides offsite backup, migrates materials to new formats and media/devices over time, is committed to supporting new access modes and delivery formats, has long-term institutional support, and has an agreement with a national archive to take materials if the archive folds). Archive physical versions of the language documentation and description (e.g. printed versions of documents; any tapes from which online materials were created). Archive electronic documents using type 1 (scalable) fonts in preference to bitmap fonts.

COMPLETE. Ensure that all aspects of language documentation and description accessible today are accessible in future. Ensure that any documentary information conveyed via dynamic or interactive behaviors is preserved in a purely declarative form.

5.7. Rights

DOCUMENTATION. Ensure that the intellectual property rights relating to the resource are fully documented.

RESEARCH. Ensure that the resource may be used for research purposes.

6. Conclusion

Today, the community of scholars engaged in language documentation and description exists in a cross-over period between the paper-based era and the digital era. We are still working out how to preserve knowledge that is stored in digital form. During this transition period, we observe unparalleled confusion in the management of digital language documentation and description. A substantial fraction of the resources being created can only be re-used on the same software/hardware platform, within the same scholarly community, for the same purpose, and then only for a period of a few years. However, by adopting a range of best practices, this specter of chaos can be replaced with the promise of easy access to highly portable resources.

Using tools as our starting point, we described a diverse range of practices and discussed their negative implications for data portability along seven dimensions, leading to a collection of advice for how to create portable resources. These three categories, tools, data, and advice, are three pillars of the infrastructure provided by OLAC, the Open Language Archives Community (Bird and Simons, 2001). Our best practice recommendations are preliminary, and we hope they will be fleshed out by the community using the OLAC Process.[39]

We leave off where we began, namely with tools. It is our use of the new tools which have led to data portability problems. And it is only with new tools, supporting the kinds of best practices we recommend, which will address these problems. An archival format is useless unless there are tools for creating, managing and browsing the content stored in that format. Needless to say, no single organization has the resources to create the necessary tools, and no third party developing general-purpose office software will address the unique needs of the language documentation and description community. We need nothing short of an open source revolution, leading to new specialized tools based on shared data models for all of the basic linguistic types, and connected to portable data formats.

Challenges and Opportunities in Portability of Human Language Technologies

Bojan Petek

Interactive Systems Laboratory
University of Ljubljana, Faculty of Natural Sciences and Engineering
Snežniška 5, 1000 Ljubljana, Slovenia
Bojan.Petek@Uni-Lj.si

Abstract

Availability of language resources (LR) is a decisive element that influences the vital issues such as linguistic and cultural identity and use of a particular language in information society. Specifically, natural interactivity in information age relies on the existence of mature Human Language Technologies (HLT) that need substantial amount of appropriate LR to be developed. Additional challenge is that research addressing portability issues in HLT is still in its infancy. In perspective, it is reasonably to expect that advances in construction of the multilingual LR [Bird, 2001] and insights into the portability issues of HLT [Lamel, 2002] could potentially lower the digital divide and increase the visibility of a much larger pool of languages than experienced today. In order to achieve this challenging goal, it is proposed to initiate an international network of excellence (NoE) on HLT portability that would complement the already established activities on HLT resources. Such NoE could actively contribute to and advise the national HLT efforts aiming to achieve the grand goal of a non-exclusive information society.

1. Introduction

Several research programs have already focused towards the next generation of intelligent conversational interfaces. Their fundamental goal is to create speech-enabled multi-modal systems that scale gracefully across modalities. Such interfaces typically include speech, graphics, gesture, and computer vision. They are capable of supporting complex conversational interaction comparable to the human-human natural interactivity.

The natural interactive systems integrate spoken language dialogue systems, multimodal communication systems, and web-based data handling tools. The long-term goal of computer-mediated natural interactivity is to transform the present computer systems to become transparent in communication tasks and to support similar communication patterns as those experienced in usual interpersonal communication.

From the theoretical point of view, traditional Human-Computer Interaction (HCI) model has recently evolved towards the enhanced Human-Human Computer Interaction (HHCI) model that also includes the information and communication technologies. The HHCI model positions the computer system as a networked facilitator of information access and sharing. Typical applications include video conferencing or distributed multimedia information systems.

In the following, this paper aims to reflect the on-going research efforts by providing an overview of the challenges and opportunities addressed by the EU HLT projects and the US DARPA programs with relevance to the portability issues in HLT.

2. EU HLT Projects

At the time of writing about 50 EU HLT projects are detailed on the HLTCentral, the gateway to speech and language technology opportunities. Some projects with high relevance to the focus of this paper (ie, portability issues in human language technologies) are overviewed in order to outline the challenges (ie, project objectives) and opportunities (ie, expected outcome and innovation perspectives) these projects describe at the HLTCentral.

2.1. CORETEX

Improving Core Speech Recognition Technology, [wwwCORETEX]

The CORETEX project aims to improve the core speech recognition technologies. This 3 year EU project started in April 2000. The project consortium includes RWTH Aachen (Germany), University of Cambridge (UK), Istituto Trentino di Cultura ITC - IRST (Italy), and Centre National de la Recherche Scientifique – CNRS (France). The proposed work is motivated by observation that the current commercial speech recognition systems perform fairly well for a limited number of tasks and languages. On the other hand, these systems are very difficult to adapt to new domains, languages, and/or changing acoustic environmental conditions. The main obstacle in efficient porting of speech applications to new tasks, languages, or new environments is a requirement for substantial investment of time, money, and expertise.

Therefore, the overall project objective is to devise generic speech recognition technologies that perform well in a task independent way. List of the CORETEX project objectives mentioned on the web is the following:

- To develop generic speech recognition technologies for a wide range of tasks with minimum domain dependencies.
- To devise methods for a rapid portability to new languages with a limited amount of training data.
- To research techniques for producing enriched symbolic speech transcription for higher level symbolic processing.
- To improve language models and provide automatic pronunciation generation.
- To integrate the methods into showcases and validate them in relevant applications.
- To propose an evaluation framework and define objective measures to assess improvements.
- To disseminate the CORETEX research results and to facilitate contact with the interested users in order to widely exploit the project results.

The project is expected to provide significant insights into how to develop conceptually new HLT that is *generic, adaptable and portable***.** Generic design of technology is analyzed by evaluating a system trained on one corpus and tested on another one. Aim of this research is to assess performance degradation under the non-optimal conditions with respect to the training and testing conditions, and in the context of new languages. Initial project phase has already defined objective evaluation criteria and measures, including common test suites and the protocol.

In summary, opportunities from the CORETEX project are an improved HLT that are less sensitive to the environmental and linguistic factors as well as efficiently portable to many languages. Evaluation and demonstration frameworks were already proposed and serve to analyze the progress on the project. Detailed descriptions of the project achievements are given in the CORETEX Annual Reports for the years 2000 and 2001.

2.2. ENABLER

*European National Activities for Basic Language Resources***,** [wwwENABLER]

The ENABLER project aims to improve collaboration activities that provide national language resources in Europe. Researchers, industry, and service providers identified the LR to be a critical issue in national HLT programs and that these efforts need to be supported by appropriate national funding. The LR are of central importance to any kind of HLT-based infrastructure. They are also of vital importance in the development of HLT applications and products, thereby fundamental for the overall industrial growth. Availability of the adequate LR for as many languages as possible is of paramount importance in the HLT development for a non-exclusive multilingual information society.

This 22-month project started in November 2001. The consortium includes Università di Pisa (Italy), Institute for Language and Speech Processing - ILSP (Greece), European Language Resources Distribution Agency – ELDA (France), Center for Sprogteknologi – CST (Denmark), as well as members from Belgium, Czech Republic, Germany, Portugal, Spain, Sweden, and the Netherlands.

The ENABLER project goals are:

- To strengthen the current network of national initiatives, creating links among them, thereby providing a regular, updated, structured and public repository of organizational and technical information.
- To provide an official and general coordination forum for exchange of information, data, best practices, sharing of tools, multilateral and bilateral co-operation on specific issues.
- To gradually enlarge the existing network by identifying representatives of national initiatives.
- To promote synergies across national activities, to enhance the compatibility and interoperability of the results, thereby facilitating efficient transfer of technologies between languages.
- To maintain compatibility across various national LR.
- To increase visibility and strategic impact of the national activities.
- To provide a forum for discussion of innovative research issues and to propose medium- and long-term research priorities.
- To provide a forum to assess industry needs and to formulate common medium and long-term priorities.
- To promote exchange of tools, specifications, validation protocols produced by the national projects.
- To create an EU center for the harmonization of metadata description of speech, text, multimedia and multi-modal LR.
- To promote industrial exploitation of LR.
- To contribute to the internationally agreed cooperative framework for the provision of LR.

In perspective, ENABLER will contribute to the natural interactivity by providing multimodal LR, and to the multilinguality by fostering harmonization of national LR.

2.3. FAME

*Facilitating Agent for Multicultural Exchange***,** [wwwFAME]

New information technology tools for human-human communication integrate speech understanding, computer vision and dialog modeling and enable communication between people from different cultures who use different languages. The FAME project aims to address the problem of integrating multiple communication modes, such as vision, speech and object manipulation. Communication support is provided by the integration of physical and virtual worlds in multi-cultural communication and problem solving. The major identified project challenges are in automatic perception of human action and in understanding of free dialog between the people from different cultures.

Consortium of Universität Karlsruhe - Interactive Systems Labs (Germany), Institut National Polytechnique de Grenoble - Laboratoire GRAVIR-IMAG (France), Université Joseph Fourier - Laboratoire CLIPS (France), Istituto Trentino di Cultura - ITC-IRST (Italy), Universitat Politècnica de Catalunya (Spain), Sony International - Europe (Germany), and Applied Technologies on Language and Speech (Spain) envisions to construct an information butler that will demonstrate the context of awareness in the problem solving scenario. This goal will be achieved by integration of computer vision, speech understanding and dialog modeling. The demonstration prototype in form of an enhanced computer human-to-human communication model will be developed for the 2004 Barcelona Cultural Fair.

2.4. HOPE/EUROMAP3

*HLT Opportunity Promotion in Europe***,** [wwwHOPE]

This project aims to accelerate the rate of technology transfer from the research to the market. The project

contains 11 National Focal Points (NFPs) from Austria, Belgium/Netherlands, Bulgaria, Denmark, Finland, France, Germany, Greece, Italy, Spain and UK. The Bulgarian, French and UK partners joined the project in October 2001. Each NFP will build on skills and expertise from the previous HLT awareness-raising actions. It will strive to achieve the following objectives:

- To increase the number of projects that deliver market-ready results.
- To accelerate awareness of benefits of the HLT systems, services and applications within the user sectors, policy makers and national administrations.
- To increase the number of state-of-the-art technology developers participating in the research projects.
- To improve the relevance of project targets, technology supplier and user needs.
- To improve the match between the HLT design, supplier and end user expectations.
- To enable user partnerships for beta testing, demonstration and other market application activities.

In perspective, the project also aims to include the EU accession countries. HOPE is a 36-month project and started in February 2000.

2.5. ISLE-HLT

International Standards for Language Engineering, [wwwISLE-HLT]

The ISLE-HLT is the most recent initiative of the *Expert Advisory Group for Language Engineering Standards* (EAGLES, [wwwEAGLES]). This 36-month project started in January 2000. Consortium consists of Consorzio Pisa Ricerche (Italy), University of Southern Denmark, Institute Dalle Molle pour les Etudes Sémantiques et Cognitives (Switzerland), Center for Sprogteknologi (Denmark), University of Pennsylvania - Computer and Information Science (USA), University of Pennsylvania - Linguistic Data Consortium (USA), New York University - Computer Science Department (USA), and University of Southern California - Information Sciences Institute (USA).

The overall project aim is to develop HLT standards within a global (EU-US) international collaboration and continuing the success of EAGLES by developing, disseminating and promoting de facto standards and guidelines for the HLT language resources, tools and products. The policy of the EAGLES/ISLE is to closely interact with academia and industry, users and providers, funding bodies and research organisations. The project objectives are put on the following three areas judged to be of a long-term significance:

- *Multilingual computational lexicons*. Initial work in this area presented survey of bi- and multilingual lexicons covering publishers' dictionaries. Next, specification of the Multilingual Isle Lexical Entry (MILE) was made. This involved work on complex Italian-English word-pairs, better understanding of word sense representation and cross-language linkages, extraction and classification of sense indicators, and development of a prototype tool to manage MILE-based lexicons. The ISLE also contributed to recommendations for MILE bilingual dictionary entries. A prototype tool for management of computational lexicons conforming to ISLE recommendations was developed.
- *Natural interaction and multimodality (NIMM)*. This work extended the previous EAGLES work on textual and spoken language resources. Surveys were done on resources, annotation schemes and tools, as well as on metadata descriptions and tools. A prototype tool was developed for NIMM data annotation. XML schemas were developed that handle ISLE metadata descriptions. Editing and browsing tools were devised using these descriptions, including across distributed resources. Future work is concentrated on producing draft guidelines for best practice in the areas covered by the project, and in refining and documenting the tools and resources intended to help users in applying the guidelines.
- *Evaluation of the HLT systems*. This work focuses on methods and metrics for Machine Translation (MT). User feedback was collected within three international workshops. This led towards a refined version of the ISLE evaluation framework.

2.6. NESPOLE!

Negotiating through Spoken Language in E-commerce, [wwwNESPOLE!]

The NESPOLE! project aims to integrate speech-to-speech translation in eCommerce and eService environments by extrapolating from the results of the large research projects (C-STAR and Verbmobil). This EU project started in January 2000 and has a duration of 30 months. Consortium includes ITC - IRST, Centro per la Ricerca Scientifica e Tecnologica (Italy), Universität Karlsruhe (Germany), Carnegie Mellon University (USA), Université Joseph Fourier (France), Aethra (Italy), and Azienda per la Promozione Turistica del Trentino (Italy). It uses standard communication protocols that allow for seamless integration of the multilinguality with the existing videoconferencing software.

NESPOLE! aims to understand issues related to the ability of people communicating ideas, concepts, thoughts and to solve problems in a collaborative framework. It also includes non-verbal communication facilities in the form of multimedia presentations, shared collaborative work spaces, multimodal interactivity and manipulation of objects. These facilities allow for sharing text, graphics, audio, video, therefore providing an improved interpersonal communication. The languages addressed in the NESPOLE! project are Italian, English, German and French.

NESPOLE! identifies the following dimensions that should allow construction of the effective eCommerce and eBusiness environments

- *Robustness*: ability to cope with distractions of spontaneous speech (interruptions, corrections, repetitions, false starts).

- *Scalability*: ability to ensure an adequate level of system performance when the number of users increases.
- *Cross-domain portability*: defined as an easy and cost-effective porting of a speech-to-speech translation system to a new domain.
- *Multimedia and multimodal support*: facilitates the close integration of, and interaction between, speech-based communication and visual cues and content.

The NESPOLE! project envisions to build three different speech to-speech translation systems, including

- A system for tourism applications, embedding multimedia features.
- A system for tourism with a larger coverage of the domain, richer interaction modalities, more sophisticated multimedia support. This should demonstrate the progress on the scalability issue.
- A system for an advanced multilingual help desk. This system should highlight the results concerning the cross-domain portability.

These demonstration systems will support the multilingual negotiations between a tourist service provider and a customer aiming to organize eg, her or his holidays. Portability is addressed by porting the developed system consisting of a video help-desk for technical support, troubleshooting and repair to a different domain.

2.7. ORIENTEL

Multilingual access to interactive communication services for the Mediterranean and the Middle East, [wwwORIENTEL]

The ORIENTEL project explores potential of the multilingual communication services for Mediterranean and the Middle East. Emphasis is put on the mobile applications that are on rise globally. Neither resources nor sufficient expertise are currently available to cope with the linguistic research challenges of the area and the problems posed for Automatic Speech Recognition technology.

The project started in June 2001 with the consortium of Philips Speech Processing (Germany), European Language Resources Distribution Agency (France), IBM Deutschland (Germany), Knowledge (Greece), Natural Speech Communication (Israel), Siemens (Germany), Universitat Politecnica de Catalunya (Spain), and Lucent Technologies Network Systems (UK).

Main objectives of the ORIENTEL project are to:

- Outline survey analysis of markets, technologies, languages and users of mobile communication.
- Gain fundamental knowledge about linguistic structure of the target languages.
- Develop strategies and standards for phonetic and orthographic transcriptions.
- Collect 23 speech databases to support mobile communication applications.
- Research for language, dialect and foreign accent adaptation techniques.
- Develop demonstrator applications.

The project outcome will therefore significantly contribute to the spoken language resources distributed by the ELRA/ELDA.

3. US DARPA Projects

The US DARPA supports a large pool of projects under the Translingual Information Detection, Extraction and Summarization (TIDES) umbrella [wwwTIDES]. These research projects also address the core issues in portability of HLT mentioned above.

4. Conclusions

This paper reflected some of the on-going research and development efforts towards the challenges and opportunities in portability of HLT. It advocates for the view that *every* language of the world contributes to the cultural richness of the information society. This vision should also be applied when the HLT support need to be developed for a small-market or non-prevalent languages [Ostler, 1999]. Furthermore, research in portability issues of HLT for prevalent languages has recently shown that a system developed with a bigger set of languages may exhibit better performance than a system trained with a large set of the target language task-specific data.

Since *every* language is constantly changing while adapting to the influences brought by globalization and increased human mobility, it is reasonably to expect that the state-of-the-art performance in HLT could only be achieved when the HLT development phase included a grand pool of languages instead of only a particular one. Additionally, robust HLT needs to be adaptive to the user and the task involved.

In conclusion, research in portability issues of HLT should be encouraged and strengthened. This could be achieved by forming a network of excellence on HLT portability under the forthcoming 6th EU framework program. Since HLT portability is a very important, difficult and challenging research problem, such NoE should include all interested major players in the field, as many national HLT entities as possible, as well as researchers concerned with the non-prevalent languages (eg., the ISCA SALTMIL SIG) [wwwSALTMIL].

Abstract

The ATLANTIS Project (Academic Training, Languages and New Technologies in the Information Society) and its outcome, The Atlantis Observatory, are presented. The project's website (www.uoc.edu/in3/atlantis) brings together totally updated information on digital tools and resources available for Lesser-Used Languages of the European Union in a searchable database. The structure and classification of the database is explained and some preliminary results are also offered.

1. Introduction

Globalisation and the development and spread of digital technology in the Information Society provide excellent opportunities for creating spaces and tools for the use of many smaller languages. But the degrees of enterprise and know-how on which to draw from within the linguistic community vary, largely as a function of the size of that community. So, unless special support is given to such communities, there is a real danger that networks will develop only in larger languages, and particularly the hegemonic languages in the respective States, in rapidly growing areas such as the Internet. Thus the smaller linguistic communities, and especially those whose language is not that of the State, need to have at their disposal both products that can satisfy new demands, and platforms which will allow them to share initiatives with partners whose languages face a similar challenge.

In this framework, The ATLANTIS Project was aimed to create a virtual network that facilitates regular contact among individuals from all European Union lesser-used languages (LUL) to share knowledge on digital tools and resources available for such linguistic communities.

In the following section, the background and the main goals of the project are presented; then in section 3 we acknowledge the languages that are the subject of study. Sections 4 and 5 are devoted to describing the main areas to be analysed and their structuring and presentation in the database. Section 6 presents some preliminary results and reports. The paper ends with some concluding remarks.

2. The ATLANTIS Project. Baseline and objectives

The ATLANTIS Project, *Academic Training, Languages and New Technologies in the Information Society*, (funded by the EU under the terms of contract nº 2001 – 0265 / 001 – 001 EDU – MLCME) has been carried conjunctly by the Internet Interdisciplinary Institute (IN3) of the Universitat Oberta de Catalunya (Open University of Catalonia, UOC), the Foundation for the European Research University of Wales and the Onderzoeks Centruum voor Meertaligheid (Multilingualism Research Centre) of the Katholieke Universiteit Brussel (Dutch Language Catholic University of Brussels).

It leads on naturally from the Euromosaic report (Euromosaic, 1996), a study of the minority language groups of the European Union (EU) in order to ascertain their current situation by reference to their potential for production and reproduction, and the difficulties which they encounter in doing so. The Euromosaic report highlighted the shift in thinking about the value of diversity for economic deployment and European integration. It argued that language is a central component of diversity, and that if diversity is the cornerstone of innovative development, then attention must be given to sustaining the existing pool of diversity within the EU.

Now focusing on one of the various social and institutional aspects whereby a language group produces and reproduces itself –digital technology in the IS–, The ATLANTIS Project was designed to accomplish the following main objectives:

a. Bring together totally updated information on digital tools and resources available for Lesser-Used Languages.

b. Place the results on a new website –The Atlantis Observatory: www.uoc.edu/in3/atlantis/ – that will consist of a searchable database of the resources detected and thus duly classified.

c. Draw up a final report that will underline areas, projects and technology which, in the view of the participants, offer greatest potential for multiplying effects from one language group to another.

It must be noticed that these aims go along to a great extent with the general aims of the SALTMIL SIG (Special Interest Group on Speech and language Technology for Minority Languages) –promotion of research, development and education in the area of Human Language Technologies for less prevalent languages. Nadeu et al. (2001) specifically point that *"the vision of the SALTMIL SIG is that sharing of information and the forming of a network of researchers is important to begin with. It is hoped that this networking will form the seed-bed out of which more substantial projects will grow"*.

3. Languages targeted

The languages included in this study are all the autochthonous languages in the European Union which are not one of the eleven official EU languages –therefore, those minority languages which are EU official on account of being the official language in a neighbouring State are not included. In a few cases (such as Albanian or Slovene), though the language is official in a neighbouring State, it has been included because that State has not yet joined the enlarged Union.

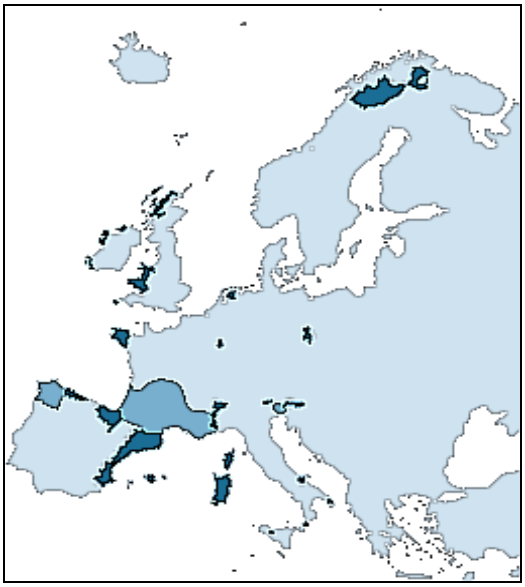

Fig. 1: Location of the languages targeted by the project

Therefore, languages targeted are the following (see Fig. 1):

1. Albanian (as spoken in Italy)
2. Asturian (Spain)
3. Basque (Spain, France)
4. Breton (France)
5. Catalan (Spain, France, Italy)
6. Cornish (UK)
7. Corsican (France)
8. Franco-provençal (Italy)
9. Frisian (Netherlands)
10. Friulian (Italy)
11. Gaelic (UK)
12. Galician (Spain)
13. Irish (UK, Ireland)
14. Ladin (Italy)
15. Luxembourgish (Luxembourg)
16. Occitan (France)
17. Sami (Finland, Sweden)
18. Sardinian (Italy)
19. Slovene (Austria, Italy)
20. Sorbian (Germany)
21. Welsh (UK)

4. Work package categories

Information from all EU LUL has been gathered in six parallel work packages:

1. Learning Platforms in LUL
2. Human Language Technology Developments
3. Information and Communication Technology: Regional Plans, computer software and Internet tools
4. Cultural Digital Resources and Linguistic Diversity
5. Convergence and LUL Broadcasting
6. Electronic Publishing and LUL

In order to do that, each partner took charge of a group of linguistic communities and distributed a comprehensive questionnaire to as many researchers, professionals and academic specialists they could contact. Those informants were also requested to circulate the questionnaire among other specialists in their fields. For those few linguistic communities where feedback resulted to be scarce, the partner in charge committed itself to gather information.

Each of the six work package categories is now described in more detail.

4.1. Learning Platforms in Lesser-used Languages

On-line learning offers cost-saving contexts for small dispersed populations and can thus be of considerable value for numerous language groups. In this section, information has been gathered on the extent to which LUL groups are incorporated into on-line learning platforms being developed in each of the European regions studied which have a LUL group. All levels of educational delivery have been studied, as well as the various associated training programmes. The information on the selected sites and products will allow potential users to see

how knowledge resources are being made available in the LUL.

4.2. Human Language Technology Developments

Human language technology for lesser-used languages is the basis for much further development. The goals of e-mail, web page translation or discussion group translation require the appropriate technology for the language pairs that involve the LUL and the state language. Before this is possible, however, the basic requirements of such development have to be available: electronic corpora, dictionaries, spell checkers, grammars etc. These developments are expected to focus in on-line learning, administration and electronic publishing.

4.3. Information and Communication Technology (ICT): Regional Plans, computer software and Internet tools

Information and Communication Technologies are advancing fast. The extent to which Regional Authorities are addressing the issue, the importance they attach to the availability of tools in the relevant language, and the range of existing computer software and internet tools in each language, are the subjects of the category.

4.4. Cultural Digital Resources and Linguistic Diversity

The development, storage and accessing of digital resources in the context of the emerging Digital Economy requires the creation of Media Asset Management Systems. The extent to which this is proceeding within each region is an object of study. The development of appropriate resource locators allow such materials to be available not merely for industrial development based on the New Media sector, but also for on-line learning developments which, increasingly, will rely on digital resources. The EU's e-Content initiative is highly relevant to these developments.

4.5. Digital Convergence and Lesser-used Language Broadcasting

Many lesser-used language groups have their own audiovisual broadcasting media. The transition from solely analogue broadcasting, to the inclusion of digital systems, which a limited number of minority language communities have already embarked upon, opens up the potential of convergence. More and more audiovisual products are being made, and even shot, in a digital format. This is relevant to some learning developments and user-friendly platforms that encourage interactivity and can increase the potential of digital democracy.

4.6. Electronic Publishing and Lesser-used Languages

Electronic publishing in most LUL is already underway, if only, as happens in some cases, only through LUL web sites. The scope for low cost newspaper and journal publication has greatly expanded thanks to the web. Data has been gathered about the progress of such developments for all the language groups.

5. Structure of the database interface

The database has been organized according to the categories described above and several corresponding subcategories in a way that users can perform searches by language, by (sub)category or by any possible cross grouping of languages and/or (sub)categories.

The first category, *Learning Platforms in LUL*, is arranged for products and resources around two main axis: level (primary, secondary, tertiary and adult education) and area (language, science, mathematics and arts & social science). Moreover, users can search for online educational projects organised in two categories: (i) for learning and information purposes, and (ii) leisure oriented (games, etc.).

Due to its complexity, the *Human Language Technologies* (HLT) package is the one that has undergone a richer and stricter organisation. It has been tailored according to Sarasola (2000) levels and categories, which acknowledge the phases a minority language should follow to incrementally develop its HLT capabilities.

Sarasola's five phases have been simplified within ATLANTIS to the following three: (i) Foundations, (ii) Tools and Resources for Application Development, and (iii) Advanced Tools and Applications. Each one of such level-categories is divided in several field subcategories – such as Lexicon, Speech, Corpus, etc. These, at their turn, subdivide in types of tools, resources or applications – such as Database, Parser, Integrated System and the so.

Foundations is detached in three subcategories: Corpus (raw text), Lexicon and Morphology (raw lists, description of phenomena, different kinds of machine-readable dictionaries) and Speech (collections of recordings, descriptions).

The *Tools and Resources* category is in turn organised around five standard levels (Corpus, Lexicon and Morphology, Syntax, Semantics and Speech) each one including several tool subcategories (such as different kinds of parsers and knowledge bases), plus an Integration of Tools and Resources level.

Last, in *Advanced Tools and Applications* the following subcategories apply: Authoring Aids (spell, grammar and style checkers), Translation (Machine Translation and integrated Computer Assisted Translation environments), Information Retrieval and Extraction systems and advanced tools, Speech (synthesis, recognition, dialog systems) and Language Learning environments.

The third main category of the database, *Information and Communication Technology–Regional Plans, computer software and Internet tools*, is searchable by two subcategories: Regional Plans, and Software and Internet Tools.

The fourth, *Cultural Digital Resources and Linguistic Diversity*, is organised around seven kinds of media or resources: TV stations, Radio stations, Libraries, Museums, Music, Voice recordings and Other.

Last, the two remaining main categories, *Convergence and Broadcasting* (in fact, Radio or TV digitised) and *Electronic Publishing*, are not subdivided.

Every search in the database returns as output the list of matching items with the following information:

- Name of the product, a link to the URL of the product, name of the organization which has developed or is the owner of the tool, resource or application.

- A record with basic information about the tool, resource or application and the set of ATLANTIS categories under which it has been classified.

6. Preliminary results and reports.

At the moment we are writing this paper most of the data are still being gathered, studied and classified in order to produce six final per-category reports and the final overall report of the project. Nevertheless, we can already offer preliminary summary reports for the following languages: Breton, Friulian, Irish, Scots Gaelic, Slovene and Welsh (**§6.1** below); and Asturian, Basque, Catalan, Corsican, Galician, Occitan and Sardinian (**§6.2**). Such groupings simply correspond to work packages as distributed to the Atlantis Project research centres.

With respect to data figures, we can only show now as being reliable the total number of entries for the languages of the second group.

6.1. Breton, Friulian, Irish, Scots Gaelic, Slovene, and Welsh

For such languages, one can state the points that are detailed below.

6.1.1. Learning Platforms in Lesser-used Languages

All states are developing connectivity and establishing ICT (Information & Communication Technology) as a basis for its educational system. Those states that do acknowledge the relevance of minority languages for learning do not necessarily develop the tools and materials required for this to operate. However, this does not guarantee development. In Italy, the frontier agreement with Slovenia means that many of the developments for the Slovene language group await developments in Slovenia. In Austria on the other hand, the same language group does have the advantage of a concerted effort to develop supporting materials for the limited amount of teaching in Slovene. The main problem here is the tendency to interpret the legal requirement liberally, which means that the service is not very effective. In Scotland, connectivity is available but the developing of materials and the use of ICT is left to each individual learning enterprise and there is little central support. The situation is similar in Ireland by reference to Irish. In Brittany on the other hand the state makes virtually no provision for Breton medium education and therefore the limited amount of on-line learning that is available is the consequence of private initiative. The best situation appears to be in Wales where institutions responsible for developing on-line learning in Welsh match connectivity. This supported by the fact that the local authorities as learning providers are obliged to have their language plans confirmed by the Welsh Language Board. Also, the National Assembly for Wales, which has the sole responsibility for education in Wales, is devoted to developing a bilingual nation. Friulian lacks any support of this nature.

6.1.2. Human Language Technology Developments

Again, the situation is highly variable. In Wales, there have been certain developments but these have yet to developing machine translation and voice recognition capacity even with Welsh/English language pair. This is partly because the issue is driven by the translation agenda, which has become a powerful lobby rather than by economic needs. In both Austria and Italy the developments depends entirely on Slovenia, which is one of the few states in Europe that has not developed full capacity. In Ireland the picture is broadly similar to that in Wales whereas in Scots Gaelic has a limited presence even though dictionaries, corpora and grammars have been developed. In Brittany much of the initiative is the result of private efforts and is limited to on-line dictionaries, grammar checkers, etc. It is clear that this area requires considerable investment, usually by private commercial enterprises. Friulian also lacks any development other than limited private initiatives.

6.1.3. Information and Communication Technology: Regional Plans, computer software and Internet tools

Not all regions have such plans. Thus in Ireland there is little such coherent development even though the new initiatives in the West are developing plans which, between them, can be said to constitute regional technology plans. However, things are in their infancy and the failure of large companies to extend broadband to these areas is holding things back. Little is happening by reference to language in these areas but the awareness of the need to do so is high. In Scotland, such plans are in the hands of the Scottish Parliament and the Highlands & Islands Enterprise. The latter has responsibility for Gaelic but its plans make little reference to ICT and Gaelic. In Friulian and the Slovene border areas regional development is limited to European Regional Development Fund initiatives and there is little reference to language in such plans. The same can be said of Carinthia (in Austria) where the plans which are developed are relatively sophisticated but have little of relevance for the Slovene language group. Wales was one of the first to develop a Regional Technology Plan under the RISI programme of the EU. This has been superseded

by the Cymru ar Lein' initiative. While there is a strong awareness of the need to incorporate Welsh development awaits the ability to incorporate the language into economic development writ large. In Brittany, the technological features of regional development make no reference to Breton.

6.1.4. Cultural Digital Resources and Linguistic Diversity

We must realise that we are in the beginning of any development of the Digital Value Chain. Thus far, it is unlikely that there is a regional DVC anywhere. Nonetheless, there are early developments. The Cymru'n Creu project in Wales is developing at least one end of the DVC. The exploitation end is emerging but is not articulated with the content end. The content end requires considerable investment whereas the production end does not. It is likely that Ireland will eventually develop one but is moving slowly in this direction at present. Scotland is in the same situation as Wales with SCRAN being an important innovative venture. SCRAN (Scottish Cultural Resources Access Network) was set up by museums, libraries and archives to create multimedia, manage digital IPR and provide educational access.

It is less likely that the other regions will be DVC regions and may well emerge as either content regions or production regions, more likely the later. This is largely because regional resources are housed in the capital region of the state so that initiatives will derive from that location on a state-wide basis. This does not preclude the emergence of regional eContent economies but it is less likely than in the historic regions with strong political autonomy. Carinthia is digitising some resources and there are multimedia companies capable of exploiting these but it is very limited. It is even less so among the Slovenes in Italy and also in Friulian. Brittany is in a similar situation. Whether the DVC regions focus on minority language digital resources depends on two things:

i. The extent to which they appreciate that diversity is driver of the Digital Economy and markets will be structured by language and not by states.

ii. The specific drive to incorporate minority languages into the New Economy.

6.1.5 Convergence and Lesser-used Language Broadcasting

This is also a matter of regional and central policy. The two language groups in north-eastern Italy will be hampered by the limited amount of exposure to media for the languages and the centralized nature of the broadcasting framework. However as costs plummet and deregulation takes hold, it will be possible to develop private initiatives. Carinthia also has a limited regional broadcasting presence and less so for Slovene. The Slovene language groups will, in all likelihood, benefit from deregulation and the entry of Slovenia into the EU, which will create a more integrated digital broadcasting region. Ireland is hampered by the size of its population and the dependence on terrestrial cabling which tends to be expensive. The main providers have recently pulled out and the state system is being partly privatised. Thus, development is hindered. Its minority language service will involve transformation of existing analogue services. Brittany has started developing a strong regional broadcasting capacity in the minority language and this will benefit from digitisation and the opportunities afforded by convergence.

6.1.6. Electronic Publishing and Lesser-used Languages

Electronic publishing is easier to conceive of partly because orthodox publishing in the minority language already exists and partly because of the relatively low cost. In all likelihood, this will be a parallel venture involving both orthodox publishing and electronic publishing existing side by side. The interesting developments involve exploiting convergence. This is already happening in Wales using Welsh where the main newspaper and the BBC are cooperating and also by reference to the community newspapers which are linked to the BBC's web service for the Welsh diaspora. As costs fall regional broadcasting and publishing will converge and will become far more localized. The publishing houses in Carinthia are also developing electronic Slovene language services. The Slovene newspaper in Italy is also available on-line but further developments are limited. Friulian has a limited development, as does the Gaelic language group in Scotland. Ireland's developments are also in a rudimentary state.

6.2. Asturian, Basque, Catalan, Corsican, Galician, Occitan and Sardinian.

For such languages we have collected and processed the following number of entries:

Asturian	50
Basque	408
Catalan	400
Corsican	50
Galician	225
Occitan	100
Sardinian	50

Some preliminary conclusions for this group are detailed below.

6.2.1 Learning Platforms in Lesser-used Languages

In this field we find a number of resources for the teaching/learning of languages on-line at different levels and for different target groups. Some are multilingual in nature, and a number are simple websites for adults, such as World Language Resources (which caters for Basque, Catalan, Galician, Sardinian, Corsican), Tandem Agency, etc. Monolingual language courses, grammars and lexicons are often offered by private individuals keen on

disseminating their language on the net. For instance, an on-line Occitan course at

http://occitanet.free.fr/cors/intro.htm. Institutional support for developing and/or disseminating language educational products can be observed in most of these languages, such as *A Palabra Herdada. Curso de Galego*, promoted by the Dirección Xeral de Política Lingüística of Galicia.

Other educational projects are not for teaching the language, but rather use it as the medium of instruction. "*Recursos educativos para ciencias naturais*" in Galician (http://www.galego21.org/ciberlingua/recur.htm) is a good example of well-sorted links to available resources of this nature, but there are not many. Another is aimed at primary school education: *CD ikastola.net*. Nearly all material aimed at primary education is for Catalan or Basque: nothing has been detected in Occitan, Sardinian or Corsican, and a few tools are in Galician or Asturian. The same can also be said about secondary education, though in this case more Galician products have been found. At university level most Catalan universities offer on-line language courses both for non-native learners and for native speakers improving their literacy skills. Other tertiary level sites offer information on literature, e.g. Biblioteca d'Autores Asturianos at http://www.araz.net/escritores/ or philosophy resources in Galician, http://filosofia.00go.com/.

These are nearly all single products unrelated to digital educational platforms as such. Others cover leisure products which range from digital games such as *Trivial Pursuit euskaraz eta on line!* in Basque, at http://www.argia.com/tribiala.htm, to distribution lists and newsgroups in Occitan (soc.culture.Occitan, or the forum at http://www.oest-gasconha.com/listadif.php3).

There are, however a number of digital learning platforms. These are to be found in the virtual campuses of many universities such as the Universitat Oberta de Catalunya, which offers a range of degree courses, both undergraduate and postgraduate, in Catalan (http://www.uoc.edu/). The universities involved are virtually all Catalan (including, of course, Valencian universities) or Basque.

6.2.2. Human Language Technology Developments

Much of the digital work in the "Foundations" section has been done on Basque, by a wide range of organisations, many of which publicly supported. But all the languages studied do have at least some work in this area. Projects include untagged corpora, speech recordings and mono- or bi-lingual dictionaries. One example of an oral archive is the *Archivu Oral de la Llingua Asturiana*, http://www.asturies.org/asturianu/archoral/. In the "Tools and Resources for Application" section, Basque, Catalan and Galician seem to be the most productive. As regards taggers and tagged corpora, most of the work appears to have been done on Catalan and, to a lesser extent, Galician. Lexical and speech databases can be found in and for Catalan, Basque, Galician and for Corsican: www.ac-corse.fr/expos_autres/webdlc2/webdlc/Acceuil.html. No such developments have been found for Asturian, Occitan or Sardinian. Several terminology research centres offer resources on the Internet including Termcat (for Catalan) and UZEI (for Basque). In the field of Lexical-Semantic knowledge bases, WordNets have been developed for Catalan and Basque, and a Galician version is being developed.

Moving now to "Advanced tools and applications" we have found Authoring aids (spelling correctors and, just for Catalan, a grammar and style checker) for the following languages: Catalan, Galician and Basque. An Asturian product is about to be launched. Bilingual machine-translation systems have been developed for Basque, Galician and Catalan, such as the Basque-Spanish tool developed by the Basque government: http://www1.euskadi.net/hizt_3000/. Speech tools include those developed by Telefónica for speech recognition and synthesis for Catalan, Basque and Galician (alongside Spanish). Philips has developed the continuous-speech recognition tool *Free Speech* for Catalan only. No other languages in our group seem to have similar tools. Linguistic information retrieval and extraction tools have been located for Catalan and Galician. Web crawlers have been developed to manage Basque, Catalan and Galician.

6.2.3 Information and Communication Technology: Regional Plans, computer software and Internet tools

Regional ICT plans of greatly varying scope and objectives have been found at least for the following: Catalan (Catalonia, Balearic Islands), Basque and Sardinia. They also vary in the importance they attach to language in the plan. The Regional Development Plan (http://dursi.gencat.es/ca/de/pla_estrategic.htm) developed by the government of Catalonia does include specific projects related to the Catalan language.

As to software developed for the internet, languages such as Basque, Catalan and Galician have developed versions of the most widely used tools, such as several operating systems, the music file manager WinAmp (available also in Asturian) and web crawlers such as Netscape. Softcatalà, Softkat (for Basque) and Proxecto Xis-Galego 21 are three organizations devoted primarily to this work, as well as to developing new software. Very little has been found for Corsican, Occitan and Sardinian.

6.2.4. Cultural Digital Resources and Linguistic Diversity

In this section the digital treatment of libraries is interesting. Several cases have national libraries with limited digital services. All languages studied have at least websites reproducing literary and/or academic texts. Some libraries are fully digital: *Biblioteca Joan-Lluís Vives* is a good example of a resource containing digital versions of important Catalan literary texts. *InterRomania* has literary texts in Sardinian, Catalan and Corsican.

The small subsection on Museums is devoted strictly to those which offer digital resources related to the area, or from its own stocks, on the Internet.

The "voice" subsection contains a heterogeneous collection of resources relating to Basque, Galician, Sardinian and Corsican, from recited toponyms to full-scale digital archives.

The musical resources are plentiful. Significantly, each language studied has at least one website offering such recordings, with MP3, given the ease with which digitisation is possible. Thus the range of resources is enormous: from versions of original recordings on record. Some are sung, others are instrumental, and they range from traditional music to rock.

The section also includes a wide variety of other digital resources related to each culture: from photography to the visual arts, cartoons, catalogues of films made and/or dubbed (in Catalan). A high quality Galician multimedia resource centre is housed at http://www.culturagalega.org

6.2.5. Convergence and Lesser-used Language Broadcasting

The situation for radio and for television is somewhat different. Radio stations are available on the Internet in most of the languages, except Asturian. Al least 11 Catalan radio stations broadcast (live or stored) on the Internet, as do several of Basque stations. As regards television, digital satellite television is available in Catalan, Basque and Galician, whereas the picture for Internet TV is different: Catalan is not available, whereas Galician and Basque, and even Occitan, broadcasts are available. France 3 Corse has uploaded some of its programmes, a few of which (local news programmes) are in Corsican: http://www.france3.fr/semiStatic/382-1250-NIL-NIL.html. France 3 promises the same for Occitan and Catalan.

6.2.6 Electronic Publishing and Lesser-used Languages

The section is very rich in quantity and variety. The "Academia de la Llingua Asturiana" has fully four digital journals of a cultural and literary nature. Indeed, every language has similar journals. There are also other journals of a non-cultural nature, such as the Basque cooperative movement Eroski's journal *Consumer*, which is published in Galician, Catalan (http://revista.consumer.es/web/ca/) and Basque as well as Spanish. http://codigocero.com/ is a Galician journal designed as a portal which offers information and news about new technologies.

Other linguistic products which have been regarded as electronic publications include multimedia encyclopædias, dictionaries (including interesting combinations such as Occitan-Basque), vocabularies and grammars. A CD-Rom on lesser-used languages, Lingua+, can also be viewed via the Internet. Publishers and/or sellers of electronic books include Basque houses, and the Catalan http://www.llibres.com, most of whose sales are still printed books. Electronic short stories in Corsican are sold through http://www.ac-corse.fr/fole2/fole.htm, where a demo can be viewed.

In dealing with daily newspapers a distinction has to be made between printed newspapers which also have an electronic edition, and strictly electronic dailies. In both cases a considerable investment is needed. Among the former there are many examples. Including http://www.egunkaria.com/ in Basque, and http://www.avui.com and http://www.diaridebalears.com/, among others, in Catalan. Among the latter we find Vieiros-Hoxe http://www.vieiros.com/ in Galician, and http://www.diaridebarcelona.com, which is run by the Barcelona city council, in Catalan.

Several languages have regular news services. Good examples are http://www.vilaweb.com, which operates in Catalan and uses mostly links with other electronic dailies, http://www.asturies.com/ in Asturian.

7. Concluding remarks

The Observatory has concluded its development phase, and has fulfilled one of its main aims: to bring together into its database a wide variety of initiatives relating to the new digital age. It is to be hoped that many of these will spur others into similar initiatives, hopefully working synergistically: as we stated at the outset, it is hoped that it will facilitate "regular contact among individuals from all European Union lesser-used languages to share knowledge on digital tools and resources available for such linguistic communities".

What remains to be done, as we write this paper, is to determine to what extent each of these communities is well placed to enter the Digital Economy. Perhaps it is too ambitious, or pretentious, to imagine that we can pinpoint, for each community, which obstacles may appear in its drive towards the Digital Economy, as lack of basic tools, weak levels of networking, etc. Were this to be feasible, the Observatory could act as a useful reference point for planners.
At a less ambitious level, we are confident that users of the database will point out the inaccuracies and help us to continuously update the information it contains.

Abstract

This paper intends to be an initial proposal to promote research and development in language independent tools. The definition of a basic HLT toolkit is vital to allow the development of lesser-used languages. Which kind of public HLT products could be integrated, at the moment, in a basic toolkit portable for any language? We try to answer this question by examining the fifty items registered in the Natural Language Software Registry as language independent tools. We propose a toolkit having standard representation of data and develop a strategy for the integration, in a common framework, of the NLP tools.

1. Introduction

SALTMIL, the ISCA SIG (International Speech Communication Association Special Interest Group) on Speech and Language Technology for Minority Languages, has the overall aim of promoting research and development in the field of speech and language technology for lesser-used languages. Actually, its main activity is providing a channel of communication between researchers by means of workshops and the discussion list. The members of SALTMIL, we often wonder how to promote research and development in a more active way. In this paper we would like to propose a medium term project to accomplish that goal: the definition of a basic toolkit for HLT. Of course, this toolkit should be designed following the basic principles of reusability and portability[1]. So, the adoption of common standards and procedures will help to minimise costs and workload in research. This way will be beneficial for any kind of language (and vital for lesser-used languages), and would define a new collaboration-space for researchers working with different languages.

The real challenge is, however, how to define a basic toolkit for HLT? In this paper we will not resolve this problem, but we want to lay some foundations to address it. First, we will try to collect an initial list of present tools and applications that are portable (usable) for different languages:

- How many of the present HLT tools and applications are portable?
- How many of them are free for academic and public uses?
- Is there any tool for any of main basic applications? or… Is there any application with no accessible tool?

In this way, by recognizing which are the most basic tools, we propose four phases as a general strategy to follow in the processing of any language. Therefore, tools considered in the first phase will be taken as more basic than the later ones.

The paper is organized as follows: Section 2 proposes a strategy to develop language technology for language, grouping linguistic resources, tools and applications in four different phases. Section 3 examines the programs registered by the Natural Language Software Registry (NLSR) in order to determine the present proportion between portable and not-portable HLT products. Section 4 proposes a standard representation of linguistic data; it is a method we use in IXA Group in order to allow the integration between different tools in the same HLT framework; the standard representation would be fundamental for any possible basic toolkit. Finally, some concluding remarks are included.

2. Recognizing basic tools and their preference

We present here an open proposal for making progress in Human Language Technology. This proposal is based on the fifteen years experience of the IXA Group with the automatic processing of Basque. Anyway, the steps here proposed do not correspond exactly with those observed in the history of the processing of English, it is due to the high capacity and computational power of present computers allows arranging problems in a different way. We must remark that our work has been centered on the processing of written language and that we do not have any reliable experience on spoken language. However, in this proposal some general steps on speech technology have included.

Language foundations and research are essential to create any tool or application; but in the same way tools and applications will be very helpful in research and improving language foundations. Therefore, these three levels (language foundations, tools and applications) have

[1] Main themes chosen for the last two ISCA SALTMIL SIG workshops were "*Re-usability and strategic priorities*" (Athens 2000) and "*Portability Issues in Human Language Technologies*" (Gran Canaria 2002).

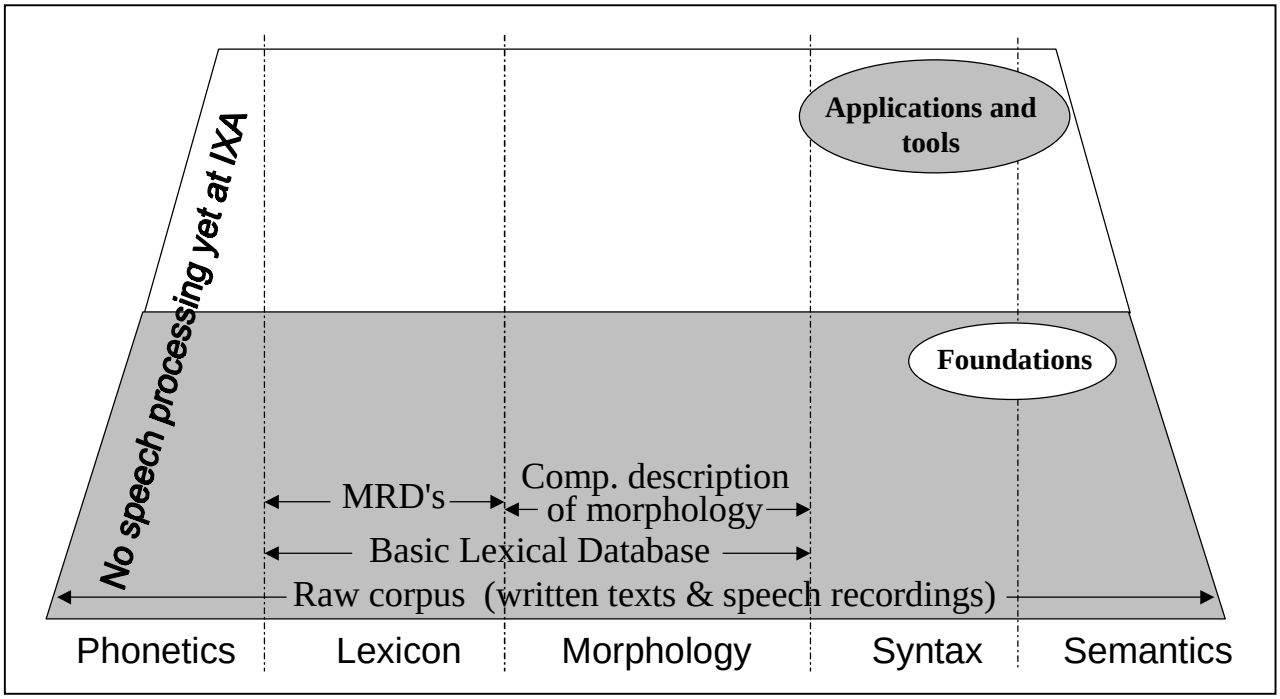

Figure 1. First phase: Foundations.

to be incrementally developed in a parallel and coordinated way in order to get the best benefit from them. Taking this into account, we propose four phases as a general strategy to follow in the processing of the language.

Initial phase: Foundations (see Figure 1).

- Corpus I. Collection of raw text without any tagging mark.
- Lexical database I. The first version could be simply a list of lemmas and affixes.
- Machine-readable dictionaries.
- Morphological description.
- Speech corpus I.
- Description of phonemes.

Second phase: Basic tools and applications.

- Statistical tools for the treatment of corpus.
- Morphological analyzer/generator.
- Lemmatizer/tagger.
- Spelling checker and corrector (although in morphologically simple languages a word list could be enough).
- Speech processing at word level.
- Corpus II. Word-forms are tagged with their part of speech and lemma.

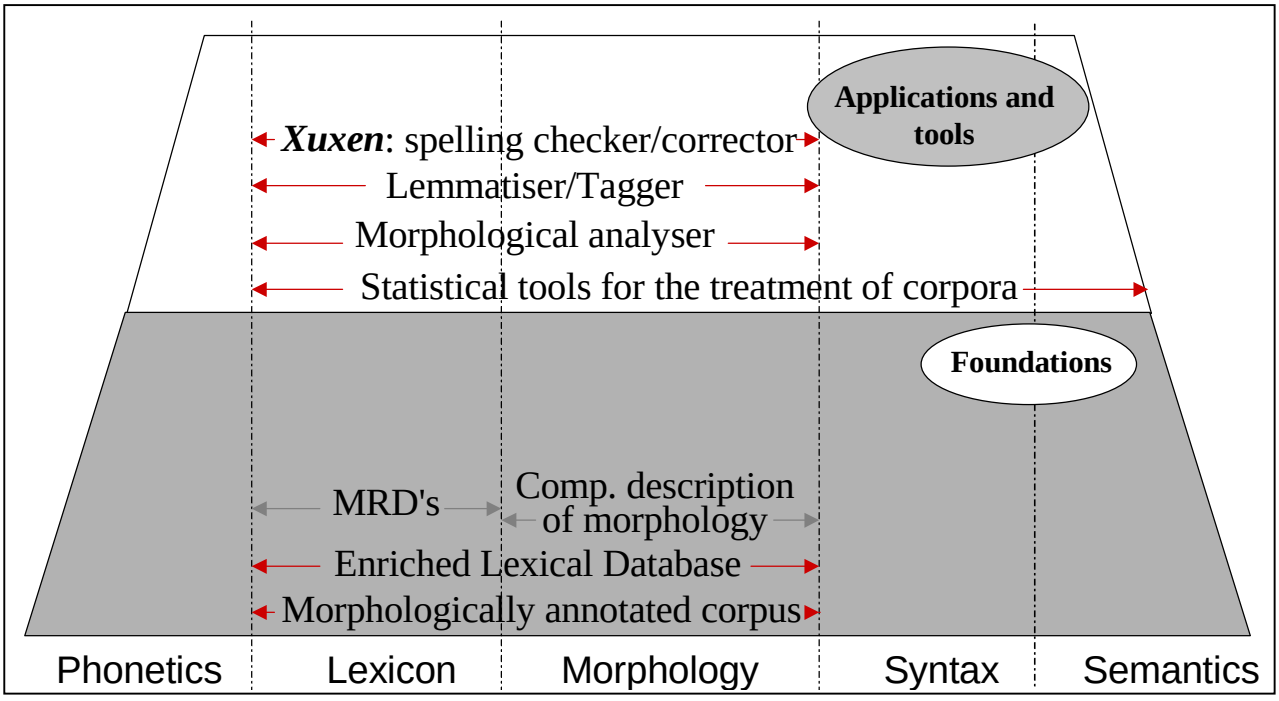

Figure 2. Second phase: Basic tools and application.

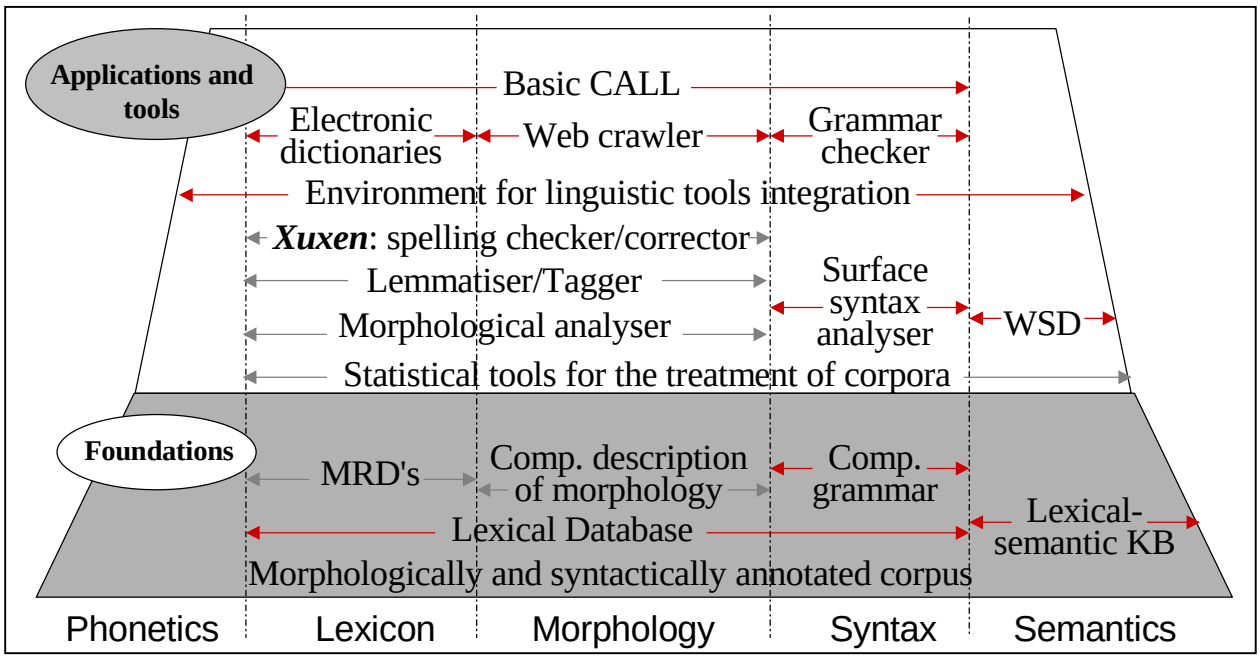

Figure 3. Third phase: advanced tools and applications.

- Lexical database II. Lexical support for the construction of general applications, including part of speech and morphological information.

Third phase: Advanced tools and applications.

- An environment for tool integration. For example, following the lines defined by TEI using XML. Section 4 describes this proposal.
- Web crawler. A traditional search machine that integrates lemmatization and language identification.
- Surface syntax.
- Corpus III. Syntactically tagged text.
- Grammar and style checkers.
- Structured versions of dictionaries. They allow enhanced functionality not available for printed or raw electronic versions.
- Lexical database III. The previous version is enriched with multiword lexical units.
- Integration of dictionaries in text editors.
- Lexical-semantic knowledge base. Creation of a concept taxonomy (e.g.: Wordnet).
- Word-sense disambiguation.
- Speech processing at sentence level.
- Basic Computer Aided Language Learning (CALL) systems.

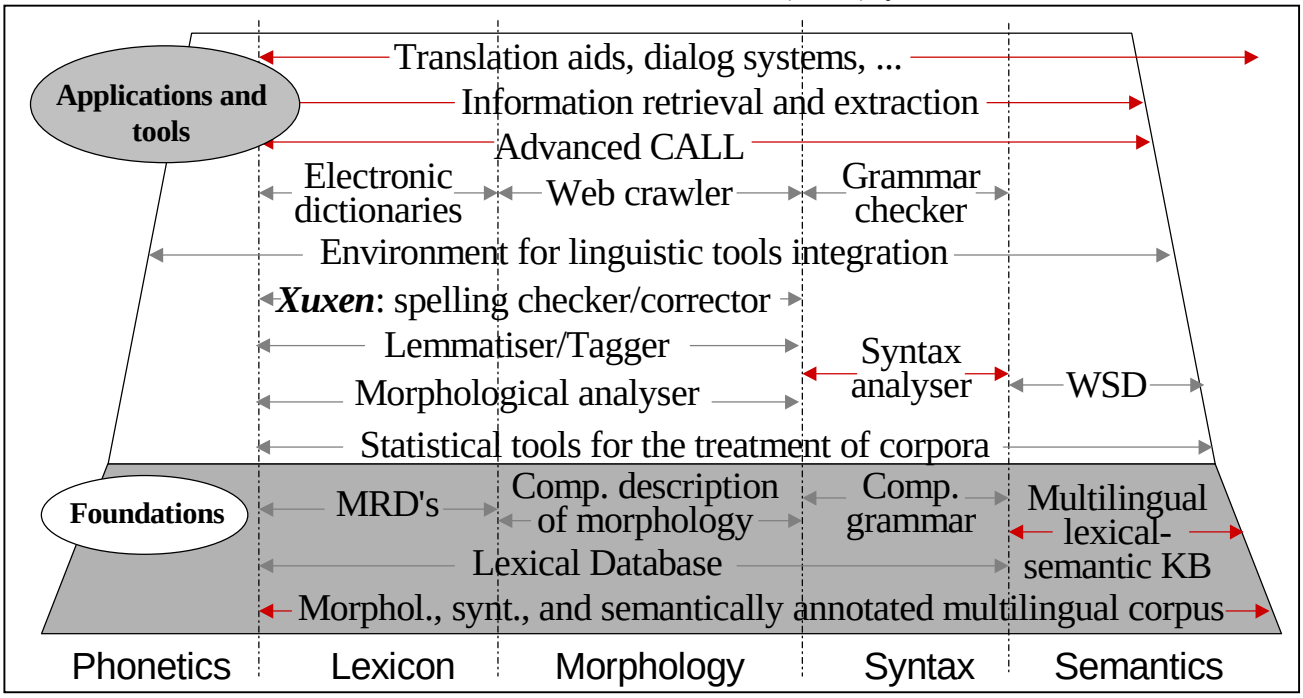

Figure 4. Fourth phase: Multilingualism and general applications..

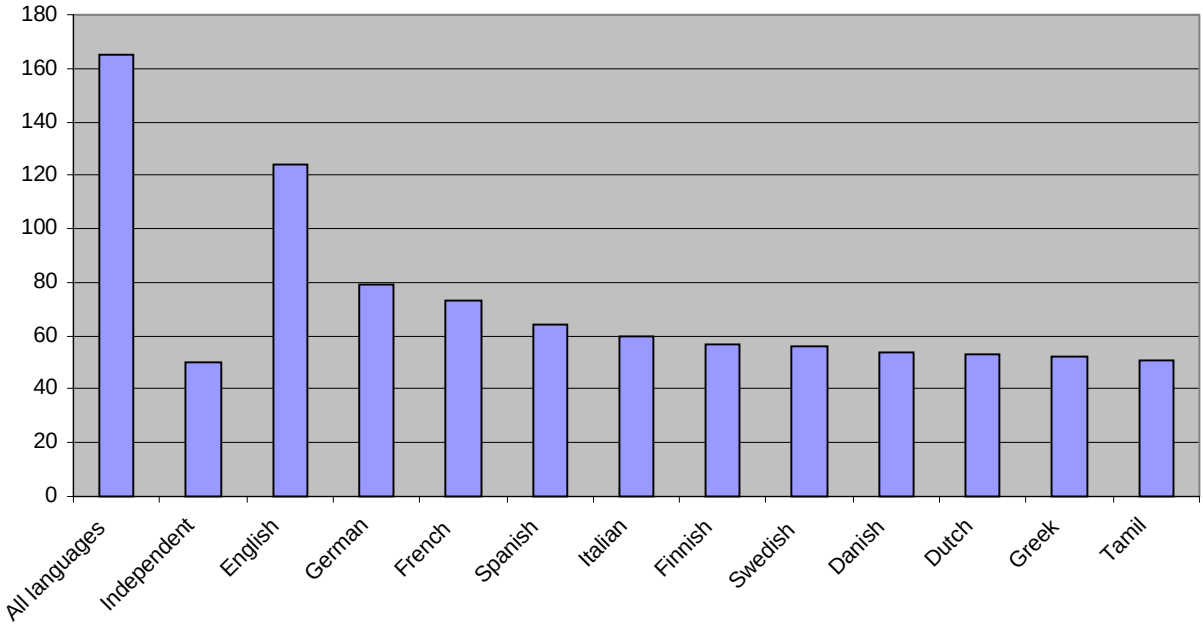

Fourth phase: Multilingualism and general applications.

- Information retrieval and extraction.
- Translation aids. Integrated use of multiple on-line dictionaries, translation of noun phrases and simple sentences.
- Corpus IV. Semantically tagged text after word-sense disambiguation.
- Knowledge base on multilingual lexico-semantic relations and its applications.
- Dialog systems.

Now that we have started working on the fourth phase, every foundation, tool and application developed in the previous phases is of great importance to face new problems.

3. Present portable HLT products

Which is the start point at the present? Which kind of public HLT products could be integrated, at the moment, in a basic toolkit portable for any language?

With the aim of looking for data to answer to those questions, we examined the programs registered in the Natural Language Software Registry[2] (NLSR), an initiative of the Computational Linguistics Association (CL) and hosted at DFKI in Saarbrücken. The NLSR concentrates on listing HLT software, but it does not exclude the listing of linguistic resources (corpus, monolingual and multilingual lexicon). Other institutions, such as ELRA/ELDA or the Linguistic Data Consortium, provide listings of such resources. However, looking for portable products, to be precise, looking for products usable for multiple languages, the NLSR result sufficient because, actually, all linguistic resources are related to particular languages and so, they are not significant in this search. Of course, there are other HLT tools that have not been submitted to the NLSR, but we think that examine this database is a good start point.

3.1. Present proportion between portable and not-portable HLT products

First of all, we looked for how many of the present HLT tools and applications support different languages. This task was not very difficult because the system allows queries with a particular value for the slot named *Supported language(s)*. Figure 5 shows that a) the all amount of programs registered is 167; b) 50 of them (30%) has been declared to be language independent; c) of course, English is the language that support most of the programs. 125 support English (75%), that means that only 42 systems have been defined for the remaining 24 languages defined in NLRS; d) German, French, Spanish and Italian are the next languages an they are supported only by 79, 73, 64 and 60 respectively; and e) other languages are supported by those fifty defined as language independent and, occasionally, by a few other programs, for example 51 hits for Tamil. Those data reveals evident the significance of portability in Natural Language Software.

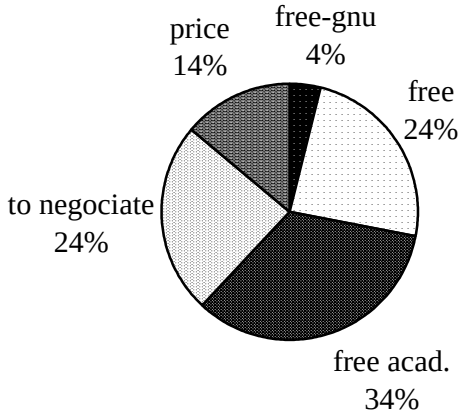

Figure 6: Price of portable HLT products

[2] http://registry.dfki.de

3.2. Price of portable HLT products

How many of the portable HLT products are free for academic and commercial uses? Among the fifty products they are 14 programs that free for any use (two of them, Zdatr and the speech synthesizer MBROLA, are distributed under the GNU Public Public License). Other 17 systems are free for academic uses. The price of 12 systems is defined as "to negotiate" even for academic uses. And finally 7 systems has a fixed price stated from $129 to $799; their average price is $546.

3.3. Distribution of portable products between HLT sections

Is there any portable tool for all the main basic sections in HLT? Or… is there any application with no accessible tools? Table 1 shows the distribution by sections of language independent software in NLSR. Similar data is shown for products that support English. We remark the following points: a) the number of products for the last four sections is not enough to be considered: b) the distribution of language independent products is similar to that of the total amount of products; c) there is any system in every section; d) the percentage of language independent products is considerable higher in Spoken Language and in NLP Development Aid.

Section	Total	Indep.	% indep.	Eng.	% Eng.
Total	167	50	0,30	125	0,75
Annotation	15	4	0,27	13	0,87
Written lang.	122	28	0,23	90	0,74
Spoken language	31	15	0,48	23	0,74
NLP development Aid	41	16	0,39	31	0,76
Lang. Resources	23	6	0,26	18	0,78
Multimedia	2	1	0,50	1	0,50
Multimodality	5	1	0,20	4	0,80
Evaluation	4	3	0,75	4	1,00

Table 1: Distribution of software by HLT sections

And now let's consider the distribution of NSLR products taking into account the kind of linguistic knowledge they manage. The kinds of knowledge to be considered are those referred in the previous section plus special points for NLP frameworks than includes facilities for lexical, morphology, syntax or speech. There is not any program to deal with dictionaries (creation of structured versions of dictionaries or integration of them in other applications), nor for semantics.

3.3.1. Corpus

Product	Description	Price
Alembic Workbench	a multi-lingual corpus annotation development tool	free
Bigram Statistics Package	Bigram analysis software	free
emdros	text database engine for linguistic analysis and research	free
PWA	Word Aligner	free acad.
SRILM -- SRI Language Modeling Toolkit	Statistical language modeling toolkit	free acad.
Entropizer 1.1	A toolbox for sequential analysis	to negotiate

Table 2: NLSR language independent products for corpus

3.3.2. Morphology

Product	Description	Price
PC-KIMMO	Two-level morphological analyzer	free acad.
TnT - Statistical Part-of-Speech Tagging	a statistical part-of-speech tagging for german, english and languages that delimit words with space	free acad.

Table 3: NLSR language independent product for morphology

3.3.3. Lexical databases

Product	Description	Price
DATR	A formalism for lexical knowledge representation	free
Xerox TermOnLine	Xerox TermOnLine is a terminology database sharing tool	to negotiate
Xerox TermOrganizer	Xerox TermOrganizer is a terminology database management system.	to negotiate

Table 4: NLSR language independent product for lexical databases

3.3.4. Speech

Product	Description	Price
IVANS: The Interactive Voice ANalysis System	Voice analysis, voice quality rating, voice/client data management	$749
CSRE - Computerized Speech Research Environment	speech analysis, editing, synthesis and processing system	$750
The OroNasal System	Nasalance measurement, analysis of oral and nasal airflow/energy in speech	$799
CSLU Toolkit	a comprehensive suite of tools to enable exploration, learning, and research into speech and human-computer interaction	free acad.
CSL -- Computerized Speech Lab	speech acquisition, analysis and playback	to negotiate
Signalyze(tm)	Interactive program for speech/signal analysis (runs only on Macintosh)	$350
TFR: The Time-Frequency Representation System	a comprehensive speech/signal analysis, editing and processing system	$599
Multi-Speech	a comprehensive speech recording, analysis, feedback, and measurement software program	to negotiate
WinPitch, WinPitch II	Speech analysis and annotation	to negotiate
ProTrain	speech analysis and speech production training system	$349
Praat	a research, publication, and productivity tool for phoneticians	free acad.
MBROLA	a speech synthesizer based on the concatenation of diphones	free-GNU
EULER	a freely available, easy-to-use, and easy-to-extend, generic multilingual TTS	to negotiate

Table 5: NLSR language independent product for speech

3.3.5. Syntax

Product	Description	Price
ASDParser and ASDEditor	Parser and editor for Augmented Syntax Diagram grammars, implemented in Java.	free
XLFG	Syntactic analysis using the LFG formalism	free
AGFL Grammar Work Lab	Formalism and tools for context free grammars	free acad.
CUF	constraint-based grammar formalism	free acad.
GULP -- Graph Unification Logic Programming	an extension of Prolog for unification-based grammar	free acad.
LexGram	development and processing of categorial grammars	free acad.

Table 6: NLSR language independent product for syntax

3.3.6. NLP framework

Product	Description	Price
Alembic	an end-to-end multi-lingual natural language processing system	free
The Quipu Grok Library	a library of Java components for performing many different NLP tasks	free
PAGE: A Platfrom for Advanced Grammar Engineering.	System for linguistic analysis and test of linguistic theory (HPSG, FUG, PATR-II). Can be used as part of a deep NLP system or as part of a speech system (a special version is used in Verbmobil).	to negotiate
TDL---Type Description Language	System for linguistic analysis and test of linguistic theory (HPSG, FUG, PATR-II). Can be used as part of a deep NLP system or as part of a speech system (a special version is used in Verbmobil).	to negotiate
QDATR	An implementation of the DATR formalism	free acad.
Kura	Kura is a system for the analysis and presentation of linguistic data such as interlinear texts.	free
Zdatr	Zdatr is a standardised DATR implementation in ANSI C	free-GNU

Table 7: NLSR language independent product for NLP frameworks

3.3.7. Applications

Product	Description	Price
BETSY - Bayesian Essay Test Scoring sYstem	Free Windows based text classifier/essay scorer	free acad.
Flag	Terminology, style and language checking	to negotiate
Universal Translator Deluxe	An omni-directional translation system	$129
Onix	High performance information retrieval engine	to negotiate
Brevity	Document summarization toolkit	to negotiate

Table 8: NLSR language independent product for applications

4. A standard representation for linguistic data using TEI conformant feature structures

The standard representation of linguistic data in order to allow the integration between different tools in the same HLT framework will be fundamental for any possible basic toolkit. In this section we present as a proposal the strategy used for the integration, in a common framework, of the NLP tools developed for Basque during the last twelve years (Artola et al.; 2000). The documents used as input and output of the different tools contain TEI-conformant feature structures (FS) coded in SGML[3]. These FSs describe the linguistic information that is exchanged among the integrated analysis tools.

The tools integrated until now are a lexical database, a tokenizer, a wide-coverage morphosyntactic analyzer, a general purpose tagger/lemmatizer, and a syntactic parser.

Due to the complexity of the information to be exchanged among the different tools, FSs are used to represent it. Feature structures are coded following the TEI's DTD for FSs, and Feature System Declaration (FSD) descriptions have been thoroughly defined.

The use of SGML for encoding the I/O streams flowing between programs forces us to formally describe the mark-up, and provides software to check that this mark-up holds invariantly in an annotated corpus.

A library of Abstract Data Types representing the objects needed for the communication between the tools has been designed and implemented. It offers the necessary operations to get the information from an SGML document containing FSs, and to produce the corresponding output according to a well-defined FSD.

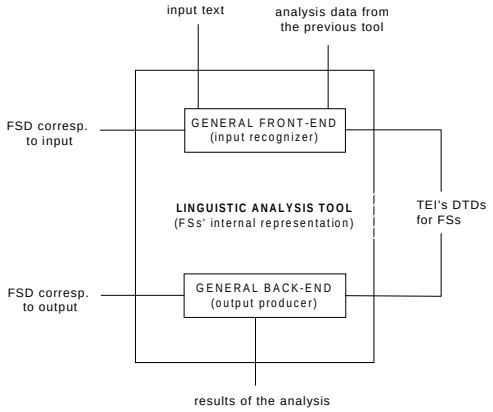

Figure 7. Schematic view of a linguistic analysis tool with its general front-end and back-end.

The use of SGML as an I/O stream format between programs has, in our opinion, the following advantages:

a) It is a well-defined standard for the representation of structured texts that provides a formal framework for the internal processing.
b) It provides widely recognized facilities for the exchange of data: given the DTD, it is easy to process any conformant document.
c) It forces us to formally define the input and the output of the tools used for the linguistic analysis of the text.
d) It facilitates the future integration of new tools into the analysis chain.
e) Pieces of software are available for checking the syntactic correctness of the documents, information

[3] All the references to SGML in this section could be replaced by references to XML.

retrieval, modifications, filtering, and so on. It makes it easy to generate the information in different formats (for processing, printing, screen-displaying, publishing in the web, or translating into other languages).

f) Finally, it allows us to store different analysis sets (segmentations, complete morphosyntactic analyses, lemmatization results, and so on) linked to a tokenized piece of text, in which any particular analysis FS will not have to be repeated.

.

5. Conclusions

If we want HLT to be of help for more than 6000 languages in the world, and not a new source of discrimination between them, the portability of HLT software is a crucial feature. Looking for language independent software in the Natural Software Registry, we saw that only 30% of the tools has been so declared; that 62% of those language independent programs are at least academic free and that they are quite homogeneously distributed among the different sections of HLT and among the kinds of knowledge they manage.

As many problems would arise when trying to coordinate several of those language independent programs, we present as a proposal the strategy used for the integration, in a common framework, of the NLP tools developed for Basque. Feature structures are used to represent linguistic information, and feature structures are coded following the TEI's DTD for FSs, and Feature System Declaration descriptions (FSD) have been thoroughly defined.

Worldwide international organizations that work for the development of culture and education should promote the definition and creation of a basic toolkit for HLT available for as many languages as possible. ISCA SALTMIL SIG should coordinate researchers and those organisations to initiate such project.

Ubiquitous multilingual corpus management in computational fieldwork

Dafydd Gibbon

Fakultät für Linguistik und Literaturwissenschaft
Universität Bielefeld
Postfach 100131
D–33501 Bielefeld
Germany
gibbon@spectrum.uni-bielefeld.de

Abstract

The present application addresses the issue of portability in the context of linguistic fieldwork, both in the sense of platform interoperability and in the sense of ultra-mobility. A three-level networked architecture, the UbiCorpus model, for information gathering in the field is described: (1) a Resource Archive server layer, (2) a Data Processing application layer, and (3) a new Corpus Pilot layer designed to support specific fieldwork sessions under adverse conditions, for on-site questionnaire presentation and metadata editing.

1. Goals

In linguistic fieldwork,[1] conceptually the initial stage in any language documentation procedure, the issue of portability is important in two senses: first, the sense of platform interoperability and second, in the sense of ultra-mobility. This issue is addressed by the present application. A three-level networked architecture, the UbiCorpus model, for information gathering in the field is described: (1) a Resource Archive server layer, typically non-mobile, and distributed; (2) a Data Processing application layer, typically a local laptop or desktop; and (3) a new Corpus Pilot layer, designed to support specific fieldwork sessions under adverse conditions with questionnaire presentation and metadata editing, and typically, it is suggested, implemented on a handheld PDA. The UbiCorpus model is based on extensive fieldwork experience, mainly in West Africa. The Corpus Pilot layer is described in detail.

Owing to severe financial and platform resource limitations in practical linguistic fieldwork situations, the general development strategy is to use available freeware or open source components as far as possible, and to augment these with custom applications which are distributed as freeware for initial testing, and subsequently published as as open source software.

Figure 1: Questionnaire-based interview on Anyi syntax with Kouamé Ama Bié by Sophie Salffner & Sandrine Adouakou in Adaou, Ivory Coast (equipment: field laryngograph, DAT, Palm, pen & paper).

2. Requirements specification

Relatively recently, issues of corpus standards and resources as developed in the field of speech technology (Gibbon et al., 1997; Gibbon et al., 2000; Bird and Liberman, 2001) have been extended to fieldwork corpora in linguistics, ethnography, and related sciences, and specific issues such as the role of metadata in resource archiving and reusability have come to the fore, adding to the complexity of the documentation task facing the fieldworker. The present application area is computational support for this fieldwork documentation task within an integrated fieldwork resource environment. This concern is on the one hand more comprehensive than the currently popular issues of annotation-based data enhancement and web-based resource dissemination, and on the other hand orthogonal to these expensive technologies in that an effective but inexpensive practical new "low end high tech" technique for grass roots applications in geographically inaccessible areas is introduced.

From the perspective of field linguistics, language documentation traditionally consists in the main of field notes, an outline of the situation of the language, transcriptions, and generally including a sketch grammar consisting of basic phonology, morphology, and grammar, together with a lexicon containing glosses and examples and perhaps a thesaurus. The prompt materials for eliciting this kind of documentation are mainly systematic linguistic and ethnographic questionnaires, and the media for production of the documentation are generally office-oriented software such

[1]Grateful acknowledgements to Sandrine Adouakou, Firmin Ahoua, Doris Bleiching, Bruce Connell, Eddi Gbery, Ulrike Gut, Ben Hell, Sophie Salffner, Thorsten Trippel and Eno-Abasi Urua for discussion of problems addressed in this contribution.

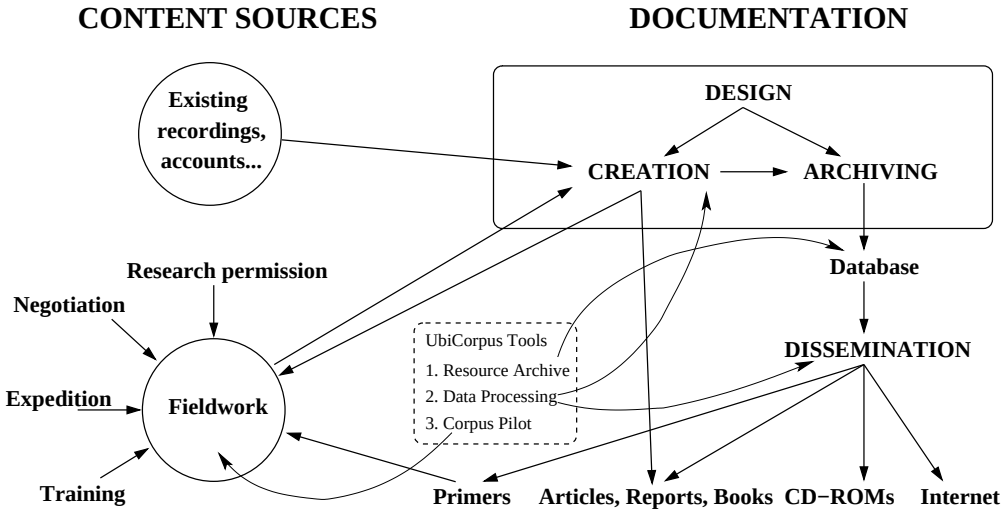

Figure 2: Language documentation logistics model.

as word processors (MS-Word etc.), DBMS (Access, FilemakerPro etc.), and spreadsheets (Excel, etc., also used for database entry). The guiding objectives of this concept of documentation are applications in the production of translations, terminologies, and alphabetisation materials.

The UbiCorpus model is designed to support this kind of fieldwork in the following main respects:

1. questionnaire presentation (either by database or in free format, as a plain text editor or with special formatting and rendering, for example by means of an IPA font),

2. transcription (either plain ASCII such as X-SAMPA, or in an IPA font),

3. metadata input.

One of the main advantages of the model is that when implemented on a modern palmtop device it provides a convenient, efficient and — important for many applications — inconspicuous method for the frequently neglected task of systematic on-site metadata logging.

However, the scope of the model is more general, and supports both the documentation of spoken language corpora in general, and further corpus processing in the form of the development of structured computational lexica (van Eynde and Gibbon, 2000) and computationally supported grammar testing. The UbiCorpus model is embedded in a comprehensive documentation model which covers not only the fieldwork activity itself, but the environment of preparation, archiving and application in which fieldwork is embedded (cf. Figure 2).

The first general operational requirement for the UbiCorpus model is portability. In the present context the term is systematically ambiguous:

- interoperability of applications on different OS and hardware platforms,

- compatibility of data formats through import and export filters for functionally equivalent or interfaced applications,

- ubiquity, i.e. time and place independent mobile deployment.

In the present context, the primary focus is on ubiquity, with interoperability and compatibility seen from this perspective.

Computational support for certain aspects of linguistic fieldwork has been available for many years, both for laptop-based data entry and initial analysis on the move or in isolated areas, and for desktop-based detailed descriptive work and document production (with increasing overlap between laptop and desktop functionalities). Software applications have been characteristically in the following areas:

- Lexical databases, either using general office DBMS such as FileMakerPro and MS-Access, or custom lexicon project software such as SIL's Shoebox; the latter also includes lexical support for textual glossing.

- Publication support such as DB export functions, fonts.

- Phonetic software, for signal analysis (e.g. general signal editors such as CoolEdit, or SIL's CECIL and signal analysis packages, or Praat) and for the symbol-signal time alignment (labelling) of digital recordings (e.g. Praat, Transcriber).

- Computational linguistic software for basic phonological, morphological and syntactic processing.

Some of this functionality (lexical databases, document production, computational linguistic processing) overlaps with the new Corpus Pilot layer, but this layer has the following characteristic additional fieldwork corpus acquisition functionality (Gibbon et al., 1997; Gibbon et al., 2000):

Pre-recording phase: planning of the overall corpus structure and contens, in particular design of corpus recording sessions, including the preparation of scenario descriptions, interview strategies, questionnaires, data prompts (for instance with prompt randomisation),

Recording phase: conduct of corpus recording sessions, including session management with the logging of metadata in a metadata editor and database, questionnaire consultation and data prompt presentation;

Post-recording phase: provision of recorded and logged data for archiving and processing, including metadata export, transcription, lexicon development, systematic sketch grammar support and document production.

3. Design: modules, interfaces

The language documentation model within which the UbiCorpus model is deployed is visualised in Figure 2; the documentation model was developed for project work in West Africa. The two components of the model with which the UbiCorpus tools are concerned are the *Creation* and *Archiving* component, and the *Fieldwork* information source. The latter is directly associated with the Corpus Pilot layer described below. The UbiCorpus model itself is visualised in Figure 3.

The three layers of the UbiCorpus model are characterised as follows:

Resource Archive (RA) layer

The bottom layer represents the archive database and the access and media dissemination functions associated with it. On the declarative side, a number of current language resource and documentation proposals may be assigned to the Resource Archive layer: a single resource database such as a corpus or a lexicon, a multiple resource database such as a browsable corpus or concordance system, a web portal constituting a large and systematic resource world, or an entire dissemination agency. On the procedural side, the Resource Archive layer provides search functions of various kinds, from standard browsing strategies to intelligent search and concordance construction, with token renderings of resources in any suitable media, whether entire corpora or lexica.

Data Processing (DP) layer

This is the layer which is familiar to the "ordinary working linguist". The data include paper fieldwork logbooks, transcriptions, sketch grammars and card index lexica; word processor and database versions of these; analog and digital audio and video recordings; time aligned digital annotations of recordings, and concordance or browsing software based on annotations; metadata catalogues for all of these Data Processing layer data types. Procedurally, the platforms and applications used at the Data Processing layer are very varied, though there is a tendency to go for platform independence and standardised data interchange formats. By using modern laptops, both the Resource Archive and Data Processing layers can be integrated into a single mobile environment.

Corpus Pilot (CP) layer

The top layer of the model represents the functionality which needs to be available in an actual fieldwork situation. This functionality can be very varied, and much — especially free format interviews and film recording — lies outside the range of systematic computational support. However, the following on-site support features can easily be covered:

1. metadata editor and database,
2. participant database for interviewee, interviewer etc.,
3. structured or free format questionnaire presentation.

Interfaces

The interfaces between these three layers, and modules within these layers, are defined mainly on the basis of generic ASCII formats, including XML annotated text, CSV database tables, and RTF formatted documents (including IPA font information). For the interface between a palmtop implementation of the Corpus Pilot layer and the Data Processing layer, conversion scripts are provided as required, in order to export palmtop database and text formats into the generic ASCII formats. Data transfer at the implementation level is via the usual synchronisation functions provided with handheld devices, or via scp, http, and ftp procotols for laptops, desktops and server.

4. Implementation: hybrid applications

Resource Archive (RA) layer

The server archive provides web portal access for the local and global linguistic communities, CD-ROM access for the local linguistic community, and analogue selections (in general, tape cassette, print media) for practical applications in the local user community. Currently, the leading models for the Resource Archive level are provided by the LDC and ELRA dissemination agencies; the E-MELD project is developing a general model for best practice in resource collation, and a meta–portal for flexible access to language resources. The local server currently used for initial database collation contains a number of specific search functionalities for corpus analysis, in particular an audio concordance (Gibbon and Trippel, 2002).

Data Processing (DP) layer

The classical environment for fieldwork data processing is a laptop, often a Mac, but also very frequently an Intel based device configured alternatively with Linux or MS based portable standard software. The kinds of application typically used are for basic corpus processing: Transcriber and Praat for transcription and annotation; Shoebox for lexical database development; MS Office or StarOffice for word processor, database and spreadsheet applications. These may be augmented with custom applications in Java (cf. the TASX engine (Milde and Gut, 2001)) and Perl (PAX audio concordance).

Corpus Pilot (CP) layer

The Corpus Pilot layer is implemented as custom-developed Palm compatible PDA applications. The rationale behind the use of the PalmOS based handhelds, as opposed to the use of a laptop, is based on the following considerations:

1. extremely inexpensive (in relation to other computational equipment),

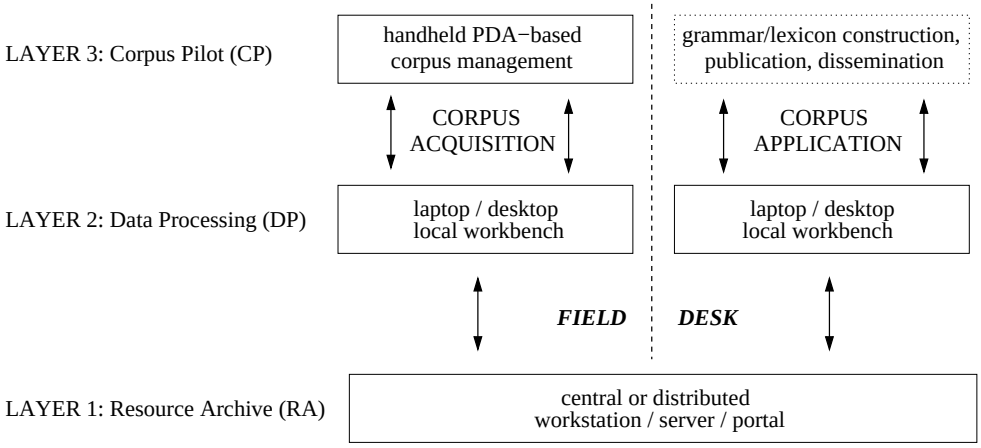

Figure 3: The three layer UbiCorpus model.

2. ultra-lightweight (lighter than other standard portable fieldwork equipment such as field laryngograph, DAT recorder),

3. long operating cycle (with normal use, around 3 weeks on 2 AAA batteries or one charge), depending on model,

4. fast and highly ergonomic in use,

5. small and unobtrusive in the interview situation,

6. an integrated environment with other PDA functionalities such as calendar, diary, address and other databases, other custom applications in C and Scheme.

Networking

The three levels are networked by standard techniques: server-to-applications in general via TCP/IP-based protocols and mobile or landline telephone. The applications-to-acquisition via dedicated sychronisation software of the kind typically used to link handheld PDAs to desktop installations.

Use in the field

The satisfaction of these criteria points towards a high level of suitability for use in extreme fieldwork situations without power supplies, for instance in isolated outdoor locations (forest, village, etc.).

The functionality which has been included in the Corpus Pilot layer so far covers the following:

- Metadata editor and database for audio/video recordings, photos, paper notes, artefact cataloguing. This application is based on a widely used PalmOS DBMS application, HanDBase, which provides a wide range of input support facilities (popups, date picker, free format notes, etc.), as well as cross-table linking.

- Questionnaire administration. In general, free text format has been used for questionnaire administration, and responses have been recorded for later out-of-field processing. For some questionnaire types (e.g. demographic information), the HanDBase DBMS is used.

- Lexicon development tools. Three applications are used for lexical database input (excluding freely formatted notes):

  1. an Excel-compatible spreadsheet, QuickSheet, which permits export in either CSV or Excel format (Excel is widely used in field linguistics as a convenient input tool for lexical databases, because of the ease with which databases may be constructed and restructed, and because it has many database-like functions, as well as built-in arithmetic functions if required for corpus work),
  2. the HanDBase DBMS which is also used for the metadata editor database,
  3. an implementation of the DATR lexicon knowledge representation language in LispMe, a Scheme implementation for the PalmOS platform (this application is a more Data Processing layer oriented tool, but is included in the Corpus Pilot layer implementation suite for convenience).

- Transcription support. In general, transcription in X-SAMPA (Gibbon et al., 2000) is used, but if required, IPA fonts may be used with the WordSmith word processor for PalmOS devices; RTF import and export facilities are available.

- Statistics package for initial evaluations. This is also a more Data Processing layer application, but integrated into the Corpus Pilot layer; functions include all the measures used in basic experimental and corpus work (including random sorting, mean, median, standard deviation, standard error, as well as standard pairwise comparison measures).

- Context-free parser package for basic grammar development. This is another Data Processing layer application, which is integrated into the Corpus Pilot layer because of the convenience of the LispMe Scheme application in which the parser suite is implemented.

The metadata application has been selected for detailed description, because it is most immediately relevant to the issue of language resources.

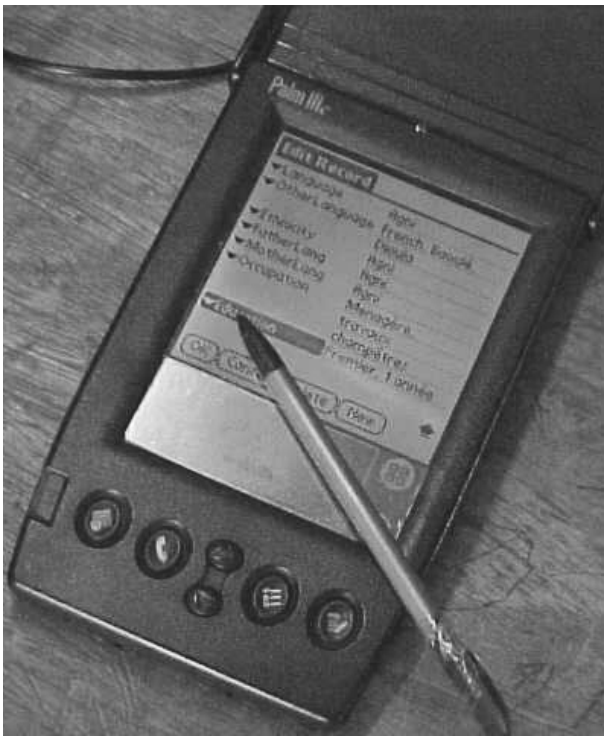

Figure 4: Palmtop metadata editor.

5. Metadata editor and database application

A metadata editor for audio/video recordings, photos, paper notes, artefact cataloguing was designed, based on a standard PalmOS relational database shell (HanDBase). The metadata editor provides a fast and inconspicuous input method for structured metadata for recordings and other field documentation, based on current work on metadata in the ISLE, E-MELD projects, and in the pilot phase of the DOBES project.

For the work in hand, standardised metadata specifications, such as the Dublin Core and IMDI sets, were taken into account. However, new resource types such as those which are characteristic of linguistic fieldwork demonstrate that the standards are still very much under development, since some of the standard metadata types are not relevant for the fieldwork data, and the fieldwork data types contain information not usually specified in metadata sets, but which are common in the characterisation of spoken language resource databases (Gibbon et al., 1997). In respect of the fieldwork resource type, it appears that it cannot be expected that a truly universal — or at least consensual — set of corpus metadata specifications will be developed in the near future, or perhaps at all, at a significant level of granularity. It may be possible to constrain the attribute list, though the existence of many different fieldwork questionnaire types belies this. However, the values of the attributes are in general unpredictable, entailing not only free string types but possibly unpredictable rendering types (e.g. different alphabets; scanned signatures of approval).

Indeed, it may be noted in passing that the expectation of fully standardising the entire metadata specification tends to reveal singularly little awareness of the potential of machine learning and text mining procedures for handling generalisation tasks of this kind. It may be predicted that such procedures will be applied in future not only to extensive resource data sets but also to increasingly extensive sets of metadata.

In consequence, the metadata specifications used in the UbiCorpus applications are deliberately opportunistic, in the sense that they are task-specific and freely extensible. A selection of attributes and values for the current fieldwork application are shown in Table 1. Metadata attributes concerned with the Resource Archive layer of archiving and property rights are omitted.

For current purposes, databases are exported in the attribute-value format shown below and converted into the TASX reference XML format (Milde and Gut, 2001). A specific example of the application of the metadata editor in the fieldwork session pictured in Figure 1 is shown in the exported record shown in Table 2.

The metadata editor and database application has been tested extensively in fieldwork on West African languages, and has proved to be an indispensable productivity tool, especially in difficult situations where very limited time is available.

6. Conclusion

Architectures using the first two levels, e.g. a server configuration and a laptop for use in the field, are very com-

mon. However, in many situations the laptop concept is unsuitable because of heavy power requirements which are not available in many fieldwork locations. For these applications, the PalmOS based family constitutes the platform of choice because of minimal size and power requirements, permitting several weeks use on one charge or small battery. Although the PalmOS platform is obviously unsuitable for signal processing applications (such as time-aligned annotation) it is well-suited for logging, transcription and reference purposes.

The power of PDA miniature computing platforms as useful components of laboratory and office environments is often underestimated, and we demonstrate that a number of applications for which even a laptop is clumsy or unsuited for the developing field of computational ethnolinguistic fieldwork may be elegantly provided on the Palm PDA platform. The addition of a foldable keyboard further enhances the text handling capacity of the devices.

In the medium term, it will be possible to integrate the hybrid applications at the Corpus Pilot, Data Processing and Resource Archive levels into a corpus management environment which not only permits seamless dataflow and workflow, a goal already achieved, but also into a non-technical user-friendly prototype which may serve as the basis of a fieldwork management product implementation.

The UbiCorpus architecture has been used as the basic specification for different kinds of language documentation work in a variety of different projects. The Resource Archive layer was originally designed and implemented for web–based lexical database development in the VerbMobil project (Wahlster, 2000), funded by the German Federal Ministry of Education and Research (BMBF). The concept has been further developed theoretically and practically in connection with the projects *Theorie und Design multimodaler Lexika* funded by the German Research Council (DFG), *Enzyklopädie der Sprachen der Elfenbeinküste* funded by the German Academic Exchange Service (DAAD) and *Ega: a documentation model for an endangered Ivorian language* in the pilot phase of the DOBES funding programme of the Volkswagen Foundation.

In its local implementation, the current Resource Archive layer version also includes support for telecooperation and web-teaching. The Data Processing layer includes numerous applications which cannot be specified here. The Corpus Pilot layer as described in the present contribution has been informally but extensively field tested at a number of fieldwork locations, most recently in the framework of DAAD funded doctoral thesis work. It is planned to apply the field testing criteria defined in (Gibbon et al., 2000) to an extended implementation of the components of UbiCorpus model.

Abstract

To discuss the portability of human natural language technology, it is necessary to define the portability precisely first. If one claims that his or her language technology works for other languages, how can we verify such claim when every language has a different set of features, i.e. speech or text tagging system? This paper presents a view of protabilty as a function of a common representable set of features and argues that the development of such representation is critical in discussing portability issues.

1. Introduction

If you try a sentence boundary identification program[1] developed for English, you will easily notice that it does not work for other language such as Korean. However, the developers never mention that the program will not work for other languages. It is a very common practice among developers to ignore the portability issues in human language related technology because it is often targeted for only one language and assumed to work for that language. Yet, such ignorance is missing too many opportunities for the future success of the technology. If a technology that works for one language can be extended to another language with a minimal modification, such technology can be regarded as the most valuable technology in its potential considering the fact that there exists more than 6,000 languages in the world.

The main difficulty of applying a technology that works for one language into another is obviously due to the set of features that are unique to one specific language. The more the technology resorts to those features, the less it will succeed on other languages. In this regard, it is necessary to separate out those features and to concentrate on the common features that every language shares for maximal portability. Finding the common grounds for all languages is not an easy task but can be achieved by abstracting levels of language processing into hierarchy. In other words, there are different levels of sources that hinders the portability during human language processing and the portability problem should be discussed in as high level as possible.

This leads to the central question of this paper: if one claims that one's language technology works for other languages, how can we verify such claims when every language has a different set of features, i.e. speech or text tagging system and quantify its portability? The only way to determine it is to test how many features are translatable into the common feature sets which are similar to the interlingua in machine translation. This paper presents a view of portability as a function of a common representable set of features and argues that the development of such representation is critical in discussing portability issues.

[1] http://l2r.cs.uiuc.edu/~cogcomp/cc-software.html

2. Sources of Portability Problem

To identify the sources of portability problem in human language technology, it seems wise to illustrate it with the actual examples that might occur in statistical machine translation, namely sentence boundary identification for aligning sentences and word sense disambiguation for word selection. Here, we identify two categories in portability problems and formalize it. For the rest of the paper, we use a term *program* to denote a particular instance of human language technology.

2.1. Representational Problem

Almost every language has its own unique set of features. At the same time, some languages share many common features. For example, semantic or syntactic features like the notion of person's name and noun phrases are quite universal. On the other hand, honorifics used in Korean or Japanese language is hard to find in European languages. Such uniqueness of features is the major obstacle for the portability of human language processing program. For example, if you want to create a sentence-aligned corpus for statistical machine translation, the first step is to identify sentence boundaries. If one program uses the notion of capitalized word to determine whether the period is used for abbreviation or not, it won't work for a language, like Korean, that doesn't have any notion of the capital word in its writing system. For a program to be fully portable, it should avoid using such features.

Clearly, we can distinguish between two different feature sets which we will call *soft* and *hard* features. If some features are common in two or more languages, we call them soft features; otherwise hard features. Soft features are ubiquitous in the same families of languages and they are all functionally equivalent. One key observation is that features are independent from the surface forms of one particular language. For example, the same parsing program can be used to parse two different languages although grammatical notations of the languages are different as long as they can be mutually translated into the equivalent representation.

2.2. Functional Problem

Although two languages share the same soft features, not all functions consistently generate the desired outputs based on them. Let's assume that we want to disambiguate

senses of English words based on the local context feature such as n-grams to find the corresponding Korean words in statistical machine translation(Ng and Lee, 1996). If you could achieve 90% of accuracy on the task with such method in English, it does not guarantee the same accuracy in Korean. The reason for such discrepancy can be attributed to the previous representational problem but the key issue that we want to emphasize here is only the performance aspect of the program. This is a separate dimension of portability problem which is related to the performance-wise consistency issue. A good portable program should perform well with the minimal variance and high accuracy across several languages. For example, if a machine translation system that performs very well on English-Korean translation fails on English-Japanese translation with the same soft set of features, we can say that such system has a functional problem in portability.

3. Theory of Portability

In this section, we present a functional view of portability in a more formal way by providing definitions and examples first and then theorems derived from them.

3.1. Definition of Portability

Definition 1 Features *are any properties of language that are used in a program P as inputs X and outputs Y. A* program *P is a collection of* functions *f.*

Example 1 *Period, question mark, and exclamation mark are features used in English for sentence boundaries.*

Definition 2 *Let's denote a set of all features for language L as $\chi(L)$.* Soft features *Z for a set of languages $L_1, \ldots, L_n$ are features s.t. $\forall z \in Z, z \in \bigcap_i^n \chi(L_i)$. All other features that are not soft features are* hard features *$Z' = \bigcup_i^n \chi(L_i) - Z$.*

Example 2 *Let $n = 2$ and L_1 is Korean and L_2 is English. Period, question mark, and exclamation marks are soft features used in both L_1 and $L2$ for sentence boundaries. The capitalization of words is a hard feature unique in L_2.*

Definition 3 *A family of languages are called* σ-similar *if $\frac{|Z|}{|Z|+|Z'|} = \sigma$ w.r.t. P.*

Example 3 *Let's assume that a sentence boundary identification program P uses only four features: period, question mark, exclamation mark, and a test value $\{0, 1\}$ for capitalization for the word that ends with a period. Again, if $n = 2$ and L_1 is Korean and L_2 is English, two languages are $\sigma(= 0.75)$-similar since $|Z| = 3$ and $|Z'| = 1$.*

Definition 4 *A function $f: X \rightarrow Y$ is called* σ-portable *for n σ-similar languages $L_1, \ldots, L_n$, if $X \subseteq Z$ and $Y \subseteq Z$ for a soft feature set Z.*

Example 4 *Let f be a classification function that uses the previous four features in Example 3 as input X and the boolean truth value $\{0, 1\}$ (to indicate a sentence boundary) as output Y. Then, f is $\sigma(= 0.80)$-portable.*

Definition 5 *A program P is* σ-portable *iff $\exists \sigma > 0$ among n languages and all f are σ-portable over $\sigma \cdot \sum_{i=1}^{n} |\chi(L_i)|$ soft features.*

Example 5 *Let P be a sentence identification program that has two functions f_1 and f_2. Let f_1 be the classification function in the previous example and f_2 be a boolean function that test the capitalization of words. Then, P is* not *σ-portable for English and Korean because f_2 uses hard feature. If P has only one function f_1, we can claim that P is σ-portable.*

Definition 6 *A function $f: X \rightarrow Y$ is called* ϵ-portable *over n languages $L_1, \ldots, L_n$, if $\forall i, j (1 \leq i, j \leq n), Pr(f_i \neq f_j) < \epsilon$*

Example 6 *Let f be a classification function in Example 4. Since Korean sentences do not use periods for abbreviation purposes, it is easy to see that $Pr(f_k = 1) > Pr(f_e = 1)$ when equal number of examples are represented with soft features. If the difference $Pr(f_k = 1) - Pr(f_e = 1)$ in such empirical performance of f over two languages is less than the predefined bound 0.02, we can say that f is $\epsilon(= 0.02)$-portable.*

Definition 7 *A program P is ϵ-portable if all functions $f \in P$ are ϵ-portable and generates the coherent output over n languages with the confidence at least $1 - \delta$ for some small ϵ, δ.*

Example 7 *Let P is a program that has only one f in Example 6. If f is tested on Japanese and also produced the result of $Pr(f_k = 1) - Pr(f_j = 1) < \epsilon$ and $Pr(f_e = 1) - Pr(f_j = 1) < \epsilon$ with at least $1 - \delta$ accuracy over many examples, we can say that P is $\epsilon(= 0.02)$-portable.*

3.2. Theory of Portability

Here, we introduce the notion of portability similar to the learnability notion in the learning theory (Valiant, 1984). The first theory is related to the representational problem.

Theorem 1 *Soft features are harder to obtain as the number of languages n increases.*

$$|Z_n| \geq |Z_{n+1}|$$

Corollary 1 *Hard features are easier to obtain as the number of languages n increases.*

$$|Z'_n| \leq |Z'_{n+1}|$$

Proof This is obvious from the definition of soft features. Since soft sets are extracted from the common feature sets, there are less features than previous n-th soft feature set unless all features are soft features in $n+1$-th language. On the other hand, hard features are obtained from the union of the feature sets and the size of them grows over n. ∎

Lemma 1 *σ is monotonically decreasing over the number of languages n increases.*

Now, let's look at the hardness of portability issue which is the main topic of this paper by combining two parameters — σ and ϵ. First, let's define probably approximately correct(PAC) portability as follows:

Definition 8 *A program P is* PAC-portable *if P is both σ-portable and ϵ-portable.*

If we apply the same technique used in (Haussler, 1988), we get the *PAC-portability bound* which is similar to the PAC-learnability bound as shown in Equation (1). It is adapted from (Mitchell, 1997) for illustration purpose.

$$m \geq \frac{1}{\epsilon}(\ln |H| + \ln(1/\delta)) \quad (1)$$

We can replace m with $\binom{n}{2} = \frac{n(n+1)}{2}$ and $|H|$ with $2^{\sigma k}$ where $k = \sum_{i=1}^{n} |\chi(L_i)|$ by assuming that the number of different functions are only dependent on the size of soft set $|Z| = \sigma k$.

Theorem 2 *If a program P is PAC-portable with some small σ, ϵ and δ, the total number of portable languages n is bounded by:*

$$\frac{n(n+1)}{2} \geq \frac{1}{\epsilon}(\sigma k \ln 2 + \ln(1/\delta)) \quad (2)$$

The following proof is essentially same as what Haussler (1988) showed.

Proof Let F be all the functions that use soft features in n languages. Clearly, there are at most $|F| = 2^{\sigma k}$ possible functions in P over σk soft features and $k = \sum_{i=1}^{n} |\chi(L_i)|$ is a constant for n languages. Let $f^1, f^2, \ldots, f^l$ be all functions in P such that each pair of functions (f_i^l, f_j^l) over two languages i, j have true error greater than ϵ. We need to consider the all pairs of functions over n languages and there exists $\binom{n}{2} = \frac{n(n+1)}{2}$ pairs for each f^l. We fail in ϵ-portability if and only if at least one of these f^l pairs fails. The probability that at least one of these will be consistent with all n languages is at most

$$l(1-\epsilon)^{\frac{n(n+1)}{2}}$$

And since $l \leq |F|$, this is at most $|F|(1-\epsilon)^{\frac{n(n+1)}{2}}$. Finally, we use an inequality that if $0 \leq x \leq 1$ then $(1-x) \leq e^{-x}$. Thus,

$$l(1-\epsilon)^{\frac{n(n+1)}{2}} \leq |F|(1-\epsilon)^{\frac{n(n+1)}{2}} \leq |F|e^{\epsilon\frac{n(n+1)}{2}}$$

upper bound holds.

We can use the above result to determine the number of languages required to reduce the portability failure below some δ.

$$|F|e^{\epsilon\frac{n(n+1)}{2}} \leq \delta$$

which means that we need

$$\frac{n(n+1)}{2} \geq \frac{1}{\epsilon}(\ln |F| + \ln(1/\delta))$$

By substituting $|F| = 2^{\sigma k}$, we get the

$$\frac{n(n+1)}{2} \geq \frac{1}{\epsilon}(\sigma k \ln 2 + \ln(1/\delta))$$

which is identical to Equation (2) ∎

This is correct because a program P can be regarded as portable for n languages as long as at least one function in F survives the portability test bounded by ϵ and δ. Consequently, it is easy to see that a program P that has many functions needs more languages to ensure portability.

4. Discussion

Although there has been a significant amount of computational linguistic research for major languages such as English for more than fifty years, the portability issue of natural language technology based on such research has not been studied until recently.

However, portability of technology is neither cheap to obtain nor trivial to implement according to our theory. From the functional perspective of language technology, the efforts of linguists can be described as finding good theories or rules that can generate both universal and local features for various languages. Likewise, one of the main reasons in the recent success of statistical natural language processing techniques(Manning and Schutze, 1999) can be found in its portability. Statistical approaches, unlike traditional symbolic approaches, are less dependent on language specific features. Our definition of portability demonstrates that as the number of soft features increases, the same technology is portable for more languages. If σ is fully dependent on n and decreases linearly, the technology is not portable. If one can find a good features that are not affected by n and a robust technology that depends only those features, then such technology can enjoy its maximum portability.

To claim portability of a technology, empirical justifications of its performance guarantee are also required over many languages and this is reflected in the parameter ϵ. What it suggests is that even if the same statistical method that uses the common features in many languages, the distribution of features could be dependent on each language and thus significantly different from others. Our theory clearly demonstrates that reducing portability error ϵ requires $O(\sqrt{n})$ languages to be verified with.

5. Conclusion

We presented a formal PAC framework for the functional view of portability. Although it is still a sketchy work, the main contribution of this work is to define portability in a formal way and show the relation among features and performance measures. Therefore, the development of good theories and rules that can work for as many languages as possible and the empirical application of them is critical in discussing the portability issues.

A requirement analysis for an open set of human language technology tasks

Fredrik Olsson

Swedish Institute of Computer Science
Box 1263, SE-164 29 Kista, Sweden
fredrik.olsson@sics.se

Abstract

This work presents a requirement analysis and a design proposal for a general architecture for a specified, yet open set of human language technology (HLT) tasks — the set chosen is dubbed *information refinement*. Apart from using information refinement as a means to focus the requirement analysis and accompanying design proposal, the analysis and proposal are based on a survey of a number of projects that have had great impact on the realisation of today's HLT architectures, as well as on the experiences gained from a long-term case study aiming at composing a general purpose tool-kit for Swedish. The analysis and design are currently used in an ongoing effort at SICS to implement an open and general architecture for information refinement.

1. Introduction

During the last few years, the need for general, reusable software for computational linguistics and human language technology (HLT) has become widely acknowledged by the research community as well as by the industry. Usually, the overall motivation of striving for reusable software is to shorten the way from the origin of an idea to its implementation in a prototype system. Utilising reusable software also means that the effort spent in building an HLT system is reduced, and thus, that personal labour can be focused on more important issues.

The aim of this paper is to present a requirement analysis and design proposal for a specified, yet open set of human language technology tasks — *information refinement* is introduced as constituting a set of related tasks intended to serve as a target for developing a general and open architecture, Kaba. The requirement analysis and design proposal presented in sections 7. and 8. are based on three parts: the notion of information refinement (Section 2.); a survey of a number of projects and software that have had great impact on how HLT software is constructed today (TIPSTER, CLE, ALEP, GATE, DARPA Communicator, and ATLAS presented in Section 3.); and on the experience gained from a case study on constructing a language processing tool-set for Swedish in a national project called SVENSK (Section 4.). See (Olsson, 2002) for an elaboration on the requirements specification and design of an open architecture for information refinement.

2. The notion of information refinement

By the term information refinement, the *process* is referred to in which text is handled with the aim of *accessing* the pieces of content that are relevant from a certain *perspective* (Olsson et al., 2001).

Information access is about providing people with different tools and methods for granting reliable and simple access to the information they need, ideally with awareness of task and context of the access situation. A system for information access is intended to see to an expressed information need. Such a need is not always static — the *process* of searching for information is a dynamic one in which the information need, sources of information, characteristics of the task, and the type of text involved may change during a search session.

Since different readers have different information needs, prerequisites, and attitudes, they also have different *perspectives* when reading one and the same text. When considering that there are different perspectives, it is natural to think of information access and refinement systems as something that should not (only) deliver texts in their entirety, but rather in some sense understand the contents of the text and tailor the information according to the reader's perspective.

Information exctraction, information retrieval and automatic summarisation are all examples of human language techniques that fall under the information refinement category. Current work concerning information refinement at SICS include protein name tagging (Eriksson et al., 2002), information access using mobile services (Hulth et al., 2001), and support of professionals in information seeking (Hansen and Järvelin, 2000).

3. Some important HLT projects

This section introduces some of the software and projects that have, or have had, impacts on the ways today's software for HLT is designed and implemented. The survey of the literature in the area is not exhaustive, but merely provides an overview of the aspects and features of some important projects.

3.1. The TIPSTER architecture

The TIPSTER project (Grishman et al., 1997) was a joint effort between a number of U.S. government agencies led by DARPA and funded by CIA, DARPA, and DoD in collaboration with NIST and SPAWAR. The project started in 1991 and ended due to lack of funding in 1998.

The main focus of TIPSTER was to improve document processing efficiency and cost effectiveness, and in doing that, technologies such as information retrieval, information extraction, and automatic text summarisation were of great interest. There were two primary goals of the TIPSTER project, the first of which was to provide developers and users with an architecture that allowed for information retrieval in several gigabytes of texts, and the second goal was to provide an environment for research in document

detection and data extraction. However, by the time the project was discontinued, no fully implemented version of the TIPSTER architecture was produced.

3.2. CLE

SRI International's Cambridge Research Centre and Cambridge University's Computer Laboratory in 1985 suggested a UK-internal project developing a Core Language Engine (CLE), a domain independent system for translating English sentences into formal representations (Moore and Jones, 1985; Alshawi et al., 1992).

SRI's CLE built on a modular-staged design in which explicit intermediate levels of linguistic representation were used as an interface between successive phases of analysis. The CLE has been applied to a range of tasks, including machine translation and interfacing to a reasoning engine. Smith (1992) gives two examples of such systems; the LF-Prolog Query Evaluator and the Order Processing Exemplar (OPEX). The modular design also proved well suited for porting to other languages and the implementation was quite efficient. Thus, the project proved its purpose. However, even though the CLE system received considerable attention, it failed to spread in the community, the main reason being that it simply was too expensive to obtain it.

3.3. ALEP

The origin of the Advanced Language Engineering Platform (ALEP), the work on which started in 1991 and ended in 1995, was the issue of the lack of a general platform for research and development of large scale natural language processing systems (Simpkins, 1995; Bredenkamp et al., 1997). ALEP was an initiative of the Commission of the European Community (CEC) based on the experiences from the Eurotra and CLE projects.

ALEP was intended to function as a catalyst for speeding up the process of going from a research prototype of a system to a ready-to-ship product. The kind of users that ALEP first and foremost was targeted at were advanced experts, i.e., researchers in computational linguistics, possibly in conjunction with application developers. Simpkins (1995) expected that the openness of ALEP would attract users for research and development. Later, it turned out that this was not the case and ALEP never became widely spread.

3.4. GATE

Since the mid 90's, the General Architecture for Text Engineering (GATE) platform as reported on by, e.g., Cunningham (2000) is being developed at the University of Sheffield and funded by the U.K. Engineering and Physical Sciences Research Council (EPSRC). GATE provides a communication and control infrastructure for linking together language engineering software. It does not adhere to a particular linguistic theory, but is rather an architecture and a development environment designed to fit the needs of researchers and application developers. GATE, currently available as version 2.0, is free for non-commercial and research purposes.

GATE supports reuse of resources, data as well as algorithms, since it provides for well-defined application programmers interfaces (APIs). Once a module has been integrated in the system, it is very easy to combine it with already existing modules to form new systems. Each component integrated into GATE has a standard I/O interface, which conforms to a subset of the TIPSTER annotation model. The infrastructure of GATE provides several levels of integration, reflecting how closely a new module should be connected to the core system.

3.5. The DARPA Communicator

Currently, the MITRE Corporation is (under DARPA funding) developing the DARPA Communicator. The goal of the DARPA Communicator is to set the scene for the next generation of conversational, multi-modal, interfaces to distributed information to be used in, e.g., travel planning, that require information from different sources to be combined.

The reference DARPA Communicator architecture builds on MIT's Galaxy-II system (Polifroni and Seneff, 2000; Seneff et al., 1999; Seneff et al., 1998). Among its key features, the authors list the ability to control system integration using a scripting language: each script includes information about the active servers, a set of operations supported by the server, as well as a set of programs. An in-depth explanation of the program control is given by Seneff et al. (1999). Essentially, the Galaxy-II system builds on a central process, the Hub, which mediates information between a number of different servers. The Galaxy-II system supports a wide range of component types, e.g., language understanding and generation, speech recognition and synthesis, dialogue management, and context tracking (Goldschen and Loehr, 1999).

There is a freely available, public version of the core DARPA Communicator.

3.6. ATLAS

The Architecture and Tools for Linguistic Analysis Systems (ATLAS) project is conducted by NIST, MITRE and LDC (Bird et al., 2000). The main goal is to develop a general architecture for annotation of linguistic data, including a formal/logical data format, a set of APIs, a tool-set, and persistent storage.

Within the ATLAS project, the participants are mainly interested in creating a formal framework for constructing, maintaining, and searching in linguistic annotations. In some aspects, the ATLAS annotation set model seems very similar to the TIPSTER annotation scheme. Bird and Liberman (2000) say that there are several ways of translating a TIPSTER-style annotation to a corresponding ATLAS one. In the end, the ATLAS working group concludes that TIPSTER-like annotations are not appropriate for audio transcriptions, except for "cases where such transcriptions are immutable in principle", (Bird and Liberman, 2000).

4. A case study — SVENSK

The SVENSK project was a national effort funded by the former Swedish National Board for Industrial and Techni-

cal Development (Nutek) and SICS addressing the problem of reusing language engineering software, see e.g., (Eriksson and Gambäck, 1997; Gambäck and Olsson, 2000). The SVENSK project was divided into three phases, spanning the spring of 1996 to the end of 1999. The aim has been to develop a multi-purpose language processing system for Swedish based, where possible, on existing components. Rather than building a monolithic system attempting to meet the needs of both academia and industry, the project has created a general tool-box of reusable language processing components and resources, primarily targeted at teaching and research.

The re-usability of the language processing components in SVENSK system arises from having each component integrated into GATE.

Collecting and distributing algorithmic resources and making different programs inter-operate present a wide range of challenges, along several different dimensions outlined next.

4.1. Diplomatic challenges

Making language processing resources freely available and, in particular, re-usability of resources is really a very uncommon concept in the computational linguistic community. Possibly this also reflects another uncommon concept, that of experiment reproducibility. In most research areas the possibility for other researchers to reproduce an experiment is taken for granted. It is even considered as the very core of what is accepted as good research at all. Strangely enough, this is seldom the case in computer science in general and even more rare within computational linguistics, perhaps because of tradition or lack of interest.

4.2. Technical challenges

From the technical point of view, one major conclusion is that the difficulties of integrating language processing software never can be over-estimated. Even when using a liberal architecture such as GATE it is hard work making different pieces of software from different sources and built according to different programming traditions meet any kind of interface standard.

In a way, it is understandable that academia does not always put much effort in packaging and documenting their software, since their main purpose is not to sell and widely distribute it. More surprising and discouraging, however, is that some of the actors on the commercial scene do not document their systems in a proper manner, either. Far too often this has resulted in inconsistencies with the input and output of other modules.

4.3. Linguistic challenges

Of course, language engineering components differ with respect to such things as language coverage, processing accuracy and the types of tasks addressed. It is also the case that tasks can be carried out at various levels of proficiency. The trouble is that there is no quality control available neither to the tool-box developer nor to the end-user. If a large number of language processing components are to be integrated, they should first be categorised so that components with a great difference in, say, lexical coverage are not combined.

A familiar problem for all builders of language processing systems relates to the adaptation to new domains. When reusing resources built by others this becomes even more accentuated, especially if a language engineering resource is available only in the black-box form (and thus relates to the issues of the previous subsection).

5. General observations and experiences

Below are some broad conclusions — focal points — drawn from the previous and present chapters, of what should be considered when creating a general HLT architecture:

1. **An architecture should be general with respect to a class of tasks, not to an entire field of research** The issue of *how* general an architecture should be needs to be considered since a too general one tends to be hard to handle.

2. **Keep the software open** There are various dimensions along which software could be considered open: distributing and licensing it; keeping its source open and inviting other people to participate in developing it; and to achieve software that are easily adaptable to new domains and types of information.

3. **Allow for use of existing programs as well as for the creation of system-specific ones** The potential drawback in using existing, externally produced software concerns issues such as, e.g., maintenance, fixing bugs, and extending/updating resources such as lexica and ontologies. All these things rely on the external program being supported by its producer.

4. **Support maintenance of systems and the components making them up** Develop tools and methods to support maintenance of components and systems, both on the linguistic level, e.g., integrated machine learning methods for lexical acquisition and grammar induction, and on the software level, e.g., new file formats and operating systems.

6. Motivation for a new architecture

The motivation for building a new architecture is primarily due to the fact that when information refinement emerged as a research area at SICS, there was no single architecture which fulfilled the demands that SICS's projects made at the time. In particular, no one of the existing platforms granted us full access to the source code and full distributional rights of the code, something which would be of great interest to us since we wanted to be able to distribute the source code of future information refinement systems freely, and since the functionality of the tools used for information refinement will have to be tuned to each new information refinement task. The latter may include changes to, e.g., the way the tools interact with each other and with the user, as well as the kind of data they produce — such changes may be difficult to achieve unless the software architecture hosting the tools is accessible at the source code level.

The work on a new HLT architecture called Kaba is an ongoing effort which was initiated in 1999 by Kristofer Franzén and Jussi Karlgren at SICS. At first, Kaba was intended to constitute an information extraction system for Swedish. An attempt at porting an existing information extraction system from English to Swedish turned out to be cumbersome (Franzén, 1999). Along the above lines, the conclusion was reached that future research in information refinement at SICS would benefit from a research vehicle having been built on site. Since 1999, the research focus has shifted slightly from information extraction to the more general goal of information refinement, which makes the need for an open and general architecture even clearer.

7. Requirement analysis

Deciding on what requirements are relevant for a given project tends to be a top-down process, going from broad issues such as, e.g., that the software under development should be portable to new operating systems, to splitting the portability into more specific sub-requirements. Requirements analysis always asks the *what*-questions regarding the software, e.g.: *what* equipment constraints exist, and *what* functions are to be incorporated. The *how*-questions are issued in the design phase described in Section 8..

Kaba is intended to function as a tool for developers of information refinement systems, first and foremost for research systems, but also for prototypes for testing ideas within information refinement. Kaba will *not* be a fixed set of tools for creating ready-to-ship products.

A typical Kaba user is a computational linguist with programming skills. This person's role is to use Kaba for the creation of information refinement systems to be used further in research and prototyping.

7.1. Project constraints and external factors

To accomplish the portability of Kaba on the software level, a widely supported programming language, such as Java, has to be used throughout the development process to implement all parts of the architecture. Further, Kaba will require (and presuppose) a linguistic processor that performs basic linguistic analysis of the texts to be processed, e.g., part-of-speech tagging and some fundamental grammatical analysis. Most likely the processor will be the Swedish and the English Functional Dependency Grammars (FDG) from Conexor Oy, Helsinki, Finland (Tapanainen and Järvinen, 1997).

Kaba must be implemented using a technology and an environment that facilitates easy integration of in-house or third party software for linguistic analysis as well as basic computational facilities, e.g., for reading and writing various file formats.

7.2. The scope of the work

Figure 1 shows three different ways that an information refinement system based on Kaba can interface with its environment, and thus gives some notion of what a developer of such a system has to deal with. What differs between the three constellations is the kind of user the system is intended for. In Figure 1 A, the system interacts with an information provider of some sort, e.g., a web site, a database,

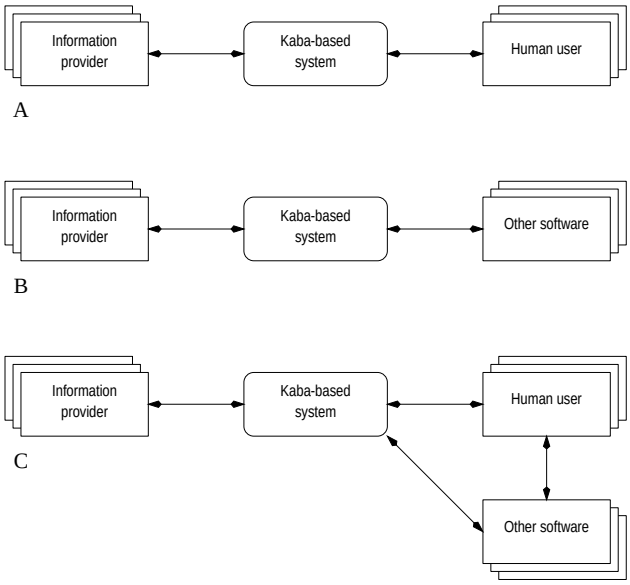

Figure 1: Characteristics of the environment of a Kaba-based system.

or a mobile service, on the one hand, and a human user on the other.

In Figure 1 B, the Kaba-based system communicates with the same kind of information provider as in Figure 1 A, but with another machine as counterpart instead of a human. The setup illustrates the case when a Kaba-based system is part of a larger system.

Finally, Figure 1 C, shows a configuration in which the system interacts with a human user as well as another machine.

7.3. The scope of the architecture

When starting to look at what a user may want to do with Kaba, it seems as a good idea to structure the requirements into what is commonly known as use cases (UC). Cockburn (1997) gives an overview of a method that deals with the identification and structuring of UCs. He defines a use case as being what happens when *actors* interact with a system to achieve a desired goal. An actor is an external entity (human or other software) that uses the system. In effect, UCs hold the functional requirements of a system in an easy-to-read format, and they represent the goal of an interaction between an actor and the system.

In total, 30 use cases have been identified for Kaba and seven of these constitute the top level of the use case hierarchy (Olsson, 2002):

UC 1: Develop an information refinement research and development prototype system.

UC 2: Evaluate an information refinement research and development prototype system.

UC 3: Port an existing system to a new domain or language.

UC 4: Document system.

UC 5: Maintain system.

UC 6: Create learning material or tutorial.

UC 7: Manage LR and PR components.

Use cases 1 and 7 each have several sub-goals which are illustrated in Figure 2 and Figure 3, respectively.

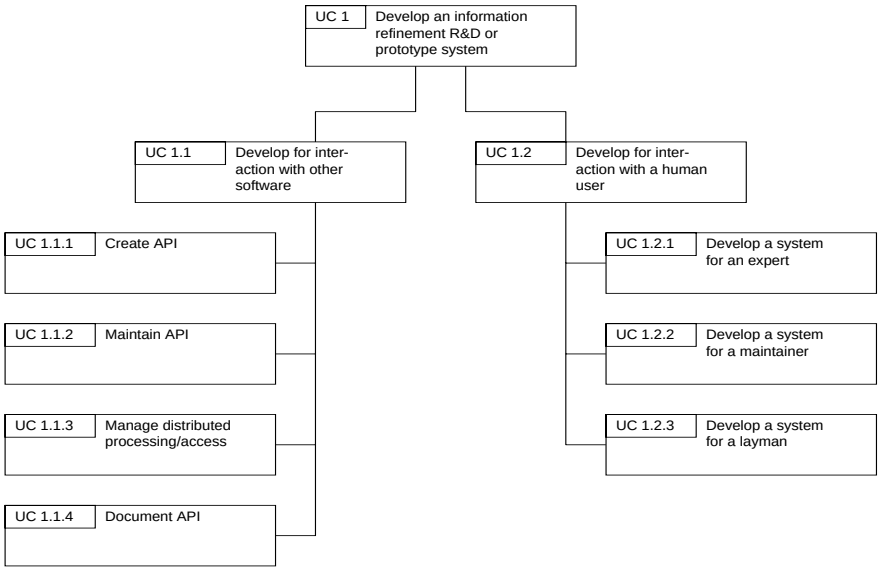

Figure 2: Schematic view of use case 1 and its sub-goals.

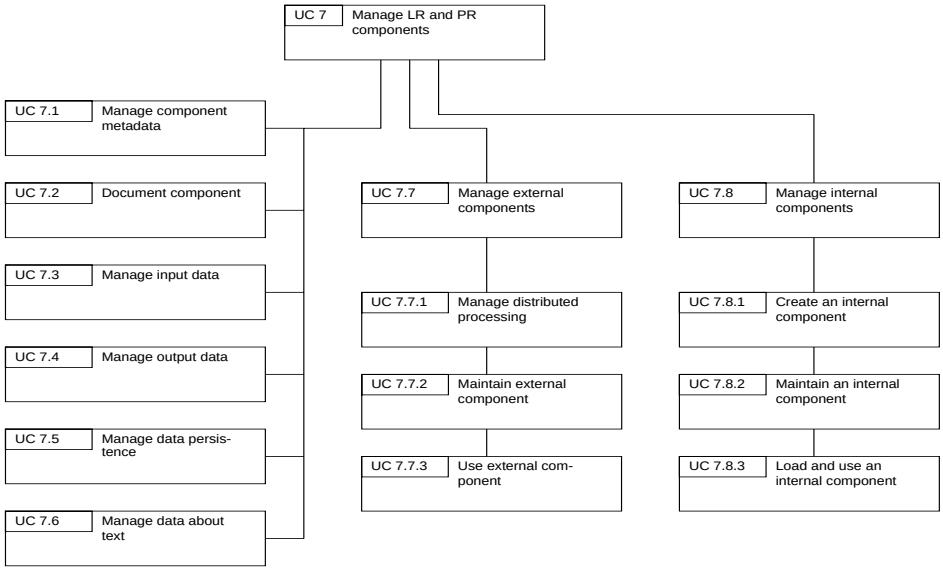

Figure 3: Schematic view of use case 7 and its sub-goals.

8. Design proposal

The design proposal is intended to give a hint as to how the requirement analysis could be realised.

8.1. Component metadata

This section covers use case 7.1 (*Manage component metadata*). Metadata about both language resources (LR) and processing resources (PR) is needed for several reasons, the first of which is to allow the developer (and the future users of the system) to browse a collection of components to see what components there are in order to build an information refinement system utilising existing components. In the same manner, metadata can be used to identify shortcomings of existing components and act as a basis for requirements analysis and specification when new language processing components need to be constructed or when new language resources need to be developed.

There are several means by which metadata can be expressed, and it seems natural to convey such data in the same format as the components themselves are annotated or produce annotations about text. Thus, the system internal format of metadata should correspond to the internal format of the data about text as described in Section 8.3., while the external format of metadata should agree with the format for data persistence described in Section 8.4..

8.2. Input and output

This section deals with use cases 7.3 (*Manage input data*) and 7.4 (*Manage output data*). The Kaba information refinement development platform presupposes that some sort of linguistic analysis has been performed on the text to be processed by a Kaba-based system. Currently, the FDG for English and Swedish are intended to be used, but it should also be possible to use any TIPSTER compliant linguistic processing component.

On the output side, a Kaba-based system should be able

to generate representations of the text it has processed in a format suitable to the user, regardless of whether the user is another computer program or a human.

8.3. System internal representation of annotated text

This section covers use case 7.6 (*Manage data about text*). Data about text can be expressed in various ways and the crucial point in all data representation is that it should facilitate rapid access to arbitrary pieces of information about the text. The representation formalism should allow for scaling up without causing the system's performance to drop.

While the format of the external and persistent data is like XML (see Section 8.4.), the internal representation is based on the TIPSTER annotation scheme. Although the two schemes are conceptually different the conversion between TIPSTER-style annotations and XML-based representations is quite straightforward.

8.4. Data persistence

This section deals with use case 7.5 (*Manage data persistence*). Data persistence is needed in order to provide Kaba with multiple-session capabilities, that is, to allow a user to work with the same source of information during several sessions and, in each session, having access to the results from the previous ones. The need for working in multiple sessions may occur, e.g., due to a system crash, for saving intermediate results, or simply because the user needs to interrupt the refinement process for other reasons.

The most suitable format is likely to be some instance of XML, partially because of the fact that it is becoming increasingly widespread in language engineering applications, and partially because there exist tools for manipulating and converting between different instantiations of XML.

8.5. Interacting with others

There are several aspects of interaction which have to be taken into account when designing an information refinement architecture like Kaba: (1) when a Kaba-based system is used by other software as a part of a larger system, (2) when a Kaba-based system utilises external components, both processing and data, as a part of an information refinement system, and (3) when a Kaba-based system needs to interact with human users.

Case (1) is reflected in use case 1.1.1 (*Create API*). In effect, what is required for a Kaba-based system to function in the context of a larger system, is a means for the developer of the larger system to have access to a restricted and well-defined set of the functionality in the Kaba-based system. Such access can be provided by means of a Java API.

Case (2) is addressed in use case 7.7.3 (*Use external component*) which concerns how to allow a Kaba-based system to use external components, i.e., components not primarily implemented for use within Kaba such as, for instance, part-of-speech taggers and ontologies. To allow Kaba to interact with external components, it is important that the components all look the same from Kaba's point of view. This means that the APIs that Kaba has to use to achieve this interaction have to be well defined and consistent.

Case (3) is addressed in use cases 1.2.1 (*Develop a system for an expert*), 1.2.2 (*Develop a system for a maintainer*), 1.2.3 (*Develop a system for layman*), all of which aim at facilitating interaction between different kinds of end-users and a Kaba-based system. Case (3) boils down to creating a connection between a tool or library for constructing GUIs, such as the Java Swing Classes (Topley, 1998), and Kaba.

8.6. Distributed processing

This section addresses use cases 1.1.3 (*Manage distributed processing/access*) and 7.7.1 (*Manage distributed processing*). In various settings, the parts making up a Kaba-based system need to be situated on different machines, connected by a network. One such setting occurs when some component, for example the one providing the initial linguistic analysis of input text, is available only for a particular operating system, while the rest of the system runs on another machine in the network. The different parts of the system then have to communicate using some protocol, e.g., SOAP.

8.7. Documentation and tutorials

This section addresses use cases 1.1.4 (*Document API*), 4 (*Document system*), 6 (*Create learning material or tutorial*), and 7.2 (*Document component*).

Kaba should come with incentives for developers, both of the Kaba architecture itself and of Kaba-based systems, to document their efforts. Such stimulus should be in the form of guide-lines and examples. There is a range of possible formats for documenting software systems, e.g., HTML and plain ASCII. It is also important that the guidelines are tied as little as possible to the chosen format. As for documenting the source code, existing tools such as Javadoc should be used.

Examples and tutorials should be encouraged by providing templates, example examples and tutorials to Kaba users and system developers.

8.8. Creating internal components

This section deals with use case 7.8.1 (*Create an internal component*). In Kaba, an internal component is one that is under the control of the developer in that it provides him with a more elaborate API than external components do. Typically, an internal component is created explicitly for use within a Kaba-based system.

A variant of the Common Pattern Specification Language (CPSL) called Kaba Pattern Specification Language (KPSL) will form the base formalism in which the functionality of the internal components will be expressed. CPSL is an effort by the TIPSTER working group that, unfortunately, has not been officially released. However, Appelt (1999) as well as Cunningham et al. (2000) present implementations of annotation engines based on CPSL. Essentially, a CPSL rule describes a finite state transducer for TIPSTER annotations.

It should be possible to construct internal components in several ways, for instance by hand-crafting rules using

a graphical rule editor, or by breeding them using machine learning methods.

8.9. Loading and using internal components

This section deals with use case 7.8.3 (*Load and use an internal component*). Once the KPSL rules making up a component have been developed, they are turned into Java code by a KPSL rule compiler. Along with the compiler come Java classes that facilitate dynamic loading of compiled sets of rules. Thus, as long as the KPSL rules have been compiled to Java and the Kaba-based system knows where to find the components, there are means by which they can be dynamically loaded into the system at run time.

8.10. Maintenance

The fundamental question when it comes to maintenance of any software is *When is maintenance necessary for this piece of software in this particular setting?* and, in the context of information refinement systems, this calls for well-defined criteria that can be used to probe the system's performance with respect to the task it is supposed to accomplish, or the system's affordance with respect to the users' expectations as to what the system is really supposed to do.

8.10.1. Maintenance of external components

This section addresses use cases 1.1.2 (*Maintain API*) and 7.7.2 (*Maintain external component*). The cases are closely related in that communication between a Kaba-based system and other software will always take place via some kind of API. Thus, maintaining an external component is in many cases the same as maintaining the API that Kaba uses for communicating with that component.

8.10.2. Maintenance of internal components

This section deals with use case 7.8.2 (*Maintain an internal component*). Maintenance of internal components should be facilitated by a graphical interface for inspecting, editing, loading, executing, and evaluating KPSL rules with respect to some success criteria set up for the component. It should be possible to do all this using the same, or a similar, graphical interface as when creating internal components.

8.10.3. Maintenance of systems

This section deals with use case 5 (*Maintain system*) which involves all other kind of maintenance mentioned previously in this section, i.e., maintenance of component APIs and external components (Section 8.10.1.), as well as of internal components (Section 8.10.2.). In addition, maintenance of systems also involves taking care of the whole formed by the pieces, e.g., seeing to it that the documentation is up to date, installing new software when needed, and monitoring the system's performance on a regular basis. This should be supported in the same way as maintenance of external components is, e.g., by giving guidelines for how to integrate the documentation of the parts into a central repository, and collect information about availability of new components.

8.11. Providing support for porting systems to new domains

This section deals with use case 3 (*Port an existing system to a new domain or language*). While maintenance may accommodate correction of minor changes to a system, there will also be occasions when the shift of domain or information need is so different from that captured by an existing system that maintenance of the system or one of its components is not enough to compensate for it. In these cases, the question of whether to use an existing system or to create a new one from scratch arises. One of the issues of providing support for porting systems to new domains and needs should be to supply the developer with clues for deciding the answer to that question. If the answer is that an existing system could probably be altered (ported) to meet the new needs, then the follow-up question should be: *What parts of the existing system can be re-used, and to what degree do they need to be modified?* Again, Kaba should provide methods that makes answering this question easier.

8.12. Providing support for evaluation

This section addresses use case 2 (*Evaluate an information refinement R&D or prototype system*). Evaluation of information refinement systems is a crucial issue in several aspects. The basic support for evaluation of information refinement systems can be of two kinds: by providing linguistically annotated data that act as a key to the questions for which a system is to be evaluated, or by providing tools that presuppose the presence of an answer-key for comparing data structures and calculating measurements of performance. Both kinds of support are necessary. In the former case, machine learning methods are often used as an aid in obtaining the correctly annotated corpora constituting the answer-key. In the latter case, the comparison of data structures should yield values in an appropriate metric, e.g., precision and recall, depending on the features that are evaluated.

9. Conclusions

When developing a general tool or architecture, it is possible to focus the technical and linguistic efforts in several ways. The most obvious one is to formulate and maintain an explicit goal regarding the kind of tasks that programs developed within the general architecture at hand should cope with. By obtaining and focusing on the goal at an early stage in the development of the open architecture, one can avoid ending up with a definition and design of a far too general system: when it comes to generality for language engineering, it should be with respect to a class of tasks, rather than to the field as such.

Taking Advantage of Spanish Speech Resources to Improve Catalan Acoustic HMMs

Jaume Padrell and José B. Mariño

TALP Research Center
Universitat Politècnica de Catalunya, Barcelona 08034, Spain
{jaume,canton}@talp.upc.es

Abstract

At TALP, we are working on speech recognition of official languages in Catalonia, i.e. Spanish and Catalan. These two languages share approximately 80 % of their allophones. The speech databases that we have available to train HMMs in Catalan have a smaller size than the Spanish databases. This difference of size of training databases results in poorer phonetic unit models for Catalan than for Spanish. The Catalan database size is not enough to allow correct training of more complex models like triphones. The aim of this work is to find segments in Spanish databases that, used in conjunction to the Catalan utterances to train the HMM models, get an improvement of the speech recognition rate for the Catalan language. To make this selection, the following information is used: the distance between the HMM which are trained separately in Spanish and Catalan, and the phonetic attributes of every allophone. A contextual acoustic unit, the demiphone, and a state tying approach are used. This tying is done by tree clustering, using the phonetic attributes of the units and the distances between the HMM states. Different tests have been carried out by using different percentage of tied states in training simultaneously in Catalan and Spanish. In this way, Catalan models are obtained that give generally better results than the models trained only with the Catalan utterances. However, we observe from one of the tests that, when the number of gaussians is increased, that improvement becomes a loss of performance. Currently, we are working on the inclusion of additional labels to avoid that tree clustering puts in the same pool phoneme realizations that are too much different.

1. Introduction

It is not strange to develop in a same laboratory speech recognition systems for different languages. In the TALP we work in official languages of Catalonia, the Spanish and the Catalan. These two languages share approximately 80% of their allophones (both come from the Latin and share geographic space).

The available speech databases to train the HMMs in Catalan have an smaller size that the available databases in Spanish.

This difference in the dimensions of the training databases is one of the causes by which poorer estimations of the Catalan phonetic units are obtained than in Spanish. Thus, whereas in Spanish the units with what we obtain higher recognition rates are triphonemes or demiphones, in Catalan the best results are obtained modeling allophones (Pachès, 1999), 3 states CDHMM with 32 Gaussian for state, since the database size is not sufficient to allow correct train of more complex models like triphones.

In other works (Mariño et al., 2000b), for bilingual recognition systems with these two languages that should work with limited resources (memory, time, etc.), a set of bilingual HMMs has been created (modeling demiphones) that share some models for both languages. These models, trained with utterances from both languages, obtain a lower recognition rate than their respective monolingual models, but the degradation is not significant.

These last recognition results suggests the possibility of a carefully selection of some utterances from the Spanish databases might the Catalan acoustic HMMs.

(Bonaventura et al., 1997; Wheatley et al., 1994) already suggested the idea to train phoneme models for a language using other languages and implemented a number of different metrics for measuring similarities among cross-language phonetic models. (Bub et al., 1997) considered this task as a question of model adaptation and (Imperl and Horvat, 1999) already used context-depending phonetic units (triphones) in multilingual models.

All these works discus the difficult to select the utterances segments to train the shared models. As a framework to do this selection, in this paper we present some preliminary results using demiphones (Mariño et al., 2000a) as context-depending phonetic units and clustering algorithms that are usually employed to train units that appear little in the training corpus. So, the aim is to use these clustering algorithms to relate contextual units from different languages.

The paper is organized as follows. Section 2. describes the work methodology, section 3. gives some preliminary results and section 4. presents conclusions and future work.

2. Procedure

The procedure that we followed has been: 1) to choose an acoustic unit inventory for both languages, 2) to choose algorithms to select and to tie acoustic units and, 3) to train and to evaluate units for the Catalan with a different percentages of units also trained with the Spanish utterances.

2.1. Spanish and Catalan Allophones Inventory

The allophone transcription is made by different softwares (Saga for the Spanish and Segre for the Catalan) developed in TALP research center. These programs use rules to turn the orthographic text to strings of allophone coded in SAMPA notation.

The transcriptor Saga uses the rules described in (Llisterri and Mariño, 1993) to obtain the phonetic transcription. The program Segre uses extern rules developed in the UAB.

The program Segre transcribes the Catalan sentences using 34 different allophones. In table 1 are shown these

allophones with the attributes[1] that we associated to them. They are used to indicate common characteristics between the units for tree-clustering. These attributes can have phonetic meaning (voiced, manner and point of articulation) or not (for example speaker gender), however, in the present case all attributes have a phonetic meaning.

Al	Attributes	L
a	vowels, open, central, voiced	C,ES
e	vowels, mid_close, front, voiced	C,ES
E	vowels, mid_open, front, voiced	C
i	vowels, close, front, voiced	C,ES

rr	consonants, alveolar, trill, voiced, rothics, vibrate	C,ES
R	Alveolar, Voiced, Rothics, vibrate	ES

Table 1: Allophone list (All.) that the program Segre (C) and Saga (ES) uses (in SAMPA notation) and attributes that are assigned to each unit.

The program Saga provides the 32 allophones for Spanish language. They are also shown in table 1. These inventory were used in the Spanish SpeechDat database (Moreno, 1997) design.

Between the 32 selected allophones to represent Spanish (ES) and the 34 to represent the Catalan (C), there are 27 allophones (C,ES) that share the same SAMPA notation, for example the vowels /a/, /e/, /i/, /o/ and /u/.

2.2. Shared Training and HMM Distance Measure

In an initial step, we trained units separately for each language. In a second step, we re-estimated the Catalan units using also utterances in Spanish. To do this, we tied the Catalan HMM states and the Spanish ones by tree-clustering (Young et al., 1999) with the separately trained HMMs values and the allophones attributes from table 1.

We sort the HMM states that have been tied in both languages by distances between their values. This will later help us to decide which units are finally shared in the experiments, when we only leave tied a ρ percentage of these HMM states.

The distance measure between two HMMs that we use is described in (Young et al., 1999). This measure is based on the sum of the probabilities that the averages that characterize HMM_1 belong to HMM_2 and vice versa. The probability is evaluated logarithmically so, in the case that HMM_1 and HMM_2 are the same model, we obtain a distance zero among them.

So, we re-estimate the HMMs of both languages jointly. The Catalan HMMs with the Catalan utterances and the Spanish HMMs with Spanish utterances. However, there is a certain ρ percentage of HMMs states shared (or tied) between both languages and therefore, that are trained simultaneously in Catalan and Spanish.

3. Experiments and Results

HTK (Young et al., 1999) software is used to train HMMs and to carry out the speech recognition experiments. A classic parametrization of four characteristics has been used, three of dimension 12 and one of dimension 2, trained respectively with a Mel-Cepstrum with mean subtraction, its first differential, its second differential and, in joint form, second and third energy differential. CDHMM are used to model the acoustic units.

3.1. Spanish and Catalan Speech Databases

3.1.1. Training Data

In order to estimate the HMMs two sets of utterances are used (in both cases the automatic transcription is done without considering coarticulation between words):

- Catalan corpus is formed by 3,981 sentences from the SpeechDat Catalan database (Hernando and Nadeu, 1999), with 639 different speakers (Catalan Eastern dialect) and 171,443 allophones according to the Segre transcription (6.5 hours of speech for training).
- Spanish corpus is formed by 4,951 sentences from 976 different speakers (Spanish speakers from Catalonia) from the SpeechDat Spanish database (Moreno, 1997). This sentences set is formed by 242,813 allophones according to the program Saga (also more than 6 hours of speech for training). This corpus represents a fourth database size than it is available for Spanish.

[1] They were designed, in addition to the TALP members, by the Laboratory of Phonetics from the UAB and by Sílvia Llach from the UG.

3	@ ESa a ESo o O ESe e E											ESi i		ESu u
4	@ ESa a ESo o O						ESe e E					ESi i		ESu u
5	@ ESa a			ESe e E			ESi i		ESo o O					ESu u
8	@	ESa a		ESe e		E	ESi i		ESo o		O			ESu u
13	@	ESa	a	ESe	e	E	ESi	i	ESo	o	O	ESu	u	

Table 2: Vowels clustering by smaller between models distances according to the final maximum number of groups (first column). The Spanish allophones are distinguished from the Catalans by the prefix ES added to its SAMPA representation.

In this paper, we focus our experiments on the ρ percentage of HMMs states tied between both languages. Future research will be addressed to the size database ratios.

Between Catalan and Spanish models we notice 27 allophones that have the same (SAMPA) representation. These are the 94.43% total number of allophones in our Spanish training corpus and the 76.95% in the Catalan one (the difference is mainly due to the allophone schwa /@/ that does not exist in Spanish and has 16.90% frequency of apparition in our Catalan database). On the other hand, the most frequent allophone in our Spanish database (/a/ with 13.04% frequency) is also in Catalan database.

3.1.2. Evaluation Data

The evaluation tests have been carried out with a database with locality names (2,633 sentences with 232 different names with length from one to five words by sentence) and with a people names database (2,956 sentences with 510 different names). All these sentences come from the Vocatel database (Nadeu et al., 1997).

3.2. Allophone Clustering

Allophone models have been trained separately for each language (CDHMM of 3 states with 4 Gaussian for state). These models objective is twofold: first, to do a preliminary analysis of distances that there are between models from both languages and, second, like a departure point for demiphone units training.

To study the correlation between SAMPA representation and HMM distance we clustered the 13 models that represent the vowels set for both languages into 8 models, matching the models that are at smaller distance. In table 2 is shown the clusters that are obtained according to their final maximum number (3, 4, 5 and 8) that are requested to the clustering algorithm. We obtain that each vowel joins with whom shares symbol SAMPA.

The table 3 shows similar experiment but clustering HMM states independently. The clusters are ordered from less distance between HMM states to more. It can be seen that the similarity between models depends on the HMM state.

We created models simultaneously training the allophones that share its SAMPA representation. The experiments gave recognition rates poorer than with the allophones trained only with Catalan utterances. Probably this is due to many shared allophones occur in different allophone contexts in both languages.

In above mentioned work (Mariño et al., 2000b), where demiphones were used for a bilingual recognition system, the degradation was not significant. In order to approach the different allophone context problem we also use the demiphone as acoustic unit, so that the context tied can be better controlled.

Cl. Order	Left State	Middle State	Right State
1	a ESa	a ESa	a ESa
2	i ESi	e ESe	e ESe
3	e E	e ESe E	o ESo
4	@ a ESa	O o	@ a ESa
5	e E ESe	i ESi	i ESi

Table 3: Clustering order depending on distance between HMM states followed by Catalan and Spanish (with prefix ES) vowels.

3.3. Demiphone Clustering

These demiphones which were trained simultaneously in both languages were chosen by tree clustering, using the allophone attributes (table 1) and the distance between the HMMs (we use the tree clustering described in (Young et al., 1999)).

In Catalan, after tree-clustering, are used 1,092 demiphones modeled by CDHMM of 2 states with 1 Gaussian for state. We also use a model for silence and one for the speaker noise, both of 3 states and 1 Gaussian for state. Following the same procedure, in Spanish 852 CDHMM for demiphones are obtained, plus one for silence and one for the speaker noise.

The analysis of the clusters that are obtained tying by trees is complex. First, we obtained different clusters depending on if we tried simultaneously to cluster all states that form a model or make clusters by state. Second, some of the clusters had that we would name phonetic explanations, but others were inexplicable from this point of view.

It is difficult to evaluate which tying improve the recognition in Catalan and which not. Preliminary experiments with our databases seems indicate that tying between some vowels (for example, /e/ /E/ and /ESe/, or /o/ /O/ and /ESo/) worsen the speech recognition in Catalan language.

Several tests have been done operating only on the tying ρ percentage allowed between demiphones pre-tied by tree-clustering with both languages.

In order to have baseline models for the evaluation demiphones CDHMM with only the Catalan utterances have been trained (it is the case of $\rho = 0.00\%$). In the table 4 are shown the different recognition rates that were obtained. In the first column it is indicated ρ, the states percentage for a total HMM sates set of $(2 * 1,092)$ states that

were tied in the training and which, therefore, were trained simultaneously both languages.

ρ(%)	Corr. Names (%)	Corr. Localities (%)
1 Gaussian for state		
0.00	71.28 [69.76,72.80]	85.26 [84.02,86.50]
12.34	71.96 [70.44,73.48]	86.75 [85.51,88.00]
24.95	71.96 [70.44,73.48]	86.06 [84.82,87.30]
34.01	72.63 [71.11,74.15]	85.72 [84.48,87.00]
4 Gaussian for state		
0.00	75.51 [74.00,77.03]	89.21 [88.14,90.28]
34.01	76.52 [75.00,78.04]	87.20 [85.96,88.44]

Table 4: Recognition rates for Catalan sentences depending on the ρ percentage of states trained simultaneously. Between parenthesis there are the probabilities margin with a level of significance of 95 %.

One of the main causes for database people names had worse recognition rate than the site names is that many names are only different by last allophone (due to the gender; for example Francesc for male and Francesc**a** for female) and, in addition, are shorter.

In the results of the table 4 Catalan models with one gaussian for state are obtained that give generally better results using a percentage of bilingual states than the models trained only with the Catalan utterances. However, when we increased the number of Gaussians the recognition improvement becomes a loss of performance for localities database experiment.

4. Conclusion and Future Work

In this paper, we described a method to take advantage of Spanish language speech resources to improve Catalan language acoustic HMMs to speech recognition. We used language as an attribute in the clustering algorithm and CDHMM modeling demiphones. They allowed a better control over the tied allophone context between languages. Further research is need to improve the phonetic transcription and the attributes of these units, for example distinguishing units that at the moment have same symbol SAMPA and, to experiment other types of distances between pdfs, for example the Hellinger distance (Settimi et al., 1999). Our next step will be to carry out experiments increasing the size of the Spanish speech databases and to carry out recognition tests with other tasks, observing the amount of used Spanish material in the training and the test, not only the shared states percentage. Once developed this tying procedure it will be interesting to extend it to other languages that have poor speech databases resources. In our center similar works between dialects of Spanish are being made (Nogueiras et al., 2002).

5. Acknowledgments

This research was supported by CICYT of Spanish government under contract TIC2000-1005-C03-01. The authors would like to thank Climent Nadeu due to his help and encouragement. The authors also wish to acknowledge the access to the VOCATEL database allowed by Telefónica I+D.

Abstract

Much of the work on parallel texts alignment tries to push the boundaries of language independence as far as possible. This has been a trend since the first approaches on sentence alignment in the early 1990s. In this paper we discuss portability issues of parallel texts alignment techniques. How language independent can they be? We examine several alignment techniques proposed by previous authors, discuss how far they went with language independent methodologies, why some authors decided to add linguistic knowledge to their systems and what improvements they attained by doing it. We will also discuss some methodologies and the problems faced by systems which aim at extracting Translation Equivalents from aligned parallel texts.

1. Introduction

Text alignment techniques aim at identifying automatically correspondences between *parallel texts*, i.e. either correspondences between text segments, words or even sequences of characters. Parallel texts are sets of texts which are translations of each other in different languages, like the proceedings of the European Parliament, which is published in the eleven official languages[1] of the European Union – the Official Journal of the European Communities –, or the proceedings of the Canadian Parliament which is published in both English and French – the Canadian Hansards.

Much of the work on parallel texts alignment tries to push the boundaries of language independence as far as possible, i.e. by not using language specific knowledge for the alignment process. This has been a trend since the first approaches on sentence alignment in the early 1990s (Kay and Röscheisen, 1993; Brown *et al*., 1991; Gale and Church, 1991). Still, some authors have resorted to adding some linguistic knowledge in order to improve the alignment results, either by adding short bilingual dictionaries to bootstrap the alignment process (Wu, 1994; Melamed, 1999) or by using word similarity measures to find similar words automatically (Simard *et al*., 1992; Melamed, 1999).

Many authors have tried not to feed linguistic knowledge to their alignment systems, in particular, short bilingual dictionaries, since this makes them easily language dependent and, consequently, hardly portable to other languages. Also, those dictionaries may be incomplete and outdated. In addition, they usually do not provide all the possible word variants due to possible language inflection. Moreover, linguistic knowledge may be expensive to get, may require much time to compile, may be hard to get especially for minority languages or languages for which there are not much linguistic resources available (as in African languages).

In this paper we discuss portability issues of parallel texts alignment techniques. How language independent can they be? We examine several alignment techniques proposed by previous authors, discuss how far these authors have gone with language independent methodologies, why some authors decided to add linguistic knowledge to their systems and what improvements they attained by doing it. We will also discuss some methodologies and the problems faced by systems which aim at extracting Translation Equivalents from aligned parallel texts.

This paper is organised as follows: the next section gives a brief overview of what parallel texts alignment is. Section 3 provides some evidence on the amount of lexical cues available in European languages. Section 4 describes previous work on alignment techniques developed by some authors, both on sentence and word level, and discusses the strategies they used regarding language independence. Section 5 describes how language independent the extraction of Translation Equivalents can be. Finally, section 6 presents the conclusions and some future work.

2. Parallel Texts Alignment

Today, it has become quite common to find parallel texts virtually everywhere from translations of books in bookshops, to consumer products information in supermarkets, instructions manuals in the industry, multilingual portals in the Internet, and it has even become trendy to find parallel versions of songs in English and Spanish. In all these parallel texts, one can notice a continuum in the 'degree of non-parallelness' from legislative texts and instructions manuals, which tend to be very faithful to the originals, to translations of books or lyrics of songs, which leave more freedom and creativity to the translator.

Text alignment techniques aim at identifying automatically correspondences between those parallel texts. Once they are aligned it is possible to start using them for various purposes. For example, an immediate application is the production of bilingual concordances. Bilingual concordances are particularly useful for the preparation of commercial bilingual dictionaries, for translators and even for foreign language learners. They allow the examination of the way specific words or terms are translated into another language, providing simultaneously part of the context in which they appear.

Furthermore, they can also be used to build Bilingual Dictionaries, Bilingual Terminology Databanks, Translation Memories, to name but a few immediate applications.

[1] Danish (da), Dutch (nl), English (en), Finnish (fi), French (fr), German (de), Greek (el), Italian (it), Portuguese (pt), Spanish (es) and Swedish (sv).

This data can then be included in Machine Translation systems, Computer Assisted Translation tools, Cross-Language Information Retrieval systems or Lexicographers workbenches.

The lexical cues found in parallel texts have been quite used. They can be identical tokens in two texts (numbers, proper names, punctuation marks), similar words (cognates, like *Comissão* and *Commission*, in Portuguese and English, respectively) or known translations (like *data* and *fecha*, in Portuguese and Spanish, respectively). These tokens, called *anchors* (from Kay and Röscheisen, 1993, p. 128), allow correspondences between the texts, and help the alignment system to keep track of the evolution of text and to avoid straying away from the correct alignment.

3. Sharing Words

Several authors have used lexical cues as potential anchors for alignment. In fact, the number of identical tokens available in parallel texts should not be underestimated.

According to the results reported in Ribeiro *et al.* (2000), almost 15% of the 'vocabulary' (different tokens) found in their texts from the Official Journal of the European Communities was found to be the same in its various official languages with respect to the Portuguese text (this number also includes names, numbers and punctuation). They used a sample of parallel texts from three sources: records of the Written Questions to the European Commission, records of Debates in the European Parliament and Judgements of The Court of Justice of the European Communities. Table 1 gives an overview of the equal vocabulary size across the ten language pairs (see footnote 1 for the abbreviations):

	Sub-Corpus			
Pair	Written Questions	Debates	Judgements	Average
pt-da	1.2k (17%)	2.0k (10%)	0.2k (19%)	1.9k (11%)
pt-de	1.0k (15%)	1.9k (10%)	0.2k (19%)	1.8k (10%)
pt-el	1.0k (15%)	1.5k (8%)	0.1k (18%)	1.5k (9%)
pt-en	1.3k (19%)	2.2k (11%)	0.2k (20%)	2.1k (12%)
pt-es	2.5k (38%)	6.5k (32%)	0.3k (36%)	6.0k (33%)
pt-fi	---	---	0.2k (19%)	0.2k (19%)
pt-fr	1.3k (19%)	2.3k (11%)	0.2k (22%)	2.1k (12%)
pt-it	1.4k (22%)	3.0k (15%)	0.2k (25%)	2.8k (16%)
pt-nl	1.2k (17%)	2.0k (10%)	0.1k (19%)	1.9k (11%)
pt-sv	---	---	0.2k (19%)	0.2k (19%)
Average	1.3k (20%)	2.7k (13%)	0.2k (22%)	2.5k (14%)

Table 1: Average size of common vocabulary per pair of parallel texts in thousands.

Table 1 also shows the average percentages with respect to the size of the vocabulary found in Portuguese parallel texts are in brackets.

For example, an average of 2500 tokens were found to be exactly the same for the Written Questions parallel texts in Portuguese and Spanish (pt-es). This corresponds to an average of 38%, i.e. 38% of the vocabulary found in the Portuguese Written Questions parallel texts was equal to the Spanish vocabulary.

In the case of close languages such as Portuguese and Spanish, the average rate rises to more than 30%; for the opposite reason, it drops to about 10% for the pair Portuguese–German. Furthermore, the number of occurrences of these shared vocabulary tokens in the parallel texts (see Table 2) reaches an average of almost 50% in parallel texts in Portuguese and Spanish. For Portuguese and German parallel texts, this number is about 20% on average.

	Sub-Corpus			
Pair	Written Questions	Debates	Judgements	Average

Table 2: Average number of common tokens per pair of parallel texts in thousands

Table 2 also shows the average percentages of common tokens with respect to the number of tokens of the Portuguese parallel text are in brackets. For example, about 1400 tokens are were found to be equal in both Greek and Portuguese for the Judgements parallel texts; this covers 31% of the total number of tokens of the Portuguese Judgements parallel texts.

This is a wealthy source of lexical cues for parallel texts alignment that should not be left unused.

Homographs, as a naive and particular form of cognates, are likely translations, which makes them potential reliable anchors. For example, *Portugal* is written like this in several European languages, which makes it a potential anchor for alignment.

These anchors end up being mainly numbers and names. Here are a few examples of anchors from a parallel text in English and Portuguese: *2002* (numbers, dates), *ASEAN* (acronyms), *Patten* (proper names), *China* (names of countries), *Manila* (names of cities), *apartheid* (foreign words), *Ltd* (abbreviations), *habitats* (Latin words), *ferry* (common words), *global* (common vocabulary).

4. Alignment Techniques

Some alignment techniques establish correspondences between sentences – *sentence alignment* – where as other techniques try to provide more fine-grained alignments by establishing correspondences between words – *word alignment*. The next section will describe some sentence alignment techniques. Section 4.2 describes word alignment techniques.

4.1. Sentence Alignment

Back in the early days of alignment, in the 1990s, sentences were set as the basic units for alignment. Each text was viewed as a sequence of sentences and alignment algorithms attempted at making correspondences between the sentences in the parallel texts.

The method proposed by Kay and Röscheisen (1993) assumed that for sentences in a translation to correspond, the words in them must also correspond. Two words were considered to have similar distributions if they tended to co-occur in the tentatively aligned sentences. In this case, if their measure of similarity was above a threshold, it would mean they were translations and, finally, sentences were aligned if the number of words associating them was greater than an empirically defined threshold.

In other alternative approaches, less knowledge based, sentences were aligned as long as they had a proportional

number of words (Brown *et al*., 1991) or characters (Gale and Church, 1991). They started from the fact that long sentences tend to have long translations and, conversely, short sentences tend to have short translations. This correlation was the basis for their statistical models. Brown *et al*. (1991, p. 175) remarked that the error rate was slightly reduced from 3.2% to 2.3% when using some linguistic knowledge like the time stamps, question numbers and author names found in the parallel texts. This confirmed that sentences could be aligned just by looking at sentence lengths measured in number of tokens and that extra linguistic knowledge did not improve the results significantly.

Although none of these algorithms depend on some word similarity measure as in later work (e.g. Simard *et al*., 1992), these algorithms tended to break down when sentence boundaries were not clearly marked.. This means full stops would have to be clearly interpreted as sentence boundaries markers. However, they are not safe markers of sentence boundaries.

Gale and Church (1991, p. 179) reported that only 53% of the full stops found in the Wall Street Journal were used to mark sentence boundaries. Full stops may be part of abbreviations (*Dr. A. Bromley*) or numbers (*1.3%*), they are not usually found in headlines (*Tyre production*), they may not even exist because they were not added, or they were either lost or were mistaken for noise in the early days when electronic versions of parallel texts were still rare and texts needed to be scanned.

Wu (1994) also aligned English–Chinese sentences with proportional lengths. He also began by applying a method similar to the one used by Gale and Church (1991) and reported results not much worse than those expected by this algorithm. Still, he claimed sentence alignment precision over 96% when the method incorporated a seed bilingual lexicon of words commonly found in the texts to be aligned (e.g. names of months, like *December* and its equivalent in Chinese 十二月). So, again Wu's work confirmed that the use of lexical cues would be beneficial for alignment.

4.2. Word Alignment

If word alignment is the main goal, alignment algorithms must be more 'careful' in order to avoid wrong word correspondences. This is a much more fine-grained alignment since it is no longer done at sentence level but at word level. In contrast with sentence alignment algorithms which permit a margin of tolerance for occasional wrong word matches, at word level, the sentence is no longer a 'safety net'. Consequently, the penalty on wrong word matches becomes much higher.

By adding some lexical information, Church (1993) showed that alignment of parallel text segments was possible by exploiting orthographic *cognates* instead of sentence delimiters. He used the rule of equal 4-grams in order to find 'cognate' (similar) sequences of characters in the parallel texts, i.e. sequences of four characters which are equal in the texts. This is a good strategy for languages which share lexical similarities like languages which share a character set.

The idea of exploiting *cognates* for alignment had been proposed one year earlier in a paper by Simard *et al*. (1992). According to the Longman Dictionary of Applied–Linguistics, a cognate is "a word in one language which is similar in form and meaning to a word in another language because both languages are related" (Richards *et al*., 1985, p. 43). For example, the words *Parliament* and *Parlement*, in English and French respectively, are cognates. They are similar in form and have the same meaning. When two words have the same or similar forms in two languages but have different meanings in each language, they are called false cognates or false friends (Richards *et al*., 1985, p. 103). For example, the English word *library* and the French word *librairie* are false cognates (Melamed, 1999, p. 114): *library* is translated as *bibliothèque* in French and, conversely, *librairie* as *bookstore* in English.

Simard *et al*. (1992) used a simple rule to check whether two words were cognates. They considered two words as cognates if their first four characters were identical (Simard *et al*., 1992, p. 71), as is the case of *Parliament* and *Parlement*. This simple heuristic proved to be quite useful, providing a greater number of lexical cues for alignment though it has some shortcomings. According to this rule, the English word *government* and the French word *gouvernement* are not cognates. Also, *conservative* and *conseil* ('council'), in English and French respectively, are wrongly considered as cognates (Melamed, 1999, p. 113). The rule is sensitive to variations in the first four letters and it does not distinguish different word endings.

In fact, both the rule proposed by Simard *et al.* (1992) and the one used by Church (1993) are two variants of Approximate String Matching Techniques. The former technique corresponds to *truncation*, where only the *n* first characters are considered. The latter technique resembles *n*-gram matching, which determines the similarity of two words by the number of common *n*-grams. A technique developed by Adamson and Boreham (1974) uses contiguous bigrams and base their word similarity score on the coefficient of Dice to compare the number of common bigrams between two words and the number of bigrams of each individual word.

McEnery and Oakes (1995) tried to improve the definition of cognates by comparing the truncation technique, the number of shared bigrams in two words with a score based on the coefficient of Dice and using dynamic programming. In experiments they performed comparing English and French vocabulary, they found that the bigram matching technique precision was 97% using a threshold of 0.9, and 81% for a similarity score between 0.8 and 0.9; the truncation technique precision was 97.5% for a length of eight characters and 68.5% for a length of six characters.

The word alignment approaches just described are not appropriate for pairs of languages for which it is not possible to find some common cues. In order to overcome this problem, Melamed (1999, p. 113) also suggests the use of *phonetic cognates* especially for languages with different alphabets. Phonetic cognates are words which are phonetically similar though written differently or in different scripts, like 'program' /pr græm/ and 'プログラム' /puroguramu/ in English and Japanese. This increases the number of cues available for alignment.

The requirement for clear sentence boundaries was dropped in Fung and Church (1994) on a case-study for English-Chinese. It was the first time alignment procedures were being tested on texts between non-Latin languages and without finding sentence boundaries. Each

parallel text was split into K pieces and word correspondences were identified by analysing their distribution across those pieces. In particular, a binary vector of occurrences with size K (hence, the K-vec) would record the occurrence of a word in each of the pieces. Should the word occur in the *i*-th piece of the text, then the *i*-th position of the vector would be set to '1'. Next, in order to find whether two words corresponded, their respective K-vecs were compared. In this way, it was possible to build a rough estimate of a bilingual lexicon. This would feed the alignment algorithm of Church (1993), where each occurrence of two translations would become a dot in the graph.

This method was extended in Fung and McKeown (1994). It was also based on the extraction of a small bilingual dictionary based on words with *similar distributions* in the parallel texts. However, instead of K-vecs, which stored the occurrences of words in each of the K pieces of a text, Fung and McKeown (1994) used vectors that stored the distances between consecutive occurrences of a word (DK-vec's). For example, if a word appeared at offsets (2380, 2390, 2463, 2565, ...), then the corresponding distances vector would be (10, 73, 102, ...). Should an English word and a Chinese word have distance vectors with a similarity above a threshold, then those two words would be used as potential anchors for alignment. Later, in Fung and McKeown (1997), rather than using only single words, the algorithm extracted terms to compile the list of reliable pairs of translations, using specific syntactic patterns. However, this made it become language dependent.

Melamed (1999) also used orthographic cognates. Moreover, he used lists of stop words to avoid matching of closed-class words (like articles and prepositions) which tended to generate much noise, which requires some linguistic knowledge to be hand-coded into the system. In order to measure word similarity, he defined the Longest Common Sub-sequence Ratio as follows:

$$Ratio(w_1, w_2) = \frac{Length(LongestCommonSub\text{-}Sequence(w_1, w_2))}{Max(Length(w_1), Length(w_2))}$$

where w_1 and w_2 are the two words to be compared (Melamed, 1999, p. 113).

This measure compares the length of the longest common sub-sequence of characters with the length of the longest token. For the previous example, the ratio is 10 (the length of *government*) over 12 (the length of *gouvernement*) whereas the ratio is just 6 over 12 for *conservative* and *conseil* (council). This measure tends to favour long sequences similar to the longest word and to penalise sequences which are too short compared to a long word. However, for this very same reason, it fails to consider *gouvernement* and *governo* in French and Portuguese as cognates because *governo* is a shorter word. Their ratio is also 6 over 12.

For alignment purposes, Melamed (1999) selects all pairs of words which have a ratio above a certain threshold, heuristically selected. However, this becomes a language dependent value. Still, this comparison measure seems to provide better results than the one first proposed by Simard *et al.* (1992) but it is not based on a statistically supported study.

Danielsson and Mühlenbock (2000) aim at aligning cognates starting from aligned sentences in two quite similar languages: Norwegian and Swedish. The 'fuzzy match' of two words is "calculated as the number of matching consonants[,] allowing for one mismatched character" (Danielsson and Mühlenbock, 2000, p. 162). For example, the Norwegian word *plutselig* (suddenly) and the Swedish word *plötsligt* would be matched through *pltslg*: all consonants match except for the 't'. However, *bakspeilet* (rear-view mirror) and *backspegeln*, in Norwegian and Swedish respectively, would not match because four consonants are not shared 'c', 'g', 'n' and 't'. This strategy resembles the technique developed by Pollock and Zamora (1984, p. 359) whereby words are coded using the first letter of the word, the remaining unique consonants in order of occurrence and, finally, the unique vowels also in order of occurrence – the *skeleton key*. For example, *plutselig* would be coded as *pltsguei* and *plötsligt* as *pltsgöi* where the sequence of consonants is equal.

Choueka *et al.* (2000) present an alignment algorithm for English and Hebrew, a highly inflected language with a different alphabet, a complex morphology and flexible word order. For example, *and since I saw him* is translated into a single Hebrew word (Choueka *et al.*, 2000, p. 74): åëùøàéúéå /ukhshereitiv/. First, texts were lemmatised, i.e. each word was reduced to its basic form as found in a dictionary entry (e.g. *saw* to *see*). This is clearly a language dependent task though it is quite difficult to solve for highly inflected languages. Also high frequency words were removed using a list of stop words. Next, parallel texts were aligned using the methodology of Fung and McKeown (1997). The lemmatisation step increases the chances of finding similar words in the aligned parallel texts in order to compile automatically a bilingual dictionary by analysing their distribution across the aligned parallel texts; otherwise, non-lemmatised words would just become too rare which would make it difficult to find trustworthy Translation Equivalents due to data sparseness.

In contrast with previous approaches, Ribeiro *et al.* (2001b) consider two words to have a high level of 'cognateness', if they share a typical sequence of characters that is common to that particular pair of

Language Pairs	pt-da	pt-de	pt-el	pt-en	pt-es	pt-fi	pt-fr	pt-it	pt-nl	pt-sv	Average
punctuation	60%	63%	66%	60%	46%	68%	59%	60%	63%	74%	62%
numbers	16%	20%	20%	21%	11%	18%	16%	12%	19%	20%	17%
names	17%	8%	7%	10%	8%	7%	6%	5%	9%	1%	8%
common words	3%	3%	6%	7%	33%	6%	14%	18%	9%	3%	10%
others	4%	6%	1%	2%	2%	2%	5%	5%	1%	1%	3%
Total	100%	100%	100%	100%	100%	100%	100%	100%	100%	100%	100%

Table 3: Percentages of types of tokens used for alignment in the alignment algorithm developed by Ribeiro *et al.* (2001).

languages. The typical sequences of characters can be extracted by statistical data analysis of contiguous and non-contiguous sequences of characters, based on the notion of 'textual unit' association. They were able to find typical sequences which lie in the beginning of words such as •*Comis*, for *Comissão* and *Comisión* in Portuguese and Spanish, lie in the middle of words as in *f_rma* which matches both *information* and *informação* in English and Portuguese respectively, cross word boundaries as *i_re•ci* for the Portuguese–French pair as in *livre•circulação–libre•circulation* ('free movement'), which made it quite adequate for the pairs of languages which use words written in the same character set. It is up to the alignment algorithm proper to confirm whether words are cognates depending on their position in the text.

This particular experiment used the Judgements sub-corpora, in three language pairs: Portuguese–English, Portuguese–French and Portuguese–Spanish. The size of the parallel texts for each language pair amounted to about 150k characters (about 30k tokens). Table 4 shows the number of typical sequences of characters extracted from each parallel text.

Language Pair	Number of Sequences
Portuguese–English	677
Portuguese–Spanish	1137
Portuguese–French	877

Table 4: Number of typical sequences of characters for each pair of languages.

Interestingly, Table 4 also confirms language similarity. Bearing in mind that Portuguese and Spanish are two quite close languages, it does not come as a surprise to see that this pair shares more typical sequences of characters than any of the other. French comes next for its closeness as a Romance language and English comes last confirming that Portuguese and English are more distant languages.

Table 3 presents an analysis of a sample of aligned parallel texts, using the previously mentioned methodology though just using equal tokens. The table shows that punctuation marks are indeed good cues for alignment. On average, more than 60% of the tokens used for correspondence points are punctuation marks. This confirms the success of early approaches that started by using sentences as the basic alignment unit and exploiting full stops for sentence alignment. It shows that the number of common words used as correspondence points is higher for similar pairs of languages like Portuguese–French, Portuguese–Italian and Portuguese–Spanish than for other pairs. It shows that, on average, 10% of the tokens used as correspondence points are common words and that 17% are numbers, which makes it more than a quarter of all tokens used as correspondence points.

5. Translation Equivalents

The extraction of Translation Equivalents is one of the most important tasks for building either Translation Memories or Bilingual Dictionaries. Translations databanks are useful language resources either for Machine Translation, Cross-Language Information Retrieval or even for human translators themselves.

Aligned parallel texts are ideal sources to extract Translation Equivalents for they provide the correspondences between the original text and their translations in other languages made by professional translators. They allow the examination of the way specific words or terms are translated into other languages. Aligned parallel texts can reduce the amount of effort necessary to build Translation Databanks.

The key issue in the extraction of Translation Equivalents is to find a correlation between co-occurrences of terms in parallel texts. In general, if two terms co-occur often in aligned text segments, then they are likely to be *equivalent*. The alignment of parallel texts splits the texts into small aligned text segments and reduces the number of words that must be checked for co-occurrence. In order to identify Translation Equivalents, their *distribution similarity* must be analysed in those aligned segments.

However, the larger the aligned text segments, the more difficult it gets to extract Translation Equivalents for more alternative translations become possible and, consequently, the search space becomes larger and with fewer evidences. This may be the case for distant languages where fewer cues may be available for alignment. As a result, the number of Translation Equivalents which can be more reliably extracted gets more reduced.

Nonetheless, the few Equivalents extracted can be subsequently fed back into the alignment system to improve the alignment proper, reduce the size of aligned text segments, and extract more Translation Equivalents in an iterative and unsupervised way. Even though it should only be possible to extract a small bilingual lexicon as in Fung and McKeown (1994), it can be quite helpful to bootstrap a more fine-grained alignment as Wu (1994) has shown.

6. Conclusions and Future Work

The exploitation of lexical cues for parallel text alignment is indeed quite helpful for alignment methods based on lexical information found in the texts. The more lexical information shared between a pair of languages, the more candidate correspondence points for alignment can be generated. As a result, this leads eventually to a more fine-grained alignment beyond the sentence level as in the early 1990s. Language similarity should be seen as bonus for alignment.

Language independent approaches are quite dear in multilingual regions where the possibility of using a single methodology to handle different languages increases portability and greatly reduces the amount of human effort. Ideally, an alignment algorithm should be completely language independent: character set independent; no previous linguistic knowledge, either from machine-readable bilingual dictionaries or hand coded seed bilingual translation lexicons; no lemmatised and/or tagged texts; no requirement for the detection of sentence boundaries.

However, as described in section 4, previous alignment approaches have often resorted to making use of sentence boundaries, lexical cues available in the parallel texts and even to hand-coding some linguistic knowledge through small bilingual lexicons and building list of stop words. This increases the number of potentially

reliable anchors for alignment and increases the chances of having more accurate alignments of parallel texts.

Nevertheless, it is wise to make good use of the lexical cues available in parallel texts. The larger the overlap between common lexical cues between two languages, the higher the number of potential anchors for alignment. Eventually, this means that the average size of aligned parallel texts gets smaller for non-sentence based alignment algorithms. The extraction of Translation Equivalent becomes more reliable and easier since there may be fewer alternative translations to choose from.

Consequently, when it comes to more distant languages like Portuguese and Chinese, where the number of lexical cues available is more reduced, the number of Translation Equivalents extracted is usually more reduced (Ribeiro *et al*., 2001a). However, it is still possible to extract some Translation Equivalents reliably in order to re-feed the alignment algorithm. Indeed, for distant languages, previous authors (Wu, 1994; Melamed, 1999) have resorted to building a small bilingual lexicon to bootstrap the alignment algorithm.

We believe that it is possible to extract some Translation Equivalents in a 'self-enriching' process instead of feeding an alignment system manually with either hand-coded bilingual lexical information or incomplete machine readable dictionaries.

By re-feeding the extracted Translation Equivalents back into the aligner it is possible to increase the number of candidate correspondence points for new lexical cues become available for the generation of correspondence points. The more candidate correspondence points, the more fine-grained the alignment and the better are the extracted equivalents. This means that the alignment precision may be improved, i.e. more correspondences may be established between words or phrases.

As the example of Choueka *et al*. (2000) has shown, it becomes more difficult to get cues for highly inflected languages where words can suffer major changes. Still, it would be interesting to test whether it should be possible to automatically lemmatise texts either by using a strategy similar to the one presented in Kay and Röscheisen (1993) whereby common suffixes and prefixes of words were automatically identified in a language independent fashion, or by extracting automatically character patterns using a methodology similar to the developed in Ribeiro *et al*. (2001b).

All in all, most work on alignment has been carried out on a wide range of 'popular' languages, most of them on English and French, but also including other Western European languages, Arabic, Chinese, Hebrew, Japanese and even some Korean. It would be quite interesting to test alignment algorithms on radically different languages to check for their degree of language independence.

Abstract

Decision tree-based approach is a well known and frequently used method for tying states of the context dependent phone models since it is able to provide good models for contexts not encountered in the training data. In contrast to the other approaches, this method allows us to include expert linguistic knowledge into the system. Our research focused on the inclusion of standard generative theory by Chomsky & Halle (1968), called the SPE theory (the Sound Pattern of English), into the decision tree building process as expert linguistic knowledge. Our attempt was to "merge" the SpeechDat2 SAMPA label set, used for English and Slovenian languages, with the SPE. We created all possible natural groups of phones (SAMPA segments defined by a set of binary phonological features) for both languages and included them into a set of questions used in the process of creating the decision trees. Based on the decision tree constructed this way, we created an English and Slovenian speech recognition systems and tested both of them. Compared with the reference speech recognition system (Lindberg et al., 2000; Johansen et al., 2000) we got some promising results that encouraged us to continue this work and to perform further testing.

1. Introduction

Much of the phonetic variation in natural speech is due to contextual effects. In order to be able to accurately model variations in natural speech a careful choice of the units represented by each model is required. In large-vocabulary speech recognition systems, modelling of vocabulary words by subword units (phonemes or units derived from phonemes) is mandatory. For example, triphone models have been one of the most successful context dependent units because of their ability to model well the co-articulation effect. Yet if we create distinct models for all possible contexts, the number of models becomes very high. In practical applications of building speech recognition systems, there is often a conflicting desire to have a large number of models and model parameters in order to achieve high accuracy, whilst at the same time having limited and uneven training data in form of labelled utterances of a particular language (Young et al., 2000). In the case of triphone context dependent models, tying of HMM states gives us a possible solution of how to overcome this problem.

In our work we analysed the influence of the decision tree method on the acoustic modelling. We also analysed parameters that influence the decision tree building process and tested the proposed method based on the theory of naturalness (the theory that phonological segments cluster into "natural groups" defined by universal features), (Chomsky et al., 1968). We first examined this issue within the Slovenian language and then also addressed its portability to other languages.

2. Decision tree

When building large vocabulary cross-word triphone systems, unseen triphones are unavoidable. A limitation of the data-driven clustering procedure is that it does not deal with triphones for which there are no examples in the training data. Decision tree based approach gives us a possibility to include expert linguistic knowledge into a procedure of creating acoustic models. This methodology provides appropriate models also for contexts that are not seen in the training data. Therefore, decision trees are used in speech recognition with large numbers of context dependent HMMs, to provide models for contexts not seen in the training data. Sharing data at the model level may not be the most appropriate method for models composed of distinct states (Odell, 1995). Sharing distributions at the state level allows for finer distinctions to be made between the models by allowing left and right contexts to be modelled separately.

2.1. Decision tree building process

A phonetic decision tree is a binary tree in which a yes/no phonetic question is attached to each node (Young et al., 2000). Initially, all states in a given item list (typically a specific phone state position) are placed at the root node of a tree. Depending on each answer, every node is successively split and this continues until the states have trickled down to leaf-nodes. All states in the same leaf node are then tied and trained from the same data.

The question at each node is chosen to (locally) maximise the likelihood of the training data (using a log likelihood criterion) and gives the best split of the node. This process is repeated until the increase in log likelihood falls below the specified threshold. As a final stage, the decrease in log likelihood is calculated for merging terminal nodes, which belong to different parents. Any pair of nodes for which this decrease is less than the threshold used to stop splitting is then merged (Young et al., 2000). The algorithm for building a decision tree is summarised in figure 1.

♦ Socrates/Erasmus exchange student under the multilateral agreement UL D-IV-1/99-JM/Kc.

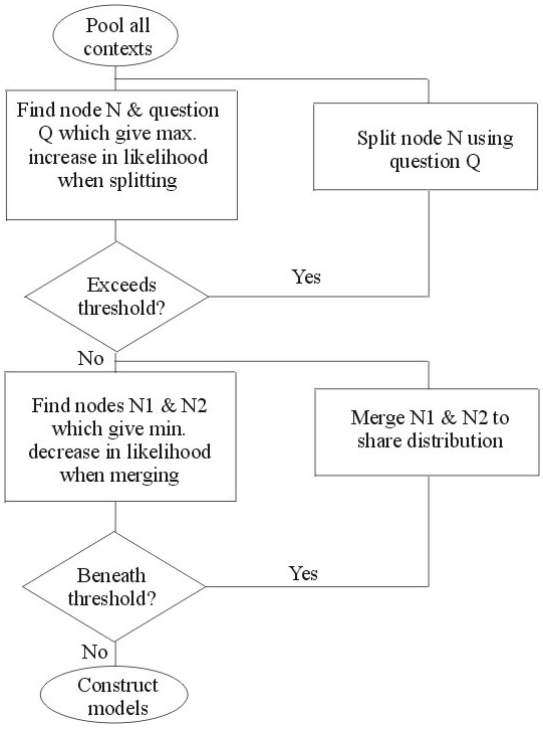

Figure 1. Algorithm for constructing decision tree (Odell, 1995)

Questions asked in the decision tree have a form:

QS "L_SL_Nasal" { m-,n-*, N-* }*

As an example, the command above defines the question "Is the left context a nasal?" where the group of nasals is represented by *{m-*, n-*,N-*}*. Only a finite set of questions can be used to divide each node. So questions have to be defined in a way that all possible natural groups of phonological segments are stated. That allows the incorporation of expert linguistic knowledge needed to predict contextual similarity when little or no data is available in order to determine which contexts are acoustically similar.

Decision tree building process has two stop criteria that determine how deep the tree will be. The first one is increase in the log likelihood that has to be achieved if node was split. In HTK (Young et al., 2000) it is defined with the command TB. The second one is the minimal occupation count that determines how many training data each node has to have. In HTK it is defined with the command RO.

3. SPE theory

Distinctive feature theory was introduced first by R. Jakobsen. He set up twelve universal inherent feature classes. Chomsky and Halle took over Jakobsens idea and defined 22 universal feature classes, which according to the standard SPE theory are sufficient for analysing expression segments of any language into distinctive oppositions.

The idea of natural phonetic groups is based on the so-called Sound pattern of English theory, "SPE", of Chomsky & Halle (1968). By this theory an inventory of expression segments can be described in terms of a hierarchical tree structure where upper nodes represent major class features (like +/- vocalic, +/- consonantal) and lower nodes cavity features, manner of articulation etc., and terminal nodes represent phones. A phonetic representation of an utterance in a given language has by this theory the form of a two-dimensional matrix in which the rows are labelled by features of universal phonetics; the columns stand for the consecutive segments of the utterance generated; and the entries in the matrix determine the binary value (+/-) of each segment with respect to the universal features (Chomsky et al., 1968). A set of phonological segments ("phonemes") sharing the same feature matrix and unequivocally defined by this matrix form a natural group. There are more degrees of naturalness. The SPE theory claims that one group is more natural than the other if the number of features defining it is smaller. The main natural groups (vowels, consonants, semi-vowels) are separated just by different values in major class features. Specific groups (e.g. back-vowels, plosives, nasals, labials) are defined by further features in the matrix and are consequently "less natural". Groups of segments that cannot be defined by a feature matrix are not natural (e.g., the pseudo group: k, a, m, h).

3.1. The use of SPE on SpeechDat2 databases

The starting point of our distinctive features composition can be described as follows:

- We intended to use the SPE as a generally accepted standard theory of phonology and with as few modifications as possible.
- Most notably, we have tried to utilise the Chomsky & Halle decomposition of English segments (1968) as directly as possible.
- Finally, we have attempted to make as few changes to the SpeechDat2 label set as possible.

Hence, our starting point can be paraphrased as attempt to "merge" the SAMPA label set used in SpeechDat2 database with the SPE.

The SPE sets up a total number of twenty-two feature classes, which according to the standard theory are sufficient for analysing expression segments (phonemes) of any language into distinctive oppositions. For a distinctive feature composition of the segments of a specific language, not all 22 feature classes are utilised. For instance, the SPE-description of English segments (Chomsky et al., 1968) makes references only to 13 feature classes. The remaining 9 classes may be regarded as redundant or "irrelevant" to English.

The set of 15 features was sufficiant to represent the set of Slovenian and English SAMPA symbols used in the SpeechDat2 database by the standard SPE theory. In general, we tried to preserve the original distinctive features used in the SPE. We had to, however, make some changes. In short, we replaced the feature vocalic with sonorant and syllabic, and added a feature front (Brøndsted, 1998). The feature +/- front is not within the set of 22 universal binary features defined in the SPE. However, the feature is needed additionally to +/-back because the SAMPA symbols include segments of a dubious phonological state, only specifiable with reference to three places of articulation: [-back, +front], [-back, -front], and [+back, -front].

3.2. Major Class Features

In standard generative phonology, the major class features sonorant, syllabic and consonantal are used to classify phonological segments into five major groups: vowels, non-syllabic liquids/nasals, syllabic liquids/nasals, glides, and obstruents. However, as the SAMPA segments defined for English and Slovenian do not include syllabic liquids/nasals, this in our case resulted in only four major groups (cf. table 1).

	Sonorant	Syllabic	Consonantal
Vowels	+	+	-
Glides	+	-	-
Syllabic Liquids and Nasals	+	+	+
Non-Syllabic Liquids and Nasals	+	-	+
Obstruents	-	-	+

Table 1: The main natural groups represented by major class features

3.3. The use of SPE on the Slovenian SpeechDat2 database

To create a distinctive feature composition table of the Slovenian SAMPA symbols used in SpeechDat2 we had to modify the phonetic transcriptions. In total, SpeechDat2 uses 46 SAMPA symbols in the Slovenian transcriptions. However, according to (Šuštaršič, 1999; Toporišič 2000) Slovenian only has 29 phonemes. Thus, 17 symbols must be considered allophonic variants. These allophones include certain composite pseudo segments (t_n, d_n, p_n, b_n, t_l, d_l) used along with the normal polyphonematic transcriptions (t n, d n ... etc.) in a way that appeared non-systematic to us. Consequently, we decided to change phonetic transcriptions in the database according to the following seven rules:

- Change string “t_n n” with two symbols “t n”
- Change string “d_n n” with two symbols “d n”
- Change string “p_n n” with two symbols “p n”
- Change string “b_n n” with two symbols “b n”
- Change string “t_l l” with two symbols “t l”
- Change string “d_l l” with two symbols “d l”
- Change symbol “W” with symbol “w”

This reduced the set of segments from 46 to 39. The resulting distinctive feature composition table of the Slovenian vowel and consonantal segments is shown in tables 2 and 3.

3.4. The use of SPE on the English SpeechDat2

Similarly we had to modify the transcriptions of the English SpeechDat2 database. The major problem was the monophonematic representation of diphtongs (as single phones). In SPE theory there are no phonological features differentiating diphthongs from monofthongs. This theory handles diphthongs with certain appropriate diphthongisation rules applied to the underlying representations (Chomsky et al., 1968). In order to provide a level of description conforming to the underlying

3.5. Definition of natural groups

During the process of creating the decision tree, groups of phones are used to define questions that may be used in each node of the decision tree. This is the most important stage in the entire model-building procedure where expert phonological knowledge can be included (another one is the prior stage, where the actual set of phones to be used for segmentation and classification of the acoustic signal is established). For that reason, groups of phones for five languages - among these both Slovenian and English - were defined as a part of the COST 249 project. As the languages partly use the same phonemic label set (SAMPA), the groups are reuseable across languages. Slovenian contributes with 45 groups and English with 17 groups. During the process of creating the decision tree, two questions are created from every group defined. One is about the left context and the other about the right one. On the basis of these definitions we created English and Slovenian reference recognition systems.

Our main goal was to create another two systems for both languages that would have phone groups defined on the basis of the SPE theory. Therefore we automatically generated all natural groups of phones from the distinctive feature compositions table set up for the two languages. This resulted in 174 natural groups for Slovenian and 171 for English. The groups were used to create the set of all possible questions to be included in the process of building the experimental SPE-based speech recognition systems.

4. Importance of the order of questions for “unseen” contexts

We hypothesised a case of why it would be not advisable to create questions that would include all possible combinations of phonemes (including "unnatural" groups) and leave to the decision tree building process to chose the best ones by it’s own criteria. This way the decision tree building process would pick up only the important questions (likely involving only "natural" groups) and leave out the irrelevant ones. The idea emerged because of the explanation in the HTK documentation considering the problem of how to build questions for a decision tree: “There is no harm in creating extra unnecessary questions, because those which are determined to be irrelevant to the data will be ignored” (Young et al., 2000). That would yield us the optimal decision tree for this particular system without including any linguistic knowledge. By this definition also the order of the questions in the file that HTK uses for creating a decision tree should have no effect on the structure of the

decision tree. But already the first experiment showed us that the order of questions in this file *does* matter.

When we changed the order of questions in the file also the structure of decision tree has changed. Considering how questions are chosen in the process of building decision tree, we got a possible explanation for this change. For example let's suppose that we in the process of deciding how to cluster the centre state of the phone */m/*. Let's assume that we have data only for the triphones *a-m+**, *b-m+**, *c-m+** and *d-m+** where * means any context. Suppose further that we have defined the questions *QS "L_context1" {a-*, b-*, x-*}* and *QS "L_context2" {a-*, b-*}* where the first one is a superset of the first one (including also the left context '*x*'). The log-likelihood can only be calculated for data that is available for training. Therefore these two questions would cause the same increase in log likelihood if they were used for splitting the node because the left context *x-** does not appear in the training data. So if *L_context1* was used, the middle state of the model with the left context *x* would be trained from the same data as middle states of the models with left contexts *a* and *b*! Likewise, if *L_context2* was used, the middle state of the model with the left context *x* would be trained from the same data as the middle states of the models with left contexts *c* and *d* so from different data as in the first case. Both situations are presented in figure 2. Increase in log-likelihood would be the same in both cases. Therefore, only the order of questions in the file where questions are defined or the procedure that defines which question to use, if more questions give the same increase in log likelihood, would decide from which data model with left context *x* was trained. This means that for the models with contexts not seen in the training data (like *x* here) the decision from which data they'll be trained would depend on the order of questions.

From this we concluded that the phone groups that are later transformed into questions must not be defined without linguistic knowledge, because of the classification of contexts not appearing in the training data.

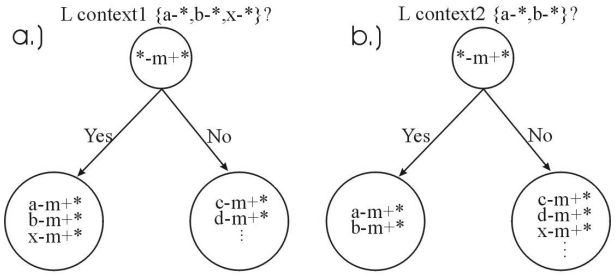

Figure 2. Effect of the order of questions on decision tree

5. Experimental methodology

The main scripts for training and testing acoustic models were implemented as Perl scripts invoking HTK. They were the outcome of the COST 249 project and intended to be used on the SpeechDat2 databases (Lindberg, 2000; Johansen, 2000) and are an extended version of the tutorial example in the HTK Book (Young et al., 2000). They can all be found on the Refrec homepage at

http://www.telenor.no/fou/prosjekter/taletek/refrec/

On this web page we can also find descriptions of standard tests and results of comparative tests done on many SpeechDat2 databases. We used hidden Markov models (HMM) having the 3-state left-right topology. We built triphone models and increased the number of Gaussian mixtures per state sequentially to 32.

5.1. The reference speech recognition systems

For building reference recognition systems we defined questions used in decision tree from groups of phones that were created as a part of the COST 249 project. For the English system we had 17 groups and for Slovenian 45 groups. During the training of acoustic models, data from labelled pronunciations of 800 speakers were used, while the data of the remaining 200 speakers was used as a test set.

The choice of good threshold values is important for the decision tree building process and requires some experimentation in practice. We therefore decided to experiment with the threshold set with the HTK RO command. This threshold determines how many training data each leaf in the decision tree must have. We built one Slovenian system with the threshold set to 100 and two English systems with thresholds set to 100 and 350, respectively (we named them sl-ref100, en-ref100 and en-ref350).

5.2. Speech recognition system with groups based on the SPE theory

In order to evaluate the effect of including the SPE theory into the decision tree building process we built five additional systems – three Slovenian and two English ones. For the model training we used the modified phonetic transcriptions as described in sec. 3.3 and 3.4. We automatically generated all natural phonetic groups from the distinctive feature compositions tables for both languages. From these groups, questions were generated that were used in the process of building decision trees for the two languages. Because of the modified phonetic transcriptions (less phones were used) and the modification of the broad classes, the number of leaves in the decision tree also changed and with that the distribution of the training data. In attempt to alter the amount of training data, we changed the threshold set with the HTK RO command for Slovenian systems from 100 to 267 and 350 and for English to 350 and 477. In this way we got five systems named sl-spe100, sl-spe267, sl-spe350, en-spe350 and en-spe477.

6. Speech recognition results

Six standard tests defined in the framework of the SpeechDat project (Johansen, 2000) were used on all reference and SPE based systems. These tests had the self-explanatory names: Yes/No test, Digits test, Connected Digits test, Application Words test, City Names test and Phonetic Rich Words test. In all tests but one (Connected Digits), each spoken test utterance consists of only one word. Therefore the word error rate (WER) is equal to the sentence error rate (SER) in these cases. Best results of tests done on all systems are given in table 6 and 7.

From these tables it can be observed that the SPE based systems performed either better or at least as good as the reference systems for both languages. The only

exception was the Application Words test on the Slovenian systems. We should also take into consideration that Yes/No, Digits and Connected Digits tests only applied to a small part of the decision tree. Specifically, the vocabulary in these tests is very limited and only a small number of triphones are therefore used.

	sl-ref100	sl-spe100	sl-spe267	sl-spe350
Yes/no	0,63	0,63	0,63	0,63
Digits	3,85	3,85	3,85	3,30
Con. Digits	4,12	3,91	3,95	3,98
App. Words	3,20	3,38	3,74	3,38
City Names	7,65	8,16	7,14	7,14
Ph. R. Words	17,62	17,36	15,93	15,51

	en-ref100	en-spe350	en-spe350	en-spe477
Yes/no	0,00	0,00	0,00	0,00
Digits	3,98	3,98	2,84	2,84
Con. Digits	5,42	5,51	4,22	4,33
App. Words	3,53	3,72	3,72	3,53
City Names	6,21	6,21	7,91	6,21
Ph. R. Words	36,83	35,01	32,68	31,56

Table 6: Lowest WER achieved by the Slovenian and English speech recognition systems in all six tests

	sl-ref100	sl-spe100	sl-spe267	sl-spe350
Con. Digits	15,75	14,56	14,56	14,32

	en-ref100	en-ref350	en-spe350	en-spe477
Con. Digits	30,72	30,92	24,50	25,10

Table 7: Lowest SER achieved by the Slovenian and English speech recognition systems in Connected Digits test

Without doubt, the most reliable evaluation of the SPE based concept can be taken from the Phonetic Rich Words test, employing the largest vocabulary (1491 words for Slovenian and 3043 for English) and more than 710 utterances. This test involves a very big part of the decision tree. This test also gave us the biggest decrease of the WER when comparing the SPE based concepts with the reference systems. The results achieved on the English systems had even bigger impact on the WER. The difference in WER of the best reference system and the best SPE based system is for Slovenian 1,85% and for the English 3,45%. Also the SER achieved with the SPE based systems in the Connected Digits test is better than the one achieved with the reference systems. The impact is again much bigger for English.

7. Conclusions

Within bounds of our experimental set-up we observed an advantage to include the SPE theory as an expert linguistic knowledge into the speech recognition systems. In general we got better results with the SPE-based processing for the English systems than for Slovenian ones. Several possible reasons can be referenced for such behaviour. One is probably the definition of phone groups for the reference systems. There were 45 phone groups defined in the Slovenian reference system while only 17 in the corresponding English one. Therefore, the increase in the number of natural groups resulting from the inclusion of the SPE theory had bigger impact on the English systems than on the Slovenian ones. Another possible reason is the presence of noise. Pronunciations in the Slovenian database were recorded in much higher presence of noise than the English ones. This could potentially have reduced the distinctive ability of some of the features used in the SPE theory.

One possible reason for achieving much better WER for the Phonetic Rich Words test and SER for the Connected Digits test with the English SPE based systems could be the fact that the English reference systems had much bigger error rates than the Slovenian ones. The lowest WER in the Phonetic Rich Words test achieved by the Slovenian reference system was 17,62% whereas it in case of English was 36,83%. The same was observed for the SER in the Connected Digits test (English reference system: 30,72%, Slovenian reference system: 15,75%).

From our experiments, we also concluded that groups of phones should never include actual "unnatural groups" and leave it to the decision tree building process to disregard them in favour of the more natural groups. That would present no significant problem to the classification of triphones that do appear in training data but would lead to the incorrect classification of triphones with contexts that do not appear in the training set.

Based on the experimental evidence we have shown that the creation of the natural groups of phonemes by the SPE theory could effectively be used in defining phone groups for the multilingual speech recognition system including multilingual triphone Markov models. When porting the HLT technology to a new target language, this provides us a promising alternative to the more widespread approach of using the union of phone group definitions from all languages (Zgank et al., 2001).

1. VIPTerm

In 2001, the "Nederlandse Taalunie"(NTU) (Dutch Language Union) initiated a project to set up a virtual informationpoint for terminology (VIPTerm). This project can be considered as the Dutch part of the information and documentation requirements as stipulated by the TDCNet project.
The TDCNet project (European Terminology Documentation Centre Network) is an EU funded project(MLIS 4000 TDCNet 24264/0) with the main objective to create a virtual terminology directory in the form of a logical and physical network of terminology information and documentation centres in Europe.
Within this framework, both bibliographical data (data collections, literature, theses, etc.) and factual data (organisations, software, events, experts and training institutes) will be exchanged between national and regional information centres and compiled in an international terminology directory.
To reach this aim, the NTU set up a project to compile the data for both the Netherlands and Dutch speaking Belgium (Flanders).
VIPTerm (short for Virtual Terminology Information Point) will fullfil the function of a terminology institute, providing a documentation service and information point for users from different backgrounds.
The VIPTerm will also be designed to take up a function in the organisation of the terminologyfield and the networking in this field (a.o. by means of exchange, e.g. through a mailing list). This type of networking and fieldsupport is not the type of task the Nederlandse Taalunie wants to take care of through its own services. Tasks like these will have to be taken up by fieldorganisations, such as NL-TERM, the Dutch terminology association.

The main focus in the structure of this portal is to create an inventory and informationbase of organisations, events, activities , etc. that support a terminology policy for the Dutch language area. Next to this, in the future also the management, maintenance and distribution of electronic resources for Dutch, which is an important task of the NTU (cfr. Euromap and the Dutch Platform for language and speech research : TST (taal en spraaktechnologie), can be organised through this VIPTerm portal.

Both input and output formats were considered carefully in this project. By input format we refer to the actual database format that can be used to register the data.
The ISIS software has been known for some time as the central archiving system used by Unesco and other important datacollectors. The Winisis is a menu-driven generalised information storage and retrieval system designed specifically for the computational management of text-oriented data. Compared to ISIS, WinISIS has a Windows GUI. The output format, on the other hand, has special requirements as well. We need to make the database available through a number of information points, a.o. the special interactive website of the NTU ('Taalunieversum'), the ETIS portal to TDCNet, and websites of other user groups such as NL-TERM, the Dutch terminology association.

In the output structure, the webportal, the following basic categories will be taken into consideration :

- general information and history (short outline of the agents in the field : NTU; Coterm, NL-TERM, and the policy concerning terminology)

- publications, literature
- termcollections
- events/projects

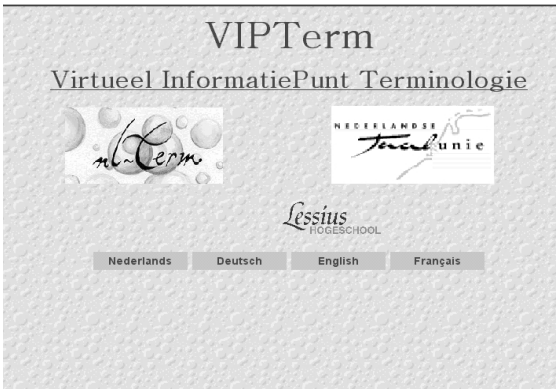
- training and education

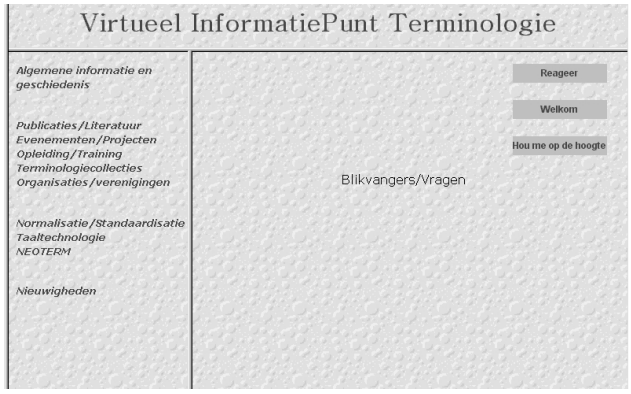
- standardisation
- language technology and terminology management tools
- neoterm
- novelties
- international links

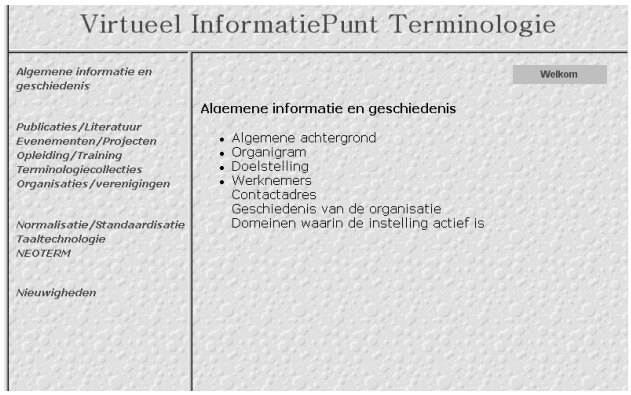
The project and pilotdesign was discussed thoroughly with our colleagues from the Fachhochschule Köln, who develop a similar project called DTP (Deutsches Terminologie Portal). We thoroughly investigated the classification of data (taking into account the existing classifications and TeDif format). We agreed on the principle to structure our portals in a similar way, so as to avoid unnessecary confusion.
Our sites will also be compatible with the ETIS server , as it was recently reprogrammed by the Union Latine.
For Dutch, an active exchange will be organised between the VIPTerm portal and ETIS, providing the data on Dutch terminology for the European level.

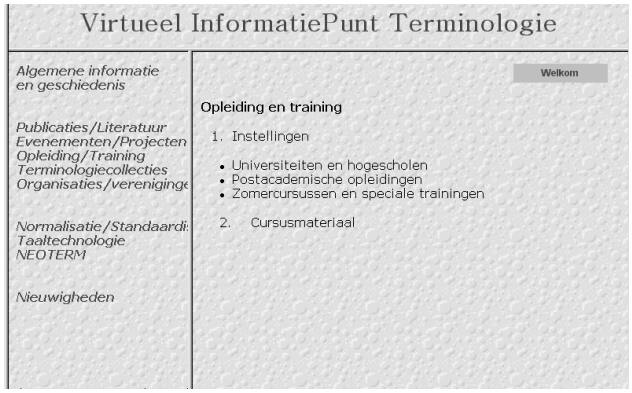
Once the analysis and study phase has been concluded, and advice has been collected through Coterm-experts and NL-TERM board members, we will build a sample portal site for this pilot project.
It will then be evaluated thouroughly and tested among a limited group of users.
If the final outcome of this evaluation is positive, then the VIPTerm project will be continued and will be organised on a more permanent basis.

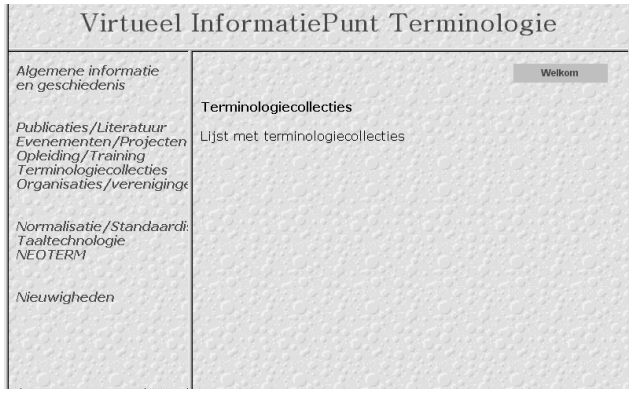
1.1. Prototype

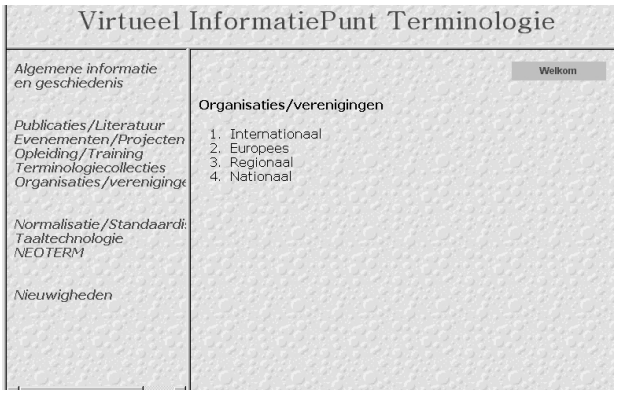


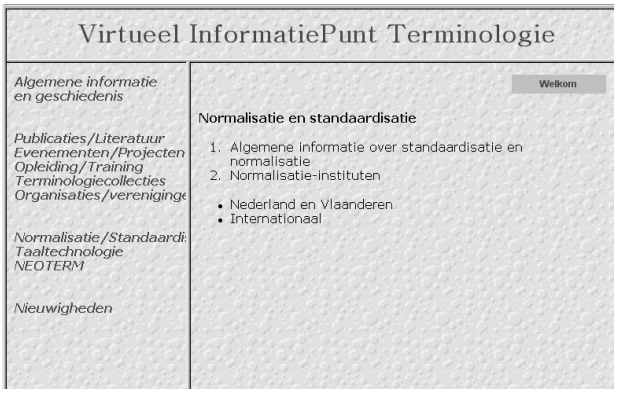


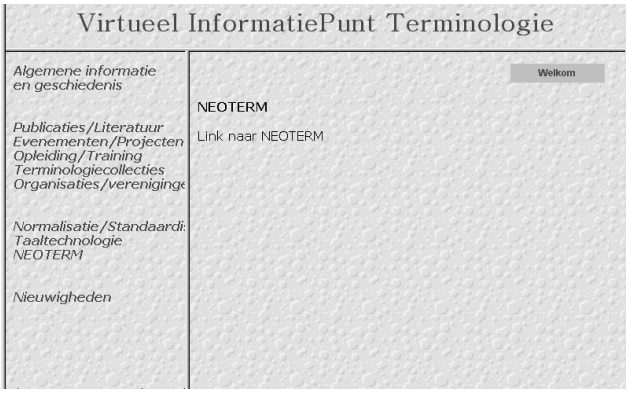


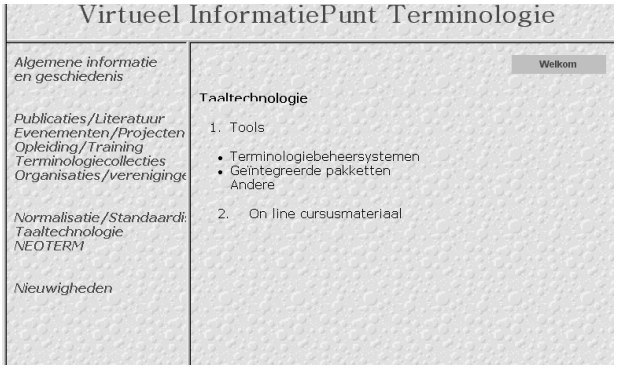












If the VIPTerm project and analogous projects such as DTP (Deutsches Terminologie Portal) are succesful and can be continued, a larger European platform for terminology is within reach and terminology awareness among experts, professionals and users will grow.

Preface

Provision of large-scale language resources, such as tagged corpora, lexicons and repositories of pre-classified text documents, is a crucial key to steady progress in an extremely wide spectrum of research, technological and business areas in the HLT sector. The continuously changing demands for language-specific and application-dependent annotated data (*e.g.* at the syntactic or at the semantic level), indispensable for design validation and efficient software prototyping, however, are daily confronted by the *resource bottleneck*. Handcrafted resources are often too costly and time-consuming to be produced at a sustainable pace, and, in some cases, they even exceed the limits of human conscious awareness and descriptive capability. The problem is even more acutely felt for low-resource languages, since the early stages of language resource development often require gathering considerable momentum both in terms of know-how and level of funding, of the order of magnitude normally deployed by large national projects.

Possible ways to circumvent, or at least minimise, these problems come from the literature on automatic knowledge acquisition and, more generally, from the machine-learning community. Of late, a number of machine learning algorithms have proved to fare reasonably well in the task of incrementally bootstrapping newly annotated data from a comparatively small sample of already annotated resources. Another promising route consists in automatically tracking down recurrent knowledge patterns in relatively unstructured or implicit information sources (such as free texts or machine readable dictionaries) for this information to be moulded into explicit representation structures (e.g. subcategorization frames, syntactic-semantic templates, ontology hierarchies etc.). In a similar vein, several strategies have been investigated aimed at merging or integrating structured information sources into a unitary comprehensive resource, or at customising general-purpose knowledge-bases for them to be of use in more technical domains. Finally, the growing availability of multi-lingual parallel resources has prompted the idea of using a high-resource language (generally English) to fertilize a low-resource language.

We believe that all these attempts at bootstrapping annotated language data are not only of practical interest, but also point to a bunch of germane theoretical issues. Gaining insights into the deep interrelation between representation and acquisition issues is likely to have significant repercussions on the way linguistic resources will be designed, developed and used for applications in the years to come. As the two aspects of knowledge representation and acquisition are profoundly interrelated, progress on both fronts can only be achieved, in our view of things, through a full appreciation of this deep interdependency.

The papers contained in this volume (13 out of 20 submissions) significantly confirm this general view. They focus on a variety of bootstrapping techniques to show their full potential for the provision of annotated language data. In particular, three areas of investigation are dealt with in some detail (often concurrently in the same paper). At the level of corpus annotation, parsers and annotated texts are increasingly used as a tightly integrated resource. Parsing robustness is no longer an end in itself but forms part of a virtuous incremental circle whereby finer grained, more accurate or simply more explicit levels of text analysis are built probabilistically on the basis of either under-specified or possibly more compact annotations. This process proves to be able to provide increasingly richer annotated data and sheds considerable light on the issue of inter-annotation translatability. At the level of lexicon design and building, a lot of effort is being put into merging complementary levels of language information (e.g. semantic and syntax, or semantic and morphology) to produce better lexical repositories for parsing and better computational models of the internalised lexical competence of a speaker. This strikes us as an extremely promising route, bound to throw in sharper relief the importance of simultaneously dealing with more information levels in parsing real texts at the level of accuracy required by HLT applications. Emphasis on the use of available machine learning technology for dealing with the novel challenges of HLT applications is the third research prong of this volume. Current and future needs for information extraction, classification and management appear to impose novel requirements on text processing and create novel tasks in the HLT sector. Once more, machine-learning approaches play an important role here. Perhaps even more significantly, these tasks provide, in turn, a key to a deeper understanding of the implicit assumptions underlying different machine-learning techniques.

We would like to thank all the authors who showed their interest by submitting papers to the workshop. We would also like to thank the members of the programme committee who kindly contributed to the reviewing process and the scientific and programme committees of LREC 2002.

Abstract

We propose a framework that enables the acquisition of annotation-heavy resources such as syntactic dependency tree corpora for low-resource languages by importing linguistic annotations from high-quality English resources. We present a large-scale experiment showing that Chinese dependency trees can be induced by using an English parser, a word alignment package, and a large corpus of sentence-aligned bilingual text. As a part of the experiment, we evaluate the quality of a Chinese parser trained on the induced dependency treebank. We find that a parser trained in this manner out-performs some simple baselines inspite of the noise in the induced treebank. The results suggest that projecting syntactic structures from English is a viable option for acquiring annotated syntactic structures quickly and cheaply. We expect the quality of the induced treebank to improve when more sophisticated filtering and error-correction techniques are applied.

1 Introduction

There is a substantial disparity between the quality of state of the art parsers available for English and those for other languages. English parsers such as those of Collins (1997) and Charniak (1999) were trained on hand annotated corpora such as the Penn Treebank Project (Marcus et al., 1993). However, experience has shown us that building hand-crafted treebanks from scratch is too time-consuming to be repeated for every language of interest. This bad news can be mitigated by leveraging English annotations to automatically acquired annotations for new languages. Recent work by Yarowsky and Ngai (2001) has shown that this type of transfer is possible for inducing part-of-speech tags for Chinese. In this paper, we explore the application of this technique to the more complex problem of inducing Chinese dependency trees.

The input to our system is a collection of sentence-aligned bilingual text (i.e., pairs of sentences that are translations of each other). Each English sentence is parsed using a high-quality English parser. For each pair of sentences, word alignment is performed using statistical MT models (Brown et al., 1990; Al-Onaizan et al., 1999). The alignment then anchors the projection of the English tree to the Chinese side (see Figure 1).

This paper presents an initial large-scale experiment, investigating the feasibility of inducing a Chinese dependency treebank using our projection algorithm and of training a parser on the resulting treebank. Due to the compounded errors of various components of the system, the induced Chinese dependency treebank is rather noisy. Applying filtering heuristics to the treebank improves its quality enough such that the parser trained on it out-performs some simple baselines. While the parser's performance is still significantly less than that of a parser trained on a clean, fully annotated (Chinese) treebank, this study suggests that projecting syntactic structures from English is viable for acquiring annotated syntactic structures quickly and cheaply.

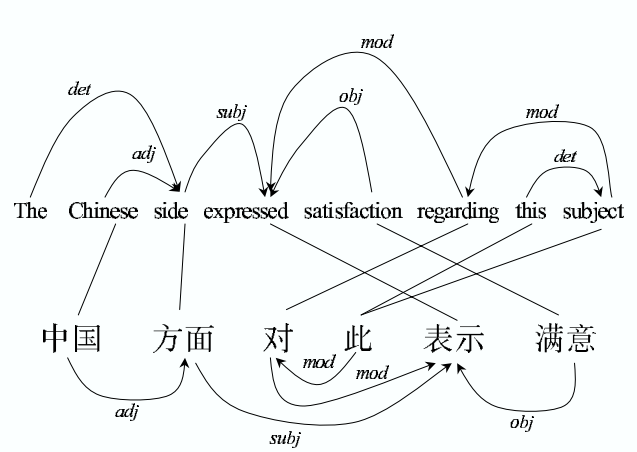

Figure 1: Given an English dependency parse tree and a set of word alignments, we infer the syntactic structure on the Chinese side via projection from its English counterpart.

2 Overview of the Algorithm

Our approach requires three resources. First, we need a sizable, sentence-aligned bilingual text as training corpus. In our experiment, we use a bilingual text of English and Chinese news articles. In Section 5 we discuss other ways in which bilingual text can be acquired and sentence aligned. Second, we require dependency parses of the English text. Our choice of dependency representation is motivated in Section 2.1. Third, word alignments are needed to relate the sentence pair on the lexical level. In this paper, we use alignments produced as a side-effect of training a statistical translation model (Brown et al., 1990; Al-Onaizan et al., 1999).

Given these resources, our system behaves as follows: for each sentence pair (E, C) in the bilingual text, the English sentence E is parsed and converted into a dependency representation. Next, word alignment is performed for the

sentence pair. Finally, the English dependency analysis is projected across the word alignment to the Chinese side according to our *Direct Projection Algorithm*, which we outline in section 2.2.

2.1 Dependency Representations as Transfer Medium

Dependency relationships specify asymmetric binary relations between two surface words: a *head* and its *modifier*. For example, in the sentence from Figure 1, *"The Chinese side expressed satisfaction regarding this subject,"* the word *side* modifies the head word *expressed*. The dependency links may optionally be annotated with information specifying grammatical relations between constituents such as *subject*, *object*, *modifier*, etc. In our example, the link between *side* and *expressed* is labeled as *subj*, indicating that the constituent *The Chinese side* is the subject of the verb *expressed*. In this section, we argue that dependency representation is right for our projection framework because it captures both structural and lexical relationships between words that are not string local; because it overcomes some of the shortcomings of evaluating against the phrase structure representation; and because it is language independent with respect to word order variations.

Syntactic analysis in terms of phrase structure has been the dominant paradigm in natural language processing, starting from early context-free grammars and continuing up to present-day stochastic formalisms. It is preferable over models that make Markov assumptions restricting interactions among words to those that occur within the window of an n-gram. Phrase structure formalisms provide a level of representation that allows significant constraint to occur between grammatical categories that are not string-local. These categories become *local* at the phrase structure level. For example, consider the following sentence from the Brown Corpus:

> *The largest hurdle the Republicans would have to face is a state law which says that before making a first race, one of two alternative courses must be taken.*

The relationship between *hurdle* and *is* exists over a long string-distance, owing to an embedded relative clause, and, similarly, *Republicans* and *face* are separated in the string by a sequence of auxiliaries and the infinitival *to*. As a result, the relationships represented in the sentence are not captured well by any n-gram model with tractable n. In contrast, the relationship between the subject NP and the predicate is easily encoded locally within a context-free rule such as S $\rightarrow$ NP VP.

To take full advantage of such relationships in models based on phrase structure, however, it is necessary to *lexicalize* the grammar formalism, so that lexically-based constraints are also localized within grammar rules. By incorporating lexical content into phrase structure rules (e.g., S(is) $\rightarrow$ NP(hurdle) VP(is)), lexicalized grammar formalisms make it possible to capture syntactic constraints such as as number agreement (e.g. the low probability of S(are) $\rightarrow$ NP(hurdle) VP(are)) as well as semantic constraints (e.g. the reasonably high probability of S(face) $\rightarrow$ NP(Republicans) VP(face)). Work taking advantage of this insight (e.g. Collins (1997; Charniak (1999)) has defined the breakthroughs leading to the current state of the art in broad-coverage parsing. Implicitly or sometimes explicitly (as in the work of Collins), what gives lexicalized context-free representations their power is the ability to probabilistically model the syntactic *dependency* relationships between words in the structure.

Moreover, dependency analysis evaluation avoids some of the shortcomings of constituency analysis evaluation (Lin, 1995; Carroll et al., 1999). Standard constituency parsing metrics compare the phrase boundaries specified by the gold standard to that of the candidate analysis. They also evaluate whether conditions on well formed trees (such as a ban on crossing branches) are respected by the candidate. However, as Lin (1995) notes, since branching structure is not directly tied to semantic interpretation, it is unclear how to interpret missing, spurious, or crossing branches. On the other hand, it is apparent that syntactic dependencies, more so than syntactic constituents, are closely tied to the who-did-what-to-whom relationships of language. Indeed, work in lexical semantics relating syntactic representations to thematic relationships such as *agent*, *theme*, *beneficiary*, has focused primarily on syntactic dependencies rather than on phrasal constituents (Baker, 1997). Since semantic dependencies form a superset based on syntactic dependencies, we are better able to gauge how likely a representation is to be interpretable, by measuring the percentage of correct dependencies.

Finally, dependency structures firmly separate precedence from dominance relations, such that word order variation between languages becomes less of a problem than in constituency trees. For example, the relative string order of a series of modifiers of a head is irrelevant in the dependency representation. All are modifiers. By contrast, a constituency tree may require a stacked structure that would not translate well if the word order were reversed in another language. In other words, dependency structures are more likely to respect a homomorphism.

These observations suggest that dependencies may be a better choice for syntactic projection across languages than phrasal constituents. To the extent that this assumption is correct, we should be able to use word alignments as a bridge between English and another language, retaining some level of confidence that if dependencies are projected across the alignment they will be correct for the new language. Experimental results from our previous work (Hwa et al., 2002), have indicated that while the assumption does not always hold true, syntactic analyses projected from English to Chinese can, in principle, yield Chinese analyses that are nearly 70% accurate (in terms of unlabeled dependencies) after application of a set of linguistically principled rules.[1]

2.2 The Direct Projection Algorithm

Our approach is based on the intuitive idea of a direct projection of dependency structures. We now describe our

[1]The experiment was performed under idealized settings, projecting human annotated English dependency analyses using human annotated word alignments.

projection algorithm in more detail. Given sentence pair (E, C), where $E = e_1, \ldots, e_n$ and $C = c_1, \ldots, c_m$, syntactic relations (denoted as $R(x, y)$) are projected from English for the following situations:

- **one-to-one** if e_i is aligned with a unique c_x and e_j is aligned with a unique c_y, if $R(e_i, e_j)$, conclude $R(c_x, c_y)$.
- **unaligned (English)** if e_j is not aligned with any word in C, then create a new empty word c_y such that for any e_i aligned with a unique c_x, $R(e_i, e_j) \Rightarrow R(c_x, c_y)$ and $R(e_j, e_i) \Rightarrow R(c_y, c_x)$.
- **one-to-many** if $e_i$is aligned with $c_x, \ldots, c_y$, then create a new empty word c_z such that c_z is the parent of $c_x, \ldots, c_y$ and set e_i to align to c_z instead. We called this a *Multiply-Aligned Component*, or MAC.
- **many-to-one** if $e_i, \ldots, e_j$ are all uniquely aligned to c_x, then delete all alignments between $e_k (i \leq k \leq j)$ and c_x except for the head of $e_i, \ldots, e_j$.

The **many-to-many** case is decomposed into a two-step process: first perform one-to-many, then perform many-to-one. In the cases of unaligned Chinese words, they are left out of the projected syntactic tree. The asymmetry of the treatment of **one-to-many** and **many-to-one** and of the unaligned words for the two languages arises from the asymmetric nature of the projection.

2.2.1 Post-Projection Transformation

The Direct Projection Algorithm by itself does not produce good dependency trees because it does not properly handle structural projection for the more complex cases when the alignment is not one-to-one. Therefore, we apply a small set of linguistically motivated rules to correct the projected trees as a post-hoc process. It is clearly an advantage to limit the correction rules to those that can apply generally, across many construction types. Wanting to avoid unending language-specific rule tweaking, we strictly limited the possible rules. Rules were permitted to refer only to closed class items, to parts of speech projected from the English analysis, or to easily enumerated lexical categories (e.g. {*dollar*, RMB, $, yen}). The majority of rule patterns are variations on the same solution to the same problem. Viewing the problem from a higher level of linguistic abstraction made it possible to find all the relevant cases in a short time and express the solution compactly; in all, fewer than twenty rules were written, and the analysis, rule writing, and verification of their correctness using the data set took a few days.

Here are two examples of the rules we developed; see (Hwa et al., 2002) for fuller discussion.

Rule for noun modification:

- If $c_x, \ldots, c_y$ are a set of Chinese words aligned to an English noun, replace the empty node introduced in the Direct Projection Algorithm by promoting the last word c_y to its place with $c_x, \ldots, c_{y-1}$ as dependents.

Rule for aspectual markers:

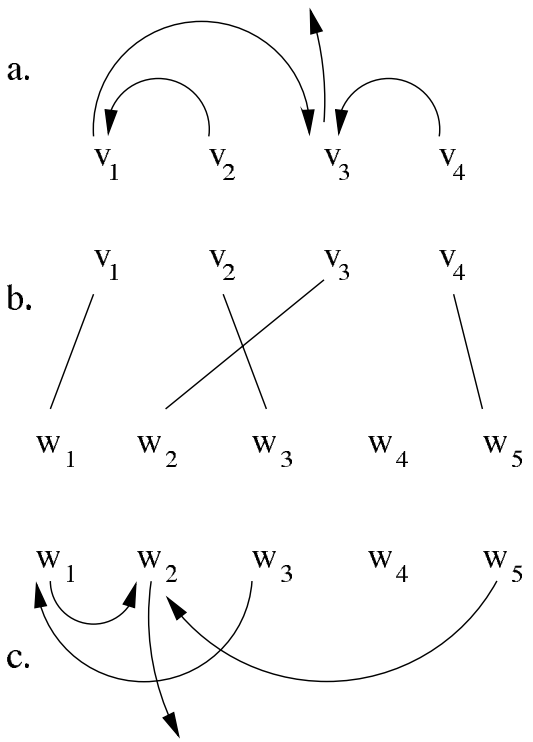

Figure 2: The direct projection of the dependency parse for $v_1 \ldots v_4$ (Figure 2a) across the word alignment (Figure 2b) results in cross dependency relationships for the link between w_1 and w_3 and the link between w_2 and w_5; and it leaves word w_4 unattached to the projected dependency tree (Figure 2c).

- If $c_x, \ldots, c_y$, a sequence of Chinese words aligned with English verbs, is followed by c_a, an aspect marker, make c_a into a modifier of the last verb c_y.

2.2.2 Remaining Shortcomings of the Direct Projection Algorithm

Although the majority of the projected trees are significantly improved, the post-projection transformation rules still do not adequately address some major deficiencies of the Direct Projection Algorithm. The algorithm does not ensure that the projected structure is indeed a well-formed structure. Thus, when given unconstrained word alignment outputs, the projected structure may contain errors such as crossing dependencies (see Figure 2). Moreover, due to the asymmetry of the algorithm, the syntactic role of unaligned foreign words cannot be inferred. The post-projection transformation rules address this problem to some extent by incorporating unaligned function words back into the parse, but an intelligent treatment of the open class of unaligned words remains a challenge of this projection approach. Furthermore, the algorithm does not address complex translation divergences (Dorr, 1993), such as the head-swapping phenomenon (in which the direction of the head-modifier dependency is reversed in the foreign language). Lopez et al. (2002) describe an alternative to the direct projection approach that addresses some of these problems.

3 Experimental Setup

Our previous results have shown that, given good English parses and clean alignments to Chinese translations, the direct projection approach from English to Chinese (together with post-processing) can lead to Chinese annotations that are substantially correct; unlabeled precision/recall on projected dependencies approaches 70% (Hwa et al., 2002). While this demonstrates that the approach holds promise in automatically inducing syntactic treebanks of reasonable quality, it is not clear how much degradation occurs when using imperfect English parsers and imperfect word alignment models. That question is our focus in this paper. We report a full-scale experiment on English and Chinese sentence pairs, evaluating the entire framework under the realistic settings of imperfect bilingual data and error-prone parsers and alignment models (see Section 3.1). Once a Chinese dependency treebank is induced, we use it to train a Chinese parser in a manner similar to that of Collins (1999). The trained parser is then evaluated on unseen test sentences taken from the Chinese Treebank (Xia et al., 2000) and compared with two baselines and an upper bound.

3.1 Resources

We use about 56,000 sentence pairs from the Hong Kong News (HKNews) corpus as our bilingual text. The data have been automatically sentence aligned and the Chinese words have been automatically segmented.[2] To parse the English sentences, we use a lexicalized statistical parser trained on the Wall Street Journal corpus (Collins, 1997).[3] To obtain word alignments for all sentence pairs, we train an off-the-shelf statistical translation model, GIZA++ (Al-Onaizan et al., 1999), using the HKNews bilingual text. Given these resources, the direction projection algorithm and the post-projection transformation process are then used to induce dependency trees for the Chinese sentences in the HKNews corpus.

3.2 Evaluation of the Induced Treebank

Because of its size, we do not directly assess the quality of the induced treebank. Instead, we evaluate the Chinese parser trained from it. To the extent that the trained parser outputs reasonable structures on unseen test sentences, it indicates that the induced treebank is a useful resource. To evaluate the quality of the trained parser, we compare it to two simple baseline dependency analyses: *always modify the previous word*, and *always modify the next word*. As an upper bound, we have also trained the same parser with clean, hand-annotated trees from the Penn Chinese Treebank (ChTB). We constructed a development set consisting of 124 sentences and a test set consisting of 88 sentences taken from the Chinese Treebank; all sentences are of 40 words or less. The remaining approximately 3800 Chinese Treebank sentences are converted into their dependency representation (similar to the algorithm described in Section 2 of the paper by Xia and Palmer (2001)) and used as training data for the upper-bound parser. We evaluate the trained parser by comparing its output (dependency) parse trees for the unseen test sentences against the human-annotated gold standard parse trees (also converted to dependency representation). The metrics used are the precision and recall scores on the unlabeled dependency relations. A parser produced dependency link is considered "correct" if the same head-modifier relationship exists in the gold standard; the dependency label does not need to match. Punctuations are not scored.

[2] We are grateful to Stefan Vogel of CMU for his assistance with this corpus.

[3] The executable of the parser is freely available at ftp://ftp.cis.upenn.edu/pub/mcollins/misc.

4 Results and Discussions

Tables 1 and 2 show performance comparisons for our automatic projection approach as compared to the lower and upper bounds. As one might expect, the quality of the treebank induced under the real-world constraints of imperfect data and components is noticeably worse than one induced using clean English parses and perfect word alignments. The Direct Projection Algorithm and its associated post-projection transformation rules are not fault-tolerant enough to recover from the compounding errors of the parser and alignment model. Without further processing, the projected treebank would contain too much noise to be useful for training a parser. Therefore, our attentions turn to filtering heuristics for poorly induced dependency trees.

We found that the most unreliable component is the word alignment model. A cursory inspection of the alignment output (for the HKNews corpus) shows that, for many sentences, the majority of the English words remain unaligned; and that often, an unusually high number of Chinese words (e.g, five or greater) are aligned to the same English word. The poor alignment output may have many causes: in particular, the sentence pair input to the alignment model is imperfect, and the alignment model does not perform well for language pairs with very dissimilar word-order patterns.

This suggests that performance might improve if we filter out sentence pairs that are known to be poorly aligned. To filter out dependency trees projected from dubious word alignments, we have devised several simple heuristics. First, we removed those sentences for which more than 30% of the English words were not aligned to any Chinese word ($EnoC \leq 0.3$). The figure 30% is empirically determined, based on the trained parser's performance on the development set. As shown in the first row of Table 1, the parser trained on the filtered treebank does outperform the modify-next baseline; however, the corpus size has been drastically cut-down from around 56,000 to less than 8,000. The second filter we apply to the corpus is to remove sentences in which the size of a multiply aligned component is greater than three (MAC > 3); that is, when more than three Chinese words are aligned to the same English word. The MAC value of 3 was also determined empirically using development data. The second line of Table 1 shows that training the parser on the induced treebank filtered by both heuristics leads to further improvement. Finally, we return to the crossing-dependency problem alluded to earlier in section 2.2.2. While we do not correct the crossing depen-

Table 1: The parser's performance on the development set (%) when the training corpus has been filtered with the following heuristics: remove sentences if too many English words have no Chinese translations (EnoC); remove sentences if too many Chinese words are aligned to one English word (MAC); remove sentences that violate many crossing-dependency constraints (NoCross).

dencies in this work, we remove sentences with the most egregious crossing-dependency violations in their analyses. Our experiments with development data suggested that a sentence should be filtered out if more than 40% of its dependency links violate the no-crossing constraint. The combination of the three filters improved the induced treebank so that a parser trained on the treebank outperforms the simple baselines; however, the draconian filters also reduced the corpus from 56,000 sentences to slightly over 5,000.

Table 2 shows the trained parser's performance on a separate test set. As before, it is compared with two baselines; and as an upper bound, we train the same parser on a clean, manually created treebank.[4] Similar to the outcome of the development set, the trained parser performs better than the baseline, but it still cannot compete with a parser trained on a clean corpus. It is interesting to note that after our current filtering techniques, the sizes of the induced treebank is comparable to the clean one. However, our method of treebank acquisition is not constrained by the laborious manual annotation process; therefore it would be easy for us to obtain a much larger bilingual corpus as a starting point, as discussed below. We conjecture that the size of the corpus will help offset the effect of the noise, as will more sophisticated sampling techniques that exclude the noisiest data.

5 Conclusion and Future Work

In this paper, we have described our framework for acquiring Chinese dependency treebanks by bootstrapping from existing linguistic resources for English. We have explicitly discussed the assumptions made and the resources required in order for our algorithm to work. An ambitious full-scale experiment using real-world data was performed to investigate the feasibility of our approach. Our results suggest that treebank acquisition through projection is indeed possible; however reducing the noise in the induced treebank is a major challenge.

This finding points us to several directions for further research. One clear avenue is to obtain larger bilingual texts, so that more data remain even when noisy sentence pairs have been filtered out. Work on mining the Web for bilingual text, such as STRAND (Resnik, 1999), BITS (Ma and Liberman, 1999), and PTMiner (Nie et al., 1999), show significant promise in this regard. Once parallel Web pages are obtained, it is possible to obtain sentence- or segment-level alignments either via alignment of HTML markup (Resnik, 1998) or via more sophisticated sentence-alignment techniques (Melamed, 1998).

Beyond simply taking a "more is better" approach to data acquisition, one way to reduce the noise in the induced treebank is to lower the error rates of the individual components in our projection framework. Of these, improving the word alignment model would benefit the overall system the most. We are actively developing alternative word alignment models that is sensitive to this syntactic projection framework (Lopez et al., 2002). Moreover, as we have shown in this study, filtering techniques that identify and remove malformed trees can help reducing noise; however, aggressive filtering alone is likely to result in over-filtering. To render nearly 90% of the bilingual text useless places too heavy a burden on even the best Web mining techniques. We are experimenting with filtering strategies that attempt to localize the potentially problematic parts of a syntactic tree so that the rest can still contribute to the training corpus. In addition, we are continuing to work on the post-projection transformation the process to improve the quality of the projected trees.

[4]The upper-bound parser's performance is on par with that of the state of the art constituency parsers trained on the Chinese Treebank, e.g. (Bikel and Chiang, 2000).

Abstract

Lexical-Functional Grammar f-structures are abstract syntactic representations approximating basic predicate-argument structure. Treebanks annotated with f-structure information are required as training resources for stochastic versions of unification and constraint-based grammars and for the automatic extraction of such resources. In a number of papers (Frank, 2000; Sadler, van Genabith and Way, 2000) have developed methods for automatically annotating treebank resources with f-structure information. However, to date, these methods have only been applied to treebank fragments of the order of a few hundred trees. In the present paper we present a new method that scales and has been applied to a complete treebank, in our case the WSJ section of Penn-II (Marcus et al, 1994), with more than 1,000,000 words in about 50,000 sentences.

1. Introduction

Lexical-Functional Grammar f-structures (Kaplan and Bresnan, 1982; Bresnan, 2001) are abstract syntactic representations approximating basic predicate-argument structure (van Genabith and Crouch, 1996). Treebanks annotated with f-structure information are required as training resources for stochastic versions of unification and constraint-based grammars and for the automatic extraction of such resources. In two companion papers (Frank, 2000; Sadler, van Genabith and Way, 2000) have developed methods for automatically annotating treebank resources with f-structure information. However, to date, these methods have only been applied to treebank fragments of the order of a few hundred trees. In the present paper we present a new method that scales and has been applied to a complete treebank, in our case the WSJ section of Penn-II (Marcus et al, 1994), with more than 1,000,000 words in about 50,000 sentences.

We first give a brief review of Lexical-Functional Grammar. We next review previous work and present three architectures for automatic annotation of treebank resources with f-structure information. We then introduce our new f-structure annotation algorithm and apply it to the Penn-II treebank resource. Finally we conclude and outline further work.

2. Lexical-Functional Grammar

Lexical-Functional Grammar (LFG) is an early member of the family of unification- (more correctly: constraint-) based grammar formalisms (FUG, PATR-II, GPSG, HPSG etc.). It enjoys continued popularity in theoretical and computational linguistics and natural language processing applications and research. At its most basic, an LFG involves two levels of representation: c-structure (constituent structure) and f-structure (functional structure). C-structure represents surface grammatical configurations such as word order and the grouping of linguistic units into larger phrases. The c-structure component of an LFG is represented by a CF-PSG (context-free phrase structure grammar). F-structure represents abstract syntactic functions such as subject, object, predicate etc. in terms of recursive attribute-value structure representations. These abstract syntactic representations abstract away from particulars of surface configuration. The motivation is that while languages differ with respect to surface representation they may still encode the same (or very similar) abstract syntactic functions (or predicate argument structure). To give a simple example, typologically, English is classified as an SVO (subject-verb-object) language while Irish is a verb initial VSO language. Yet a sentence like *John saw Mary* and its Irish translation *Chonaic Seán Máire*, while associated with very different c-structure trees, have structurally isomorphic f-structure representations, as represented in **Figure 1**.

C-structure trees and f-structures are related in terms of projections (indicated by the arrows in the examples in **Figure 1**). These projections are defined in terms of f-structure annotations in c-structure trees (describing f-structures) originating from annotated grammar rules and lexical entries. A sample set of LFG grammar rules with functional annotations (f-descriptions) is provided in **Figure 2**. Optional constituents are indicated by brackets.

3. Previous Work: Automatic Annotation Architectures

It would be desirable to have a treebank annotated with f-structure information as a training resource for probabilistic constraint (unification) grammars and as a resource for extracting such grammars. The large number of CFG rule types in treebanks ($> 19,000$ for Penn-II) makes manual f-structure annotation of grammar rules extracted from complete treebanks prohibitively time consuming and expensive. Recently, in two companion papers (Frank, 2000; Sadler, van Genabith and Way, 2000) a number of researchers have investigated the possibility of automatically annotating treebank resources with f-structure information. As far as we are aware, we can distinguish three different types of automatic f-structure annotation architectures (these have all been developed within an LFG framework and although we refer to these as automatic f-structure an-

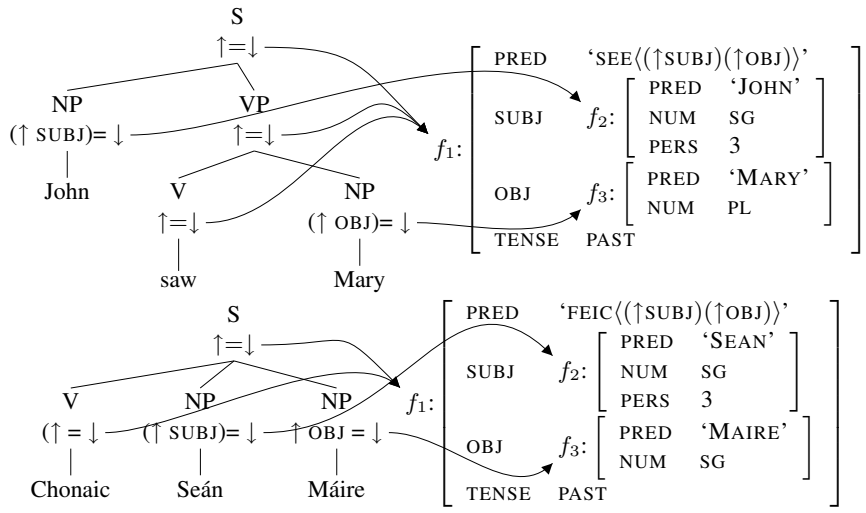

Figure 1: C- and f-structures for an English and corresponding Irish sentence

$$\text{S} \rightarrow \text{NP}_{\uparrow \text{SUBJ} = \downarrow} \quad \text{VP}_{\uparrow = \downarrow} \quad \left(\text{ADV}_{\downarrow \in \uparrow \text{ADJN}}\right)$$

$$\text{NP} \rightarrow \text{Det}_{\uparrow = \downarrow} \quad \text{N}_{\uparrow = \downarrow}$$

$$\text{VP} \rightarrow \text{V}_{\uparrow = \downarrow} \quad \left(\text{NP}_{\uparrow \text{OBJ} = \downarrow}\right) \quad \left(\text{VP}_{\uparrow \text{XCOMP} = \downarrow}\right) \quad \left(\text{S}_{\uparrow \text{COMP} = \downarrow}\right)$$

notation architectures they could equally well be used to annotate treebanks with e.g. HPSG feature structure or with Quasi-Logical Form (QLF) (Liakata and Pulman, 2002) annotations):

- regular expression based annotation (Sadler, van Genabith and Way, 2000)
- tree description set based rewriting (Frank, 2000)
- annotation algorithms

More recently, we have learnt about the QLF annotation work by (Liakata and Pulman, 2002). Much like (Frank, 2000), their approach is based on matching configurations in a flat, set based tree description representation.

Below we will briefly describe the first two architectures. The new work presented in this paper is based on an annotation algorithm and discussed at length in Sections 4 and 5 of the paper.

3.1. Regular Repression Based Annotation

(Sadler, van Genabith and Way, 2000) describe a regular expression based automatic f-structure annotation methodology. The basic idea is very simple: first, the CFG rule set is extracted from the treebank (fragment); second, regular expression based annotation principles are defined; third, the principles are automatically applied to the rule set to generate an annotated rule set; fourth, the annotated rules are automatically matched against the original treebank trees and thereby f-structures are generated for these trees. Since the annotation principles factor out linguistic generalisations their number is much smaller than the number of CFG treebank rules. In fact, the regular expression based f-structure annotation principles constitute a principle-based LFG c-structure/f-structure interface. We will explain the method in terms of a simple example. Let us assume that from the treebank trees we extract CFG rules expanding `vp` of the form (amongst others):

```
vp:A > v:B s:C
vp:A > v:B v:C s:D
vp:A > v:B v:C v:D s:E
     ..
vp:A > v:B s:C pp:D
vp:A > v:B v:C s:D pp:E
vp:A > v:B v:C v:D s:E pp:F
     ..
vp:A > advp:B v:C s:D
vp:A > advp:B v:C v:D s:E
vp:A > advp:B v:C v:D v:E s:F
     ..
vp:A > advp:B v:C s:D pp:E
vp:A > advp:B v:C v:D s:E pp:F
vp:A > advp:B v:C v:D v:E s:F pp:G
```

Each CFG category in the rule set has been associated with a logical variable designed to carry f-structure information. In order to annotate these rules we can define a set of regular expression based annotation principles:

```
vp:A > * v:B v:C *
```

```
     @ [B:xcomp=C,B:subj=C:subj]
vp:A > *(~v) v:B *
     @ [A=B]
vp:A > * v:B s:C *
     @ [B:comp=C]
```

The first annotation principle states that if anywhere in a rule RHS expanding a `vp` category we find a `v v` sequence the f-structure associated with the second `v` is the value of an `xcomp` attribute in the f-structure associated in the first `v` ('`*`' is the Kleene star and, if unattached to any other regular expression, signifies any string). It is easy to see how this annotation principle matches many of the extracted example rules, some even twice. The second principle states that the leftmost `v` in `vp` rules is the head. The leftmost constraint is expressed by the fact that the rule RHS may consist of an initial string that may not contain a `v`: `*(~v)`. Each of the annotation principles is partial and underspecified: they underspecify CFG rule RHSs and annotate matching rules partially. The annotation interpreter applies all annotation principles to each CFG rule as often as possible and collects all resulting annotations. It is easy to see that we get, e.g., the following (partial) annotation for:

```
vp:A > advp:B v:C v:D v:E s:F pp:G
     @ [A=C,
        C:xcomp=D,C:subj=D:subj,
        D:xcomp=E,D:subj=E:subj,
        E:comp=F]
```

In their experiments with the publicly available subsection of the AP treebank, (Sadler, van Genabith and Way, 2000) achieve precision and recall results in the low to mid 90 percent region against a manually annotated "gold standard". The method is order independent, partial and robust. To date, however, the method has been applied to only small CFG rule sets (of the order of 500 rules approx.).

3.2. Rewriting of Flat Tree Description Set Representations

In a companion paper, (Frank, 2000) develops an automatic annotation method that in many ways is a generalisation of the regular expression based annotation method. The basic idea is again simple: first, trees in treebanks are translated into a flat set representation format in a tree description language; second, annotation principles are defined in terms of rewriting rules employing a rewriting system originally developed for transfer based machine translation architectures (Kay, 1999). We will illustrate the method with a simple example

```
     s:A
    /   \              dom(A,B), dom(A,C),
np:B    vp:C           dom(C,D), ..
  |       |      =>    pre(B,C),
John     v:D           cat(A,s), cat(C,vp),
           |           cat(D,v), ..
         left
```

```
dom(X,Y), dom(X,Z), pre(Y,Z),
cat(X,s), cat(Y,np), cat(Z,vp)
        ==>
subj(X,Y), eq(X,Z)
```

Trees are described in terms of (immediate and general) dominance and precedence relations, labelling functions assigning categories to nodes and so forth. In our example node identifiers `A`, `B`, etc. do double duty as f-structure variables. The annotation principle states that if node `X` dominates both `Y` and `Z` and if `Y` preceeds `Z` and the respective CFG categories are `s`, `np` and `vp` then `Y` is the subject of `X` and `Z` is the same as (i.e. is the head of) `X`.

The tree description rewriting method has a number of advantages:

- in contrast to the regular expression based method, annotation principles formulated in the flat tree description method can consider arbitrary tree fragments (and not just only local CFG rule configurations).
- in contrast to the regular expression based method which is order independent, the rewriting technology can be used to formulate both order dependent and order independent systems. Cascaded, order dependent systems can support a more compact and perspicuous statement of annotation principles as certain transformations can be assumed to have already applied earlier on in the cascade.

For a more detailed, joint presentation of the two approaches consult (Frank et al, 2002). Like the regular expression based annotation method, the tree description based set rewriting method has to date only been applied to small treebank fragments of the order of serveral hundred trees.

3.3. Annotation Algorithms

The previous two automatic annotation architectures enforce a clear separation between the statement of annotation principles and the annotation procedure. In the first case the annotation procedure is provided by our regular expression interpreter, in the second by the set rewriting machinery. A clean separation between principles and processing supports maintenance and reuse of annotation principles. There is, however, a third possible automatic annotation architecture and this is an annotation algorithm. In principle, two variants are possible. An annotation algorithm may

- directly (recursively) transduce a treebank tree into an f-structure – such an algorithm would more appropriately be referred to as a tree to f-structure transduction algorithm;
- annotate CFG treebank trees with f-structure annotations from which an f-structure can be computed by a constraint solver.

The first mention of an automatic f-structure annotation algorithm we are aware of is unpublished work by Ron Kaplan (p.c.) who as early as 1996 worked on automatically generating f-structures from the ATIS corpus to generate data for LFG-DOP (Bod and Kaplan, 1998) applications.

Kaplan's approach implements a direct tree to f-structure transduction. The algorithm walks the tree looking for different configurations (e.g. np under s, 2nd np under vp, etc.) and "folds" the tree into the corresponding f-structure. By contrast, our approach develops the second, more indirect tree annotation algorithm paradigm. We have designed and implemented an algorithm that annotates nodes in the Penn-II treebank trees with f-structure constraints. The design and the application of the algorithm is explained below.

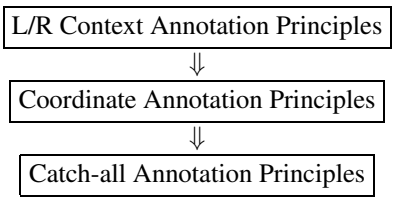
4. Automatic Annotation Algorithm Design

In our work on the automatic annotation algorithm we want to achieve the following objectives: we want an annotation method that is robust and scales to the whole of the Penn-II treebank with 19,000 CFG rules for 1,000,000 words with 50,000 sentences approx. The algorithm is implemented as a recursive procedure (in Java) which annotates Penn-II treebank tree nodes with f-structure information. The annotations describe what we call "proto-f-structures". Proto-f-structures

- encode basic predicate-argument-modifier structures;
- may be partial or unconnected (i.e. in some cases a sentence may be associated with two or more unconnected f-structure fragments rather than a single f-structure);
- may not encode some reentrancies, e.g. in the case of wh- and other movement or distribution phenomena (of subjects into VP coordinate structures etc.).

Compared to the regular expression and the set rewriting based annotation methods described above, the new algorithm is somewhat more coarse grained, both with respect to resulting f-structures and with respect to the formulation of the annotation principles.

Even though the method is encoded in the form of an annotation algorithm (i.e. a procedure) we did not want to completely hard code the linguistic basis for the annotation into the procedure. In order to achieve a clean design which supports maintainability and reusability of the annotation algorithm and the linguistic information encoded in it, we decided to design the algorithm in terms of three main components that work in sequence:



Each of the components of the algorithm is presented below.

In addition, at the lexical level, for each Penn-II preterminal category type, we have a lexical macro associating any terminal under the category with the required f-structure information. To give a simple example, a singular common noun nns, such as e.g. *company* is annotated by the lexical macro for nns as $\uparrow$ pred = company, $\uparrow$ num = sg, $\uparrow$ pers = 3rd.

4.1. L/R Context Annotation Principles

The annotation algorithm recursively traverses trees in a top-down fashion. Apart from very few exceptions (e.g. possessive NPs), at each stage of the recursion the algorithm considers local subtrees of depth one (i.e. effectively CFG rules). Annotation is driven by categorial and simple configurational information in a local subtree.

In order to annotate the nodes in the trees, we partition each sequence of daughters in a local subtree (i.e. rule RHS) into three sections: left context, head and right context. The head of a local tree is computed using Collins' Collins (1999) head lexicalised grammar annotation scheme (except for coordinate structures, where we depart from Collins' head scheme). In a preprocessing step we transform the treebank into head lexicalised form. During automatic annotation we can then easily identify the head constituent in a local tree as that constituent which carries the same terminal string as the mother of the local tree. With this we can compute left and right context: given the head constituent, the left context is the prefix of the local daughter sequence while the right context is the suffix. For each local tree we also keep track of the mother category. In addition to the positional (reduced to the simple tripartition into head with left/right context) and categorial information about mother and daughter nodes we also employ an LFG distinction between subcategorisable (subj, obj, obj2, obl, xcomp, comp ...) and non-subcategorisable (adjn, xadjn ...) grammatical functions. Subcategorisable grammatical functions characterise arguments, while non-subcategorisable functions characterise adjuncts (modifiers).

Using this information we construct what we refer to as an "annotation matrix" for each of the rule LHS categories in the Penn-II treebank grammar. The x-axis of the matrix is given by the tripartition into left context, head and right context. The y-axis is defined by the distinction between subcategorisable and non-subcategorisable grammatical functions.

Consider a much simplified example: for rules (local trees) expanding English np's the rightmost nominal (n, nn, nns etc.) on the RHS is (usually) the head. Heads are annotated $\uparrow{=}\downarrow$. Any det or quant constituent in the left context is annotated $\uparrow$ spec $=\downarrow$. Any adjp in the left context is annotated $\downarrow\in\uparrow$ adjn. Any nominal in the left context (in noun noun sequences) is annotated as a modifier $\downarrow\in\uparrow$ adjn. Any pp in the right context is annotated as $\downarrow\in\uparrow$ adjn. Any relcl in the right context as $\downarrow\in\uparrow$ relmod, any nominal (phrase - usually separated by commas following the head) as an apposition $\downarrow\in\uparrow$ app and so forth. Information such as this is used to populate the np annotation matrix, partially represented in **Table 1**.

In order to minimise mistakes, the annotation matrices are very conservative: subcategorisable grammatical functions are only assigned if there is no doubt (e.g. an np following a preposition in a pp is assigned $\uparrow$ obj $=\downarrow$; a vp following a v in a vp constituent is assigned $\uparrow$ xcomp $=\downarrow$, $\uparrow$ subj $=\uparrow$ xcomp : subj and so forth). If, for any constituent, the argument - modifier status is in doubt, we annotate the constituent as an adjunct: $\downarrow\in\uparrow$ adjn.

Treebanks have an interesting property: for each cate-

np	left context	head	right context
subcat functions	det, quant : ↑ spec =↓	n, nn, nns : ↑=↓	...
non-subcat functions	adjp : ↓∈↑ adjn n, nn, nns : ↓∈↑ adjn ...		relcl : ↓∈↑ relmod pp : ↓∈↑ adjn n, nn, nns : ↓∈↑ app

Table 1: Simplified, partial annotation matrix for np rules

gory, there is a small number of very frequently occurring rules expanding that category, followed by a large number of less frequent rules many of which occur only once or twice in the treebank (Zipf's law).

For each particular category, the corresponding annotation matrix is constructed from the most frequent rules expanding that category. In order to guarantee similar coverage for the annotation matrices for the different rule LHS in the Penn-II treebank, we design each matrix according to an analysis of the most frequent CFG rules expanding that category, such that the token occurrences of those rules cover more than 80% of the token occurrences of all rules expanding that LHS category in the treebank. In order to do this we need to look at the following number of most frequent rule types for each category given in **Table 2**.

Although constructed based on the evidence of the most frequent rule types, the resulting annotation matrices do generalise to as yet unseen rule types in the following two ways:

- during the application of the annotation algorithm, annotation matrices annotate less frequent, unseen rules with constituents matching the left/right context and head specifications. The resulting annotation might be partial (i.e. some constituents in less frequent rule types may be left unannotated).

- in addition to monadic categories, the Penn-II treebank contains versions of these categories associated with functional annotations (-LOC, -TMP etc. indicating locative, temporal, etc. and other functional information). If we include functional annotations in the categories there are approx. 150 distinct LHS categories in the CFG extracted from the Penn-II treebank resource. Our annotation matrices were developed with the most frequent rule types expanding monadic categories only. During application of the annotation algorithm, the annotation matrix for any given monadic category C is also applied to all rules (local trees) expanding C-LOC, C-TMP etc., i.e. instances of the category carrying functional information.

In our work to date we have not yet covered "constituents" marked frag(ment) and x (unknown constituents) in the Penn-II treebank.

Finally, note that L/R context annotation principles are only applied if the local tree (rule RHS) does not contain any instance of a coordinating conjunction cc. Constructions involving coordinating conjunctions are treated separately in the second component of the annotation algorithm.

4.2. Coorordinating Conjunction Annotation Principles

Coordinating constructions come in two forms: like and unlike (UCPs) constituent coordinations. Due to the (often too) flat treebank analyses these present special problems. Because of this, an integrated treatment of coordinate structures with the other annotation principles would have been too complex and messy. For this reason we decided to treat coordinate structures in a separate module. Here we only have space to talk about like constituent coordinations.

The annotation algorithm first attempts to establish the head of a coordinate structure (usually the rightmost coordination) and annotates it accordingly. It then uses a variety of heuristics to find and annotate the various coordinated elements. One of the heuristics employed simply states that if both the immediate left and the immediate right constituents next to the coordination have the same category, then find all such categories in the left context of the rule and annotate these together with the immediate left and right constituents of the coordination as individual elements ↓∈↑ coord in the f-structure set representation of the coordination.

4.3. Catch-All Annotation Principles

The final component of the algorithm utilises functional information provided in the Penn-II treebank annotations. Any constituent, no matter what category, left unannotated by the previous two annotation algorithm components, that carries a Penn-II functional annotation other than SBJ and PRD, is annotated as an adjunct ↓∈↑ adjn.

5. Results and Evaluation

The annotation algorithm is implemented in terms of a Java program. Annotation of the complete WSJ section of the Penn-II treebank takes less than 30 minutes on a Pentium IV PC. Once annotated, for each tree we collect the feature structure annotations and feed them into a simple constraint solver implemented in Prolog.

Our constraint solver can handle equality constraints, disjunction and simple set valued feature constraints. Currently, however, our annotations do not involve disjunctive constraints. This means that for each tree in the treebank we either get a single f-structure, or, in the case of partially annotated trees, a number of unconnected f-structure fragments, or, in case of feature structure clashes, no f-structure.

As pointed out above, in our work to date we have not developed an annotation matrix for frag(mentary) constituents. Furthermore, as it stands, the algorithm completely ignores "movement" (or dislocation and control)

ADJP	ADVP	CONJP	FRAG	LST	NAC	NP	NX	PP	PRN	PRT	QP	RRC
25	3	3	184	4	6	64	14	2	35	2	11	12
S	SBAR	SBARQ	SINV	SQ	UCP	VP	WHADJP	WHADVP	WHNP	WHPP	X	
11	3	20	16	68	78	146	2	2	2	1	37	

Table 2: # of most frequent rule types analysed to construct annotation matrices

phenomena marked in the Penn-II annotations in terms of coindexation (of traces). This means that the f-structures generated in our work to date miss some reentrancies a more fine-grained analysis would show.

Furthermore, because of the limited capabilities of our constraint solver, in our current work we cannot use functional uncertainty constraints (regular expression based constraints over paths in f-structure) to localise unbounded dependencies to model "movement" phenomena. Also, again because of limitations of our constraint solver, we cannot express subsumption constraints in our annotations to, e.g., distribute subjects into coordinate `vp` structures.

To give an illustration of our method, we give the first sentence of the Penn-II treebank and the f-structure generated as an example in **Figure 3**.

Currently we get the following general results with our automatic annotation algorithm summarised in **Table 3**:

# f-structure (fragments)	# sentences	percentage
0	2701	5.576
1	38188	78.836
2	4954	10.227
3	1616	3.336
4	616	1.271
5	197	0.407
6	111	0.229
7	34	0.070
8	12	0.024
9	6	0.012
10	4	0.008
11	1	0.002

Table 3: Automatic annotation results

The Penn-II treebank contains 49167 trees. The results reported in **Table 3** ignore 727 trees containing `frag`(ment) and `x` (unknown) constituents as we did not provide any annotation for them in our work to date. At this early stage of our work, 38188 of the trees are associated with a complete f-structure. For 2701 trees no f-structure is produced (due to feature clashes). 4954 are associated with 2 f-structure fragments, 1616 with 3 fragments and so forth.

5.1. Evaluation

In order to evaluate the results of our automatic annotation we distinguish between "qualitative" and "quantitative" evaluation. Qualitative evaluation involves a "gold-standard", quantitative evaluation doesn't.

5.1.1. Qualitative Evaluation

Currently, we evaluate the output generated by our automatic annotation qualitatively by manually inspecting the f-structures generated. In order to automate the process we are currently working on a set of 100 randomly selected sentences from the Penn-II treebank to manually construct gold-standard annotated trees (and hence f-structures). These can then be processed in a number of ways:

- manually annotated gold-standard trees can be compared with the automatically annotated trees using the labelled bracketing precision and recall measures from `evalb`, a standard software package to evaluate PCFG parses. This presupposes that we treat annotated tree nodes as atoms (i.e. a complex string such as `np:`$\uparrow$ `obj` $=\downarrow$ is treated as an atomic label) and that in cases where nodes receive more than one f-structure annotation the order of these is the same in both the gold-standard and the automatically annotated version.

- gold-standard and automatically generated f-structures can be translated into a flat set of functional descriptions (`pred(A,see), subj(A,B), pred(B,John), obj(A,C), pred(C,Mary)`) and precision and recall can be computed for those.

- f-structures can be transformed (or unfolded) into trees by sorting attributes alphabetically at each level of embedding and by coding reentrancies as indices. After this transformation, gold-standard and automatically generated f-structures can be compared using `evalb`. This presupposes that both the gold-standard and the automatically generated f-structure have identical "terminal" yield.

5.1.2. Quantitative Evaluation

For purely quantitative evaluation (that is evaluation that doesn't necessarily assess the quality of the generated resources) we currently employ two related measures. These measures give an indication how partial our automatic annotation is at the current stage of the project. The first measure is the percentage of RHS constituents in grammar rules that receive an annotation. The table lists the annotation percentage for RHS elements of some of the Penn-II LHS categories. Because of the functional annotations provided in Penn-II the complete list of LHS categories would contain approx. 150 entries. Note that the percentages listed below ignore punctuation markers (which are not annotated):

The second, related measure gives the average number of f-structure fragments generated for each treebank tree (the more partial our annotation the more unconnected f-structure fragments are generated for a sentence). For 45739 sentences, the average number of fragments per sentences is currently: 1.26 (note again that the number excludes sentences containing `frag` and `x` constituents).

6. Conclusion and Further Work

In this paper we have presented an automatic f-structure annotation algorithm and applied it to annotate the Penn-II treebank resource with f-structure information. The resulting representations are proto-f-structures showing basic predicate-argument-modifier structure. Currently, 38,188 sentences (78.8% of the 48,440 trees without `frag` and `x` constituents) receive a complete f-structure; 4954 sentences are associated with two f-structure fragments, 1,616 with three fragments. 2,701 sentences are not associated with an f-structure.

In future work we plan to extend and refine our automatic annotation algorithm in a number of ways:

- We are working on reducing the the amount of f-structure fragmentation by providing more complete annotation principles.

- Currently the `pred` values (i.e. the predicates) in the f-structures generated are surface (i.e. inflected) rather than root forms. We are planning to use the output of a two-level morphology to annotate the Penn-II strings with root forms which can then be picked up by our lexical macros and used as `pred` values in the automatic annotations.

- Currently our annotation algorithm ignores the Penn-II encoding of "moved" constituents in topicalisation, wh-constructions, control constructions and the like. These (often non-local) dependencies are marked in the Penn-II tree annotations in terms of indices. In future work we intend to make our annotation algorithm sensitive to such information. There are two (possibly complementary) ways of achieving this: The first is to make the annotation algorithm sensitive to the index scheme provided by the Penn-II annotations either during application of the algorithm or in terms of undoing "movement" in a treebank preprocessing step. The latter route is explored in recent work by (Liakata and Pulman, 2002). The second possibility is to use the LFG machinery of functional uncertainty equations to effectively localise unbounded dependency relations in a functional annotation at a particular node. Functional uncertainty equations allow the statement of regular expression based paths in f-structure. Currently we cannot resolve such paths with our constraint solver.

- We are currently experimenting with probabilistic grammars extracted from the automatically annotated version of the Penn-II treebank. We will be reporting on the results of these experiments elsewhere (Cahill et al, 2002).

- We are planning to exploit the f-structure/QLF/UDRS correspondences established by (van Genabith and Crouch, 1996; van Genabith and Crouch, 1997) to generate semantically annotated versions of the Penn-II treebank.

Abstract

The linguistic knowledge represented in contemporary language resource annotations becomes very complex. Its acquiring and management requires an enormous amount of human work. In order to minimize such a human effort we need rigorous methods for representation of such knowledge, methods for supporting the annotation process, methods for exploiting all results from the annotation process, even those that usually disappear after the annotation has been completed. In this paper we present a formal set-up for annotation within HPSG linguistic theory. We present also an algorithm for annotation scheme specialization based on the negative information from the annotation process. The negative information includes the analyses, rejected by the annotator.

1. Introduction

In our project (Simov et. al., 2001a), (Simov et al., 2002) we aim at the creation of syntactically annotated corpus (treebank) based on the HPSG linguistic theory (Head-driven Phrase Structure Grammar — (Pollard and Sag, 1987) and (Pollard and Sag, 1994)). Hence, the elements of the treebank are not trees, but feature graphs. The annotation scheme for the construction of the treebank is based on the appropriate language-specific version of the HPSG sort hierarchy. On one hand, such an annotation scheme is very detailed and flexible with respect to the linguistic knowledge, encoded in it. But, on the other hand, because of the massive overgeneration, it is not considered to be annotator-friendly. Thus, the main problem is: how to keep the consistency of the annotation scheme and at the same time to minimize the human work during the annotation. In our annotation architecture we envisage two sources of linguistic knowledge in order to reduce the possible analyses of the annotated sentences:

- Reliable partial grammars.
- HPSG-based grammar: universal principles, language specific principles and a lexicon.

The actual annotation process includes the following steps:

- Partial parsing step:

  This step comprises several additional steps: (1) Sentence extraction from the text archive; (2) Morphosyntactic tagging; (3) Part-of-speech disambiguation; (4) Partial parsing;

  The result is considered a 100 % accurate partial parsed sentence.

- HPSG step:

  The result from the previous step is encoded into an HPSG compatible representation with respect to the sort hierarchy. It is sent to an HPSG grammar tool, which takes the partial sentence analysis as input and evaluates all the attachment possibilities for it. The output is encoded as feature graphs.

- Annotation step:

  The feature graphs from the previous step are further processed as follows : (1) their intersection is calculated; (2) on the base of the differences, a set of constraints over the intersection is calculated as well; (3) during the actual annotation step, the annotator tries to extend the intersection to full analysis, adding new information to it. The constraints determine the possible extensions and also propagate the information, added by the annotator, in order to minimize the incoming choices.

This architecture is being currently implemented by establishing an interface between two systems: CLaRK system for XML based corpora development (Simov et. al., 2001b) and TRALE system for HPSG grammar development (TRALE is a descendant of (Götz and Meurers, 1997)). The project will result in an HPSG corpus based on feature graphs and reliable grammars. One of the intended applications of these language resources consists of their exploration for improving the accuracy of the implemented HPSG grammar.

The work, reported in this paper, is a step towards establishing an incremental mechanism, which uses already annotated sentences for further specializing of the HPSG grammar and for reducing the number of the possible HPSG analyses. In fact, we consider the rejected analyses as negative information about the language and therefore the grammar has to be appropriately tuned in order to rule out such analyses.

The structure of the paper is as follows: in the next section we define formally what a corpus is with respect to a grammar formalism and apply this definition to the definition of an HPSG corpus. In Sect. 3. we present a logical formalism for HPSG, define a normal form for grammars in the logical formalism and on the basis of this normal form we define feature graphs that constitute a good representation for both — HPSG grammars and HPSG corpora. Sect. 4. presents the algorithm for specialization of an

HPSG grammar on the basis of accepted and rejected by the annotator analyses produced by the grammar. Then Sect. 5. demonstrates an example of such specialization. The last section outlines the conclusions and outlook.

2. HPSG Corpus

In our work we accept that the corpus is complete with respect to the analyses of the sentences in it. This means that each sentence is presented with all its acceptable syntactic structures. Thus a good grammar will not overgenerate, i.e. it will not assign more analyses to the sentences than the analyses, which already exist in the corpus. Before we define what an HPSG corpus is like, let us start with a definition of a grammar-formalism-based corpus in general. Such an ideal corpus has to ensure the above assumption.

Definition 1 (Grammar Formalism Corpus) *A corpus C in a given grammatical formalism G is a sequence of analyzed sentences where each analyzed sentence is a member of the set of structures defined as a* **strong generative capacity** *(*$\mathtt{SGC}$*) of a grammar Γ in this grammatical formalism:*

$\forall S.S \in C \rightarrow S \in \mathtt{SGC}(\Gamma)$,

where Γ is a grammar in the formalism G, and if $\sigma(S)$ is the phonological string of S and $\Gamma(\sigma(S))$ is the set of all analyses assigned by the grammar Γ to the phonological string $\sigma(S)$, then

$\forall S'.S' \in \Gamma(\sigma(S)) \rightarrow S' \in C$.

The grammar Γ is unknown, but implicitly represented in the corpus C. We could state that if such a grammar does not exist, then we consider the corpus inconsistent or uncomplete.

In order to define a corpus in HPSG with respect to this definition, we have to define a representation of HPSG analysis over the sentences. This analysis must correspond to a definition of strong generative capacity in HPSG. Fortunately, there exist such definitions - (King 1999) and (Pollard 1999). We adopt them for our purposes. Thus in our work we choose:

- A logical formalism for HPSG — King's Logic (SRL) (King 1989);
- A definition of strong generative capacity in HPSG as a set of feature structures closely related to the special interpretation in SRL (exhaustive models) along the lines of (King 1999) and (Pollard 1999).
- A definition of corpus in HPSG as a sequence of sentences that are members of $\mathtt{SGC}(\Gamma)$ for some grammar Γ in SRL.

It is well-known that an HPSG grammar in SRL formally comprises two parts: a signature and a theory. The signature defines the ontology of the linguistic objects in the language and the theory constraints the shape of the linguistic objects. Usually the descriptions in the theory part are presented as implications. In order to demonstrate in a better way the connection between the HPSG grammar in SRL and the HPSG corpus, we offer a common representation of the grammar and the corpus.

We define a normal form for HPSG grammars which ideologically is very close to the feature structures defining the strong generative capacity in HPSG as it has proposed in the work of (King 1999) and (Pollard 1999). We define both the corpus and the grammar in terms of clauses (considered as graphs) in a special kind of matrices in SRL. The construction of new sentence analyses can be done using the inference mechanisms of SRL. Another possibility is such a procedure to be defined directly using the representations in the normal form. In order to distinguish the elements in our normal form from the numerous of kinds of feature structures we call the elements in the normal form *feature graphs*. One important characteristic about our feature graphs is that they are viewed as descriptions in SRL, i.e. as syntactic entities.

In other works (Simov, 2001) and (Simov, 2002) we showed how from a corpus, consisting of feature graphs, a corpus grammar could be extracted along the lines of Rens Bod's ideas on Data-Oriented Parsing Model (Bod, 1998). Also, in (Simov, 2002) we showed how one could use the positive information in the corpus in order to refine an existing HPSG grammar. In this paper we discuss and illustrate the usage of the negative information compiled as a by-product during the annotation of the corpus.

3. Logical Formalism for HPSG

In this section we present a logical formalism for HPSG. Then a normal form (exclusive matrices) for a finite theory in this formalism is defined and then we show how it can be represented as a set of feature graphs. These graphs are considered a representation of grammars and corpora in HPSG.

3.1. King's Logic — SRL

This section presents the basic notions of Speciate Reentrancy Logic (SRL) (King 1989).

$\Sigma = \langle \mathcal{S}, \mathcal{F}, \mathcal{A} \rangle$ is a finite **SRL signature** iff $\mathcal{S}$ is a finite set of *species*, $\mathcal{F}$ is a set of *features*, and $\mathcal{A} : \mathcal{S} \times \mathcal{F} \rightarrow Pow(\mathcal{S})$ is an *appropriateness function*. $\mathcal{I} = \langle \mathcal{U}_\mathcal{I}, \mathcal{S}_\mathcal{I}, \mathcal{F}_\mathcal{I} \rangle$ is a **SRL interpretation** of the signature Σ (or Σ-interpretation) iff

$\mathcal{U}_\mathcal{I}$ is a non-empty set of objects,
$\mathcal{S}_\mathcal{I}$ is a total function from $\mathcal{U}_\mathcal{I}$ to $\mathcal{S}$,
  called **species assignment function**,
$\mathcal{F}_\mathcal{I}$ is a total function from $\mathcal{F}$ to the set of partial function from $\mathcal{U}_\mathcal{I}$ to $\mathcal{U}_\mathcal{I}$ such that
  for each $\phi \in \mathcal{F}$ and each $\upsilon \in \mathcal{U}_\mathcal{I}$, if $\mathcal{F}_\mathcal{I}(\phi)(\upsilon)\downarrow$[1]
    then $\mathcal{S}_\mathcal{I}(\mathcal{F}_\mathcal{I}(\phi)(\upsilon)) \in \mathcal{A}(\mathcal{S}_\mathcal{I}(\upsilon), \phi)$, and
  for each $\phi \in \mathcal{F}$ and each $\upsilon \in \mathcal{U}_\mathcal{I}$, if $\mathcal{A}(\mathcal{S}_\mathcal{I}(\upsilon), \phi)$
    is not empty then $\mathcal{F}_\mathcal{I}(\phi)(\upsilon)\downarrow$,
$\mathcal{F}_\mathcal{I}$ is called **feature interpretation function**.

τ is a term iff τ is a member of the smallest set $\mathcal{TM}$ such that (1) : $\in \mathcal{TM}$, and (2) for each $\phi \in \mathcal{F}$ and each $\tau \in \mathcal{TM}$, $\tau\phi \in \mathcal{TM}$. For each Σ-interpretation $\mathcal{I}$, $\mathcal{P}_\mathcal{I}$ is a **term interpretation function** over $\mathcal{I}$ iff (1) $\mathcal{P}_\mathcal{I}(:)$ is the identity function from $\mathcal{U}_\mathcal{I}$ to $\mathcal{U}_\mathcal{I}$, and (2) for each $\phi \in \mathcal{F}$ and each $\tau \in \mathcal{TM}$, $\mathcal{P}_\mathcal{I}(\tau\phi)$ is the composition of the partial functions $\mathcal{P}_\mathcal{I}(\tau)$ and $\mathcal{F}_\mathcal{I}(\phi)$ if they are defined.

[1] $f(o)\downarrow$ means the function f is defined for the argument o.

δ is a **description** iff δ is a member of the smallest set $\mathcal{D}$ such that (1) for each $\sigma \in \mathcal{S}$ and for each $\tau \in \mathcal{TM}$, $\tau \sim \sigma \in \mathcal{D}$, (2) for each $\tau_1 \in \mathcal{TM}$ and $\tau_2 \in \mathcal{TM}$, $\tau_1 \approx \tau_2 \in \mathcal{D}$ and $\tau_1 \not\approx \tau_2 \in \mathcal{D}$, (3) for each $\delta \in \mathcal{D}$, $\neg\delta \in \mathcal{D}$, (4) for each $\delta_1 \in \mathcal{D}$ and $\delta_2 \in \mathcal{D}$, $[\delta_1 \wedge \delta_2] \in \mathcal{D}$, $[\delta_1 \vee \delta_2] \in \mathcal{D}$, and $[\delta_1 \rightarrow \delta_2] \in \mathcal{D}$. **Literals** are descriptions of the form $\tau \sim \sigma$, $\tau_1 \approx \tau_2$, $\tau_1 \not\approx \tau_2$ or their negation. For each Σ-interpretation $\mathcal{I}$, $\mathcal{D}_\mathcal{I}$ is a **description denotation function** over $\mathcal{I}$ iff $\mathcal{D}_\mathcal{I}$ is a total function from $\mathcal{D}$ to the powerset of $\mathcal{U}_\mathcal{I}$, such that

$\mathcal{D}_\mathcal{I}(\tau \sim \sigma) = \{\upsilon \in \mathcal{U}_\mathcal{I} \mid \mathcal{P}_\mathcal{I}(\tau)(\upsilon)\downarrow, \mathcal{S}_\mathcal{I}(\mathcal{P}_\mathcal{I}(\tau)(\upsilon)) = \sigma\}$,
$\mathcal{D}_\mathcal{I}(\tau_1 \approx \tau_2) = \{\upsilon \in \mathcal{U}_\mathcal{I} \mid \mathcal{P}_\mathcal{I}(\tau_1)(\upsilon)\downarrow, \mathcal{P}_\mathcal{I}(\tau_2)(\upsilon)\downarrow,$ and $\mathcal{P}_\mathcal{I}(\tau_1)(\upsilon) = \mathcal{P}_\mathcal{I}(\tau_2)(\upsilon)\}$,
$\mathcal{D}_\mathcal{I}(\tau_1 \not\approx \tau_2) = \{\upsilon \in \mathcal{U}_\mathcal{I} \mid \mathcal{P}_\mathcal{I}(\tau_1)(\upsilon)\downarrow, \mathcal{P}_\mathcal{I}(\tau_2)(\upsilon)\downarrow,$ and $\mathcal{P}_\mathcal{I}(\tau_1)(\upsilon) \neq \mathcal{P}_\mathcal{I}(\tau_2)(\upsilon)\}$,
$\mathcal{D}_\mathcal{I}(\neg\delta) = \mathcal{U}_\mathcal{I} \setminus \mathcal{D}_\mathcal{I}(\delta)$,
$\mathcal{D}_\mathcal{I}([\delta_1 \wedge \delta_2]) = \mathcal{D}_\mathcal{I}(\delta_1) \cap \mathcal{D}_\mathcal{I}(\delta_2)$,
$\mathcal{D}_\mathcal{I}([\delta_1 \vee \delta_2]) = \mathcal{D}_\mathcal{I}(\delta_1) \cup \mathcal{D}_\mathcal{I}(\delta_2)$, and
$\mathcal{D}_\mathcal{I}([\delta_1 \rightarrow \delta_2]) = (\mathcal{U}_\mathcal{I} \setminus \mathcal{D}_\mathcal{I}(\delta_1)) \cup \mathcal{D}_\mathcal{I}(\delta_2)$.

Each subset $\theta \subseteq \mathcal{D}$ is an **SRL theory**. For each Σ-interpretation $\mathcal{I}$, $\mathcal{T}_\mathcal{I}$ is a **theory denotation function** over $\mathcal{I}$ iff $\mathcal{T}_\mathcal{I}$ is a total function from the powerset of $\mathcal{D}$ to the powerset of $\mathcal{U}_\mathcal{I}$ such that for each $\theta \subseteq \mathcal{D}$, $\mathcal{T}_\mathcal{I}(\theta) = \cap\{\mathcal{D}_\mathcal{I}(\delta) | \delta \in \theta\}$. $\mathcal{T}_\mathcal{I}(\emptyset) = \mathcal{U}_\mathcal{I}$. A theory θ is **satisfiable** iff for some interpretation $\mathcal{I}$, $\mathcal{T}_\mathcal{I}(\theta) \neq \emptyset$. A theory θ is **modelable** iff for some interpretation $\mathcal{I}$, $\mathcal{T}_\mathcal{I}(\theta) = \mathcal{U}_\mathcal{I}$, $\mathcal{I}$ is called a **model** of θ. The interpretation $\mathcal{I}$ **exhaustively models** θ iff

$\mathcal{I}$ is a model of θ, and
for each $\theta' \subseteq \mathcal{D}$,
if for some model $\mathcal{I}'$ of θ,
$\mathcal{T}_{\mathcal{I}'}(\theta') \neq \emptyset$,
then $\mathcal{T}_\mathcal{I}(\theta') \neq \emptyset$.

An HPSG grammar $\Gamma = \langle\Sigma, \theta\rangle$ in SRL consists of: (1) a signature Σ which gives the ontology of entities that exist in the universe and the appropriateness conditions on them, and (2) a theory θ which gives the restrictions upon these entities.

3.2. Exclusive Matrices

Following (King and Simov, 1998) in this section we define a normal form for finite theories in SRL — called **exclusive matrix**. This normal form possesses some desirable properties for representation of grammars and corpora in HPSG.

First, we define some technical notions. A **clause** is a finite set of literals interpreted *conjunctively*. A **matrix** is a finite set of clauses interpreted *disjunctively*.

A matrix μ is an **exclusive matrix** iff for each clause $\alpha \in \mu$,

(E0) if $\lambda \in \alpha$ then λ is a positive literal,
(E1) $:\approx: \in \alpha$,
(E2) if $\tau_1 \approx \tau_2 \in \alpha$ then $\tau_2 \approx \tau_1 \in \alpha$,
(E3) if $\tau_1 \approx \tau_2 \in \alpha$ and $\tau_2 \approx \tau_3 \in \alpha$ then $\tau_1 \approx \tau_3 \in \alpha$,
(E4) if $\tau\phi \approx \tau\phi \in \alpha$ then $\tau \approx \tau \in \alpha$,
(E5) if $\tau_1 \approx \tau_2 \in \alpha$, $\tau_1\phi \approx \tau_1\phi \in \alpha$ and $\tau_2\phi \approx \tau_2\phi \in \alpha$ then $\tau_1\phi \approx \tau_2\phi \in \alpha$,
(E6) if $\tau \approx \tau \in \alpha$ then for some $\sigma \in \mathcal{S}$, $\tau \sim \sigma \in \alpha$,
(E7) if for some $\sigma \in \mathcal{S}$, $\tau \sim \sigma \in \alpha$ then $\tau \approx \tau \in \alpha$,
(E8) if $\tau_1 \approx \tau_2 \in \alpha$, $\tau_1 \sim \sigma_1 \in \alpha$ and $\tau_2 \sim \sigma_2 \in \alpha$ then $\sigma_1 = \sigma_2$,
(E9) if $\tau \sim \sigma_1 \in \alpha$ and $\tau\phi \sim \sigma_2 \in \alpha$ then $\sigma_2 \in \mathcal{A}(\sigma_1, \phi)$,
(E10) if $\tau \sim \sigma \in \alpha$, $\tau\phi \in \mathit{Term}(\mu)$ and $\mathcal{A}(\sigma, \phi) \neq \emptyset$ then $\tau\phi \approx \tau\phi \in \alpha$,
(E11) if $\tau_1 \not\approx \tau_2 \in \alpha$ then $\tau_1 \approx \tau_1 \in \alpha$ and $\tau_2 \approx \tau_2 \in \alpha$,
(E12) if $\tau_1 \approx \tau_1 \in \alpha$ and $\tau_2 \approx \tau_2 \in \alpha$ then $\tau_1 \approx \tau_2 \in \alpha$ or $\tau_1 \not\approx \tau_2 \in \alpha$, and
(E13) $\tau_1 \approx \tau_2 \notin \alpha$ or $\tau_1 \not\approx \tau_2 \notin \alpha$,

where $\{\sigma, \sigma_1, \sigma_2\} \subseteq \mathcal{S}$, $\phi \in \mathcal{F}$, and $\{\tau, \tau_1, \tau_2, \tau_3\} \subseteq \mathcal{TM}$, and $\mathtt{Term}$ is a function from the powerset of the sets of literals to the powerset of $\mathcal{TM}$ such that

$\mathtt{Term}(\alpha) = \{\tau \mid (\neg)\tau\phi \approx \tau' \in \alpha, \tau \in \mathcal{TM}, \phi \in \mathcal{F}^*\} \cup$
$\{\tau \mid (\neg)\tau' \approx \tau\phi \in \alpha, \tau \in \mathcal{TM}, \phi \in \mathcal{F}^*\} \cup$
$\{\tau \mid (\neg)\tau\phi \not\approx \tau' \in \alpha, \tau \in \mathcal{TM}, \phi \in \mathcal{F}^*\} \cup$
$\{\tau \mid (\neg)\tau' \not\approx \tau\phi \in \alpha, \tau \in \mathcal{TM}, \phi \in \mathcal{F}^*\} \cup$
$\{\tau \mid (\neg)\tau\phi \sim \sigma \in \alpha, \tau \in \mathcal{TM}, \phi \in \mathcal{F}^*\}$.

There are two important properties of an exclusive matrix $\mu = \{\alpha_1, \ldots, \alpha_n\}$: (1) each clause α in μ is satisfiable (for some interpretation $\mathcal{I}$, $\mathcal{T}_\mathcal{I}(\alpha) \neq \emptyset$), and (2) each two clauses α_1, α_2 in μ have disjoint denotations (for each interpretation $\mathcal{I}$, $\mathcal{T}_\mathcal{I}(\alpha_1) \cap \mathcal{T}_\mathcal{I}(\alpha_1) = \emptyset$). Also in (King and Simov, 1998) it is shown that each finite theory with respect to a finite signature can be converted into an exclusive matrix which is semantically equivalent to the theory. Relying on the definition of model (where each object in the domain is described by the theory) and the property that each two clauses in an exclusive matrix have disjoint denotation, one can easy prove the following proposition.

Proposition 2 *Let θ be a finite SRL theory with respect to a finite signature, μ be the corresponding exclusive matrix and $\mathcal{I} = \langle\mathcal{U}, \mathcal{S}, \mathcal{F}\rangle$ be a model of θ. For each object $\upsilon \in \mathcal{U}$ there exists a unique clause $\alpha \in \mu$ such that $\upsilon \in \mathcal{T}(\alpha)$.*

3.3. Feature Graphs

As it was mentioned above, an HPSG corpus will comprise a set of feature structures representing the HPSG analyses of the sentences. We interpret these feature structures as descriptions in SRL (clauses in an exclusive matrix).

Let $\Sigma = \langle\mathcal{S}, \mathcal{F}, \mathcal{A}\rangle$ be a finite signature. A directed, connected and rooted graph $\mathcal{G} = \langle\mathcal{N}, \mathcal{V}, \rho, \mathcal{S}\rangle$ such that

$\mathcal{N}$ is a set of **nodes**,
$\mathcal{V}: \mathcal{N} \times \mathcal{F} \rightarrow \mathcal{N}$ is a partial **arc function**,
ρ is a **root node**,
$\mathcal{S}: \mathcal{N} \rightarrow \mathcal{S}$ is a total **species assignment function**, such that
for each $\nu_1, \nu_2 \in \mathcal{N}$ and each $\phi \in \mathcal{F}$
if $\mathcal{V}\langle\nu_1, \phi\rangle\downarrow$ and $\mathcal{V}\langle\nu_1, \phi\rangle = \nu_2$,
then $\mathcal{S}\langle\nu_2\rangle \in \mathcal{A}\langle\mathcal{S}\langle\nu_1\rangle, \phi\rangle$,

is a **feature graph** wrt Σ.

A feature graph $\mathcal{G} = \langle\mathcal{N}, \mathcal{V}, \rho, \mathcal{S}\rangle$ such that for each node $\nu \in \mathcal{N}$ and each feature $\phi \in \mathcal{F}$ if $\mathcal{A}\langle\mathcal{S}\langle\nu\rangle, \phi\rangle\downarrow$ then $\mathcal{V}\langle\nu, \phi\rangle\downarrow$ is called a **complete feature graph** (or complete graph).

According to our definition feature graphs are a kind of feature structures which are treated syntactically rather than semantically. We use complete feature graphs for representing the analyses of the sentences in the corpus.

We say that the feature graph $\mathcal{G}$ is **finite** if and only if the set of nodes is finite.

For each graph $\mathcal{G}=\langle\mathcal{N},\mathcal{V},\rho,\mathcal{S}\rangle$ and node ν in $\mathcal{N}$ with $\mathcal{G}\,|_\nu=\langle\mathcal{N}_\nu,\mathcal{V}\,|_{\mathcal{N}_\nu},\rho_\nu,\mathcal{S}\,|_{\mathcal{N}_\nu}\rangle$ we denote the **subgraph** of $\mathcal{G}$ starting on node ν.

Let $\mathcal{G}_1=\langle\mathcal{N}_1,\mathcal{V}_1,\rho_1,\mathcal{S}_1\rangle$ and $\mathcal{G}_2=\langle\mathcal{N}_2,\mathcal{V}_2,\rho_2,\mathcal{S}_2\rangle$ be two graphs. We say that graph $\mathcal{G}_1$ **subsumes** graph $\mathcal{G}_2$ ($\mathcal{G}_2\sqsubseteq\mathcal{G}_1$) iff there is an *isomorphism* $\gamma:\mathcal{N}_1\rightarrow\mathcal{N}_2'$, $\mathcal{N}_2'\subseteq\mathcal{N}_2$, such that

$\gamma(\rho_1)=\rho_2$,

for each $\nu,\nu'\in\mathcal{N}_1$ and each feature ϕ,

$\mathcal{V}_1\langle\nu,\phi\rangle=\nu'$ iff $\mathcal{V}_2\langle\gamma(\nu),\phi\rangle=\gamma(\nu')$, and

for each $\nu\in\mathcal{N}_1$, $\mathcal{S}_1\langle\nu\rangle=\mathcal{S}_2\langle\gamma(\nu)\rangle$.

The intuition behind the definition of subsumption by isomorphism is that each graph describes "exactly" a chunk in some SRL interpretation in such a way that every two distinct nodes are always mapped to distinct objects in the interpretation.

For each two graphs $\mathcal{G}_1$ and $\mathcal{G}_2$ if $\mathcal{G}_2\sqsubseteq\mathcal{G}_1$ and $\mathcal{G}_1\sqsubseteq\mathcal{G}_2$ we say that $\mathcal{G}_1$ and $\mathcal{G}_2$ are **equivalent.** For convenience, in the following text we consider each two equivalent graphs equal.

For a finite feature graph $\mathcal{G}=\langle\mathcal{N},\mathcal{V},\rho,\mathcal{S}\rangle$, we define a translation to a clause. Let

$Term(\mathcal{G})=\{:\}\cup\{\tau\mid\tau\doteq:\phi_1\ldots\phi_n,n\leq\|\mathcal{N}\|,\mathcal{V}\langle\rho,\tau\rangle\downarrow\}$[2] be a set of terms. We define a clause $\alpha_\mathcal{G}$:

$\alpha_\mathcal{G}=\{\tau\sim\sigma\mid\tau\in Term(\mathcal{G}),\mathcal{V}\langle\rho,\tau\rangle\downarrow,\mathcal{S}\langle\mathcal{V}\langle\rho,\tau\rangle\rangle=\sigma\}\cup$

$\{\tau_1\approx\tau_2\mid\tau_1\in Term(\mathcal{G}),\tau_2\in Term(\mathcal{G}),$

$\mathcal{V}\langle\rho,\tau_1\rangle\downarrow,\mathcal{V}\langle\rho,\tau_2\rangle\downarrow,$ and $\mathcal{V}\langle\rho,\tau_1\rangle=\mathcal{V}\langle\rho,\tau_2\rangle\}\cup$

$\{\tau_1\not\approx\tau_2\mid\tau_1\in Term(\mathcal{G}),\tau_2\in Term(\mathcal{G}),$

$\mathcal{V}\langle\rho,\tau_1\rangle\downarrow,\mathcal{V}\langle\rho,\tau_2\rangle\downarrow,$ and $\mathcal{V}\langle\rho,\tau_1\rangle\neq\mathcal{V}\langle\rho,\tau_2\rangle\}$.

We interpret a finite feature graph via the interpretation of the corresponding clauses

$\mathcal{R}_\mathcal{I}(\mathcal{G})=\mathcal{T}_\mathcal{I}(\alpha_\mathcal{G})$.

Let $\mathcal{G}$ be an infinite feature graph. Then we interpret it as the intersection of the interpretations of all finite feature graphs that subsume it:

$\mathcal{R}_\mathcal{I}(\mathcal{G})=\cap_{\mathcal{G}\sqsubseteq\mathcal{G}',\mathcal{G}'<\omega}\mathcal{R}_\mathcal{I}(\alpha_{\mathcal{G}'})$.

The clauses in an exclusive matrix μ can be represented as feature graphs. Let μ be an exclusive matrix and $\alpha\in\mu$, then

$\mathcal{G}_\alpha=\langle\mathcal{N}_\alpha,\mathcal{V}_\alpha,\rho_\alpha,\mathcal{S}_\alpha\rangle$ is a feature graph such that

$\mathcal{N}_\alpha=\{|\tau|_\alpha\mid\tau\approx\tau\in\alpha\}$ is a set of nodes,

$\mathcal{V}_\alpha:\mathcal{N}_\alpha\times\mathcal{F}\rightarrow\mathcal{N}_\alpha$ is a partial **arc function**, such that

$\mathcal{V}_\alpha\langle|\tau_1|_\alpha,\phi\rangle\downarrow$ and $\mathcal{V}_\alpha\langle|\tau_1|_\alpha,\phi\rangle=|\tau_2|_\alpha$ iff

$\tau_1\approx\tau_1\in\alpha,\tau_2\approx\tau_2\in\alpha,\phi\in\mathcal{F}$, and $\tau_1\phi\approx\tau_2\in\alpha$,

ρ_α is the root node $|:|_\alpha$, and

$\mathcal{S}_\alpha:\mathcal{N}_\alpha\rightarrow\mathcal{S}$ is a **species assignment function**, such that

$\mathcal{S}_\alpha\langle|\tau|_\alpha\rangle=\sigma$ iff $\tau\sim\sigma\in\alpha$.

Proposition 3 *Let μ be an exclusive matrix and $\alpha\in\mu$. Then the graph $\mathcal{G}_\alpha$ is semantically equivalent to α.*

3.4. Inference with Feature Graphs

In this paper we do not present a concrete inference mechanism exploiting feature graphs. As it was mentioned above, one can use the general inference mechanisms of SRL in order to construct sentence analyses. However, a much better solution is to employ an inference mechanism, which uses directly the graph representation of a theory. Such an inference mechanism can be defined along the lines of *Breadth-First Parallel Resolution* in (Carpener 1992) despite the difference in the treatment of the feature structure in (Carpener 1992) (Note that (Carpener 1992) treats feature structures as semantic entities, but we consider our feature graphs syntactic elements.). One has to keep in mind that finding models in SRL is undecidable (see (King, Simov and Aldag 1999)) and some restrictions in terms of time or memory will be necessary in order to use Breadth-First Parallel Resolution-like algorithm. A presentation of such an algorithm is beyond the scope of this paper.

[2] $\|X\|$ is the cardinality of the set X

3.5. Graph Representation of an SRL Theory

Each finite SRL theory can be represented as a set of feature graphs. In order to make this graph transformation of a theory completely independent from the SRL particulars, we also need to incorporate within the graphs the information from the signature that is not present in the theory yet. For each species the signature encodes the defined features as well as the species of their possible values. We explicate this information in the signature by constructing a special theory:

$$\theta_\Sigma=\{\bigvee_{\sigma\in\mathcal{S}}[\bigwedge_{\mathcal{A}(\sigma,\phi)\neq\emptyset,\phi\in\mathcal{F}}[:\phi\approx:\phi]]\}.$$

Then for each theory θ we form the theory $\theta^e=\theta\cup\theta_\Sigma$ which is semantically equivalent to the original theory (because we add only the information from the signature which is always taken into account, when a theory is interpreted). We convert the theory θ^e into an exclusive matrix which in turn is converted into a set of graphs $\mathcal{GR}$ called **graph representation** of θ.

The graph representation of a theory inherits from the exclusive matrixes their properties: (1) each graph $\mathcal{G}$ in $\mathcal{GR}$ is satisfiable (for some interpretation $\mathcal{I}$, $\mathcal{R}_\mathcal{I}(\mathcal{G})\neq\emptyset$), and (2) each two graphs $\mathcal{G}_1,\mathcal{G}_2$ in $\mathcal{GR}$ have disjoint denotations (for each interpretation $\mathcal{I}$, $\mathcal{R}_\mathcal{I}(\mathcal{G}_1)\cap\mathcal{R}_\mathcal{I}(\mathcal{G}_2)=\emptyset$). We can reformulate here also the Prop. 2.

Proposition 4 *Let θ be a finite SRL theory with respect to a finite signature, μ be the corresponding exclusive matrix, $\mathcal{GR}$ be the graph representation of θ and $\mathcal{I}=\langle\mathcal{U}_\mathcal{I},\mathcal{S}_\mathcal{I},\mathcal{F}_\mathcal{I}\rangle$ be a model of θ. For each object $\upsilon\in\mathcal{U}$ there exists a unique graph $\mathcal{G}\in\mathcal{GR}$ such that $\upsilon\in\mathcal{R}(\mathcal{G})$.*

There exists also a correspondence between complete graphs with respect to a finite signature and the objects in an interpretation of the signature.

Definition 5 (Object Graph) *Let $\Sigma=\langle\mathcal{S},\mathcal{F},\mathcal{A}\rangle$ be a finite signature, $\mathcal{I}=\langle\mathcal{U}_\mathcal{I},\mathcal{S}_\mathcal{I},\mathcal{F}_\mathcal{I}\rangle$ be an interpretation of Σ and υ be an object in $\mathcal{U}$, then the graph $\mathcal{G}_\upsilon=\langle\mathcal{N},\mathcal{V},\rho,\mathcal{S}\rangle$, where*

$\mathcal{N}=\{\upsilon'\in\mathcal{U}\mid\exists\tau\in\mathcal{TM}$ and $\mathcal{P}(\tau)(\upsilon)=\upsilon'\}$

$\mathcal{V}:\mathcal{N}\times\mathcal{F}\rightarrow\mathcal{N}$ is a partial **arc function***, such that*

$\mathcal{V}\langle\upsilon_1,\phi\rangle\downarrow$ and $\mathcal{V}\langle\upsilon_1,\phi\rangle=\upsilon_2$ iff

$\upsilon_1\in\mathcal{N},\upsilon_2\in\mathcal{N},\phi\in\mathcal{F}$, and $\mathcal{F}_\mathcal{I}(\phi)(\upsilon_1)=\upsilon_2$,

$\rho=\upsilon$ is the root node, and

$\mathcal{S}:\mathcal{N}\rightarrow\mathcal{S}$ is a **species assignment function***, such that*

$\mathcal{S}\langle\upsilon'\rangle=\mathcal{S}_\mathcal{I}\langle\upsilon'\rangle$,

is called **object graph**.

It is trivial to check that each object graph is a complete feature graph. Also, one easy can see the connection between the graphs in the graph representation of a theory and object graphs of objects in a model of the theory.

Proposition 6 *Let θ be a finite SRL theory with respect to a finite signature, $\mathcal{GR}$ be the graph representation of θ, $\mathcal{I} = \langle \mathcal{U}_\mathcal{I}, \mathcal{S}_\mathcal{I}, \mathcal{F}_\mathcal{I} \rangle$ be a model of θ, υ be an object in $\mathcal{U}_\mathcal{I}$, and $\mathcal{G}_\upsilon = \langle \mathcal{N}, \mathcal{V}, \rho, \mathcal{S} \rangle$ be its object graph. For each node $\nu \in \mathcal{N}$, there exists a graph $\mathcal{G}_i \in \mathcal{GR}$, such that $\mathcal{G}\,|_\nu \sqsubseteq \mathcal{G}_i$.*

This can be proved by using the definition of a model of a theory, the Prop. 4 and the definition of a subgraph started at a node.

3.6. Outcomes: Feature Graphs for HPSG Grammar and Corpus

Thus we can sum up that feature graphs can be used for both:

- Representation of an HPSG corpus. Each sentence in the corpus is represented as a complete feature graph. One can easily establish a correspondence between the objects in an exhaustive model of (King 1999) and complete feature graphs or a correspondence between the elements of strong generative capacity of (Pollard 1999) and complete feature graphs. Thus complete feature graphs are a good representation for an HPSG corpus;

- Representation of an HPSG grammar as a set of feature graphs. The construction of a graph representation of a finite theory demonstrates that using feature graphs as grammar representation does not impose any restrictions over the class of possible finite grammars in SRL. Therefore we can use feature graphs as a representation of the grammar used during the construction of an HPSG corpus, as described above.

Additionally, we can establish a formal connection between a grammar and a corpus using the properties of feature graphs.

Definition 7 (Corpus Grammar) *Let C be an HPSG corpus and Γ be an HPSG grammar. We say that Γ is a* **grammar of the corpus** *C if and only if for each graph $\mathcal{G}_C$ in C and each node $\nu \in \mathcal{G}_C$ there is a graph $\mathcal{G}_G$ in G such that $\mathcal{G}_C\,|_\nu \sqsubseteq \mathcal{G}_G$.*

It follows by the definition that if C is an HPSG corpus and Γ is a corpus grammar of C then Γ accepts all analyses in C.

4. Incremental Specialization using Negative Information

Let us now return to the annotation process. We start with an HPSG grammar which together with the signature determines the annotation scheme. We convert this grammar into a graph representation $\mathcal{GR}_0$. In the project we rely on the existing system (TRALE) for processing of HPSG grammars (TRALE is based on (Götz and Meurers, 1997)). TRALE works with HPSG grammars represented as general descriptions, but the result from the sentence processing is equivalent to a complete feature graph. It is also relatively easy to convert the grammar into a set of feature graphs.

Having $\mathcal{GR}_0$ we can analyze partial analyses of the sentences as it was described in the introduction. The partial analyses are used in order to reduce the number of the possible analyses. Let us suppose that the set of complete feature graphs $\mathcal{GRA}$ is returned by the TRALE system. Then these graphs are processed by the annotator within the CLaRK system and some of the analyses are accepted to be true for the sentence. Thus, they are added to the corpus and the rest of the analyses are rejected. Let $\mathcal{GRN}$ be the set of rejected analyses and $\mathcal{GRC}$ be the set of all analyses in the corpus up to now plus the new accepted ones. Our goal now is to specialize the initial grammar $\mathcal{GR}_0$ into a grammar $\mathcal{GR}_1$ such that it is still a grammar of the corpus $\mathcal{GRC}$ and it does not derive any of the graphs in $\mathcal{GRN}$. Using Prop. 6 we can rely on a very simple test for acceptance or rejection of a complete graph by the grammar: "If for each node in a complete graph there exists a graph in the grammar that subsumes the subgraph started at the same node, then the complete graph is accepted by the grammar." So, in order to reject a graph $\mathcal{G}$ in $\mathcal{GRN}$ it is enough to find a node ν in $\mathcal{G}$ such that for the subgraph $\mathcal{G}\,|_\nu$ there is no graph $\mathcal{G}' \in \mathcal{GR}_1$ such that $\mathcal{G}\,|_\nu \sqsubseteq \mathcal{G}'$. We will use this dependency in the process of guiding the specialization of the initial grammar.

In order to apply this test we have to consider not only the graphs in $\mathcal{GRC}$ and $\mathcal{GRN}$, but also their complete subgraphs. We process further the graphs in $\mathcal{GRN}$ and $\mathcal{GRC}$ in order to determine which information encoded in these graphs is crucial for the rejection of the graphs in $\mathcal{GRN}$. Let $sub(\mathcal{GRN})$ be the set of the complete graphs in $\mathcal{GRN}$ and their complete subgraphs and let $sub(\mathcal{GRC})$ be the set of the complete graphs in $\mathcal{GRC}$ and their complete subgraphs. We divide the set $sub(\mathcal{GRN})$ into two sets: $\mathcal{GRN}^+$ and $\mathcal{GRN}^-$, where $\mathcal{GRN}^+ = sub(\mathcal{GRN}) \cap sub(\mathcal{GRC})$ contains all graphs that are equivalent to some graph as well in $\mathcal{GRP}$[3] and $\mathcal{GRN}^- = sub(\mathcal{GRN}) \setminus sub(\mathcal{GRC})$ contains subgraphs that are presented only in $sub(\mathcal{GRN})$.

Then we choose all graphs $\mathcal{G}$ in $\mathcal{GR}_0$ such that for some $\mathcal{G}' \in \mathcal{GRN}^-$ it holds $\mathcal{G}' \sqsubseteq \mathcal{G}$. Let this set be $\mathcal{GR}_0^-$. This is the set of graphs in the grammar $\mathcal{GR}_0$ which we have to modify in order to achieve our goal.

Then we select from $sub(\mathcal{GRC})$ all graphs such that they are subsumed by some graph from $\mathcal{GR}_0^-$. Let this set be $\mathcal{GRP}$. These are the graphs that might be rejected by the modified grammar. Thus, the algorithm has to disallow such a rejection.

Thus our task is to specialize the graphs in the set $\mathcal{GR}_0^-$ in such a way that the new grammar (after substitution of $\mathcal{GR}_0^-$ with the new set of more specific graph into $\mathcal{GR}_0$) accepts all graphs in $\mathcal{GRP}$ and rejects all graphs in $\mathcal{GRN}$.

The algorithm works by performing the following steps:

[3] This is based on the fact that the accepted analyses can share some subgraphs with the rejected analyses.

1. It calculates the set $\mathcal{GRN}^-$;
2. It selects a subset $\mathcal{GR}_0^-$ of $\mathcal{GR}_0$;
3. It calculates the set $\mathcal{GRP}$;
4. It tries to calculate a new set of graphs $\mathcal{GR}_1^-$ such that each graph $\mathcal{G}$ in the new set $\mathcal{GR}_1^-$ is either member of $\mathcal{GR}_0^-$ or it is subsumed by a graph in $\mathcal{GR}_0^-$. Each new graph in $\mathcal{GR}_1^-$ can not have more nodes than the nodes in the biggest graph in the sets $\mathcal{GRP}$ and $\mathcal{GRN}$. This condition ensures the algorithm termination. If the algorithm succeeds to calculate a new set $\mathcal{GR}_1^-$ then it proceeds with the next step. Otherwise it stops without producing a specialization of the initial grammar.
5. It checks whether each graph in $\mathcal{GRP}$ is subsumed by a graph in $\mathcal{GR}_1^-$. If 'yes' then it prolongs the execution with the next step. Otherwise it returns to step 4 and calculates a new set $\mathcal{GR}_1^-$.
6. It checks whether there is a graph in $\mathcal{GRN}$ such that it is subsumed by a graph in $\mathcal{GR}_1^-$ and all its complete subgraphs in $\mathcal{GRN}^-$ are subsumed by a graph in $\mathcal{GR}_1^-$. If 'yes' then it returns to step 4 and calculates a new set $\mathcal{GR}_1^-$. Otherwise it returns the set $\mathcal{GR}_1^-$ as a specialization of the grammar $\mathcal{GR}_0^-$.

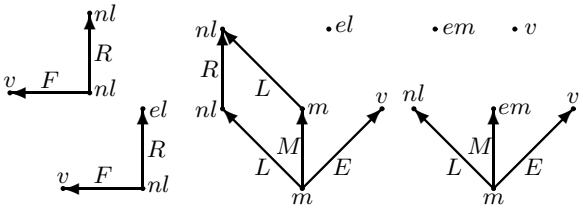
When the algorithm returns a new set of graphs $\mathcal{GR}_1^-$ which is a specialization of the graph set $\mathcal{GR}_0^-$, then we substitute the graph set $\mathcal{GR}_0^-$ with $\mathcal{GR}_1^-$ in the grammar $\mathcal{GR}_0$ and the result is a new, more specific grammar $\mathcal{GR}_1$ such that it accepts all graphs in the corpus $\mathcal{GRC}$ and rejects all graphs in $\mathcal{GRN}$.

In general, of course, there exist more than one specialization. Deciding which one is a good one becomes a problem, which cannot be solved only on the base of the graphs in the two sets $\mathcal{GRP}$ and $\mathcal{GRN}$. In this case two repairing strategies are possible: either additional definition of criteria for choosing the best extension, or the application of some statistical evaluations.

If the algorithm fails to produce a new set of graphs $\mathcal{GR}_1^-$ then there is an inconsistency in the acceptance of the graphs in $\mathcal{GRC}$ and/or in the rejection of the graphs in $\mathcal{GRN}$. This could happen if the annotator marks as wrong an analysis (or a part of it) which was marked as true for some previous analysis.

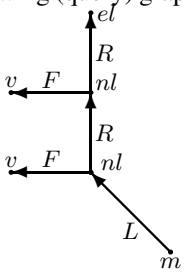
5. Example

In this section we present an example. This example is based on the notion of list and member relation encoded as feature graphs. The lists are encoded by two species: nl for non-empty lists and el for empty lists. Two features are defined for non-empty lists: F for the first element of the list and R for the rest of the list. The elements of a list are of species v. The member relation is also encoded by two species: m for the recursive step of the relation and em for the non-recursive step. For the recursive step of the relation (species m) three features are defined: L pointing to the list, E for the element which is a member of the list and M for the next step in the recursion of the relation. The next set of graphs constitutes an incomplete grammar for member relation on lists. The incompleteness results from the fact that there is no restriction on the feature E.



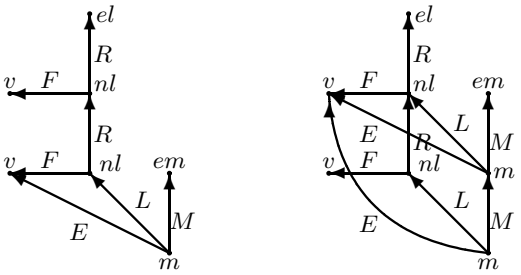
Here the two graphs on the left represent the fact that the rest of a non-empty list could be a non-empty list or an empty list. They also state that each non-empty list has a value. Then there are two graphs for the species m. The first states that the relation member can have a recursive step as a value for the feature M if and only if the list of the second recursive step is the rest of the list of the first recursive step. The second graph just completes the appropriateness for the species m saying that the value of the feature L is also of species non-empty list when the value of the feature M is non-recursive step of the member relation. There are also three graphs with single nodes for the case of empty lists, non-recursive steps of member relations and for the values of the lists. They are presented at the top right part of the picture. Now let us suppose that the annotator would like to enumerate all members of a two-element list by evaluation of the following (query) graph with respect to the above grammar.

Query graph:



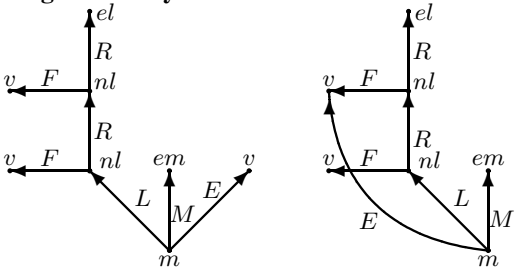
The grammar returns two acceptable analyses. One for the first element of the list and one for the second element of the list.

Positive analyses:

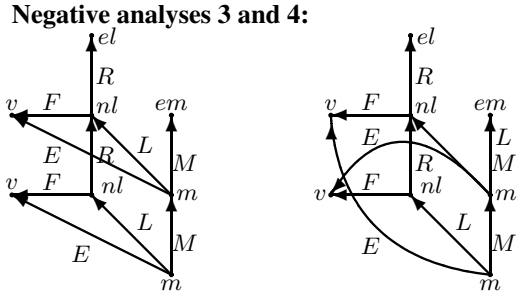


The grammar also accepts 11 wrong analyses in which the E features either point to wrong elements of the list or they are not connected with element of the list at all. Here are the wrong analyses.

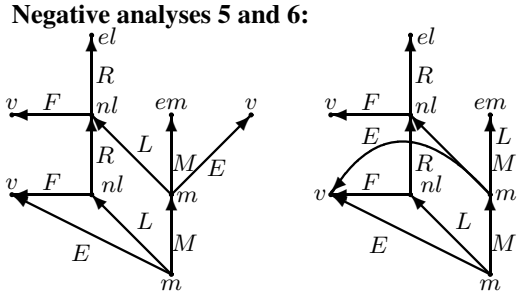
Negative analyses 1 and 2:



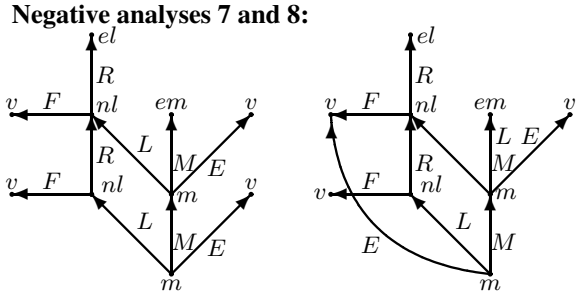
Negative analyses 3 and 4:



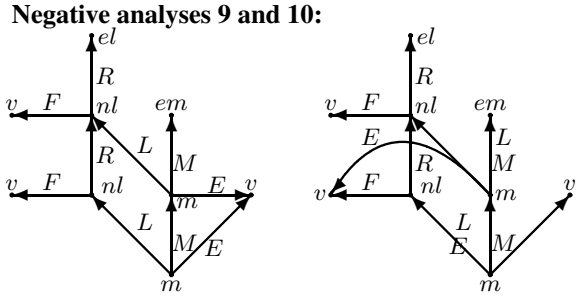
Negative analyses 5 and 6:



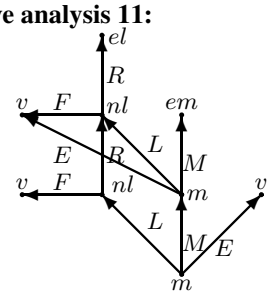
Negative analyses 7 and 8:



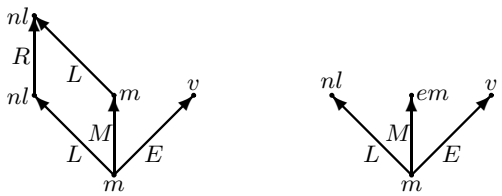
Negative analyses 9 and 10:



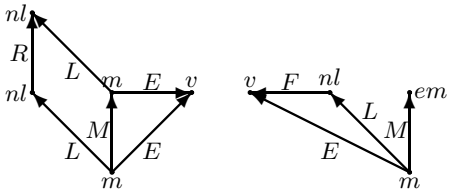
Negative analysis 11:



The next step is to determine the set $\mathcal{GRN}^-$. This set contains 12 complete graphs: all graphs in the set $\mathcal{GRN}$ and one subgraph that is not used in the positive analyses. We will not list these graphs here. The graphs from the grammar that subsumes the graphs in $\mathcal{GRN}^-$ are the two graphs for the member relation. We repeat them here.



Now we have to make them more specific in order to reject the negative examples from $\mathcal{GRN}^-$ but still to accept the two positive examples. The next two graphs are an example of such more specific graphs.



By the first graph the negative examples 3, 4, 5, 7, 8, 10 and 11 are rejected, and by the second graph the negative examples 1, 2, 5, 6, 7, 8, 9, 10 are rejected. Thus both specializations are necessary in order to reject all negative examples. The new grammar still accepts the two positive examples.

6. Conclusion

The presented approach is still very general. It defines a declarative way to improve an annotation HPSG grammar represented as a set of feature graphs. At the moment we have implemented only partially the connection between TRALE system and CLaRK system. Thus, a demonstration of the practical feasibility of the approach remains for future work.

Similar approach can be established on the base of the positive information only (see (Simov, 2001) and (Simov, 2002)), but the use of the negative information can speed up the algorithm. Also, the negative as well as positive information can be used in creation of a performance model for the new grammar along the lines of (Bod, 1998).

7. Acknowledgements

The work reported here is done within the BulTreeBank project. The project is funded by the Volkswagen Stiftung, Federal Republic of Germany under the Programme *"Co-operation with Natural and Engineering Scientists in Central and Eastern Europe"* contract I/76 887.

We would like to thank Petya Osenova for her comments on earlier versions of the paper. All errors remain ours, of course.

Abstract

We present an approach to automatic classification of adjectives in German with respect to a range functional categories. The approach makes use of the grammatical evidence that (i) the functional category of an adjectival modifier determines its relative ordering in an NP, and (ii) only modifiers that belong to the same category may appear together in a coordination. The coordination context algorithm is discussed in detail. Experiments carried out with this algorithm are described and an evaluation of the experiments is presented.

1. Introduction

Traditionally, corpora are annotated with POS, syntactic structures, and, possibly, also with word senses. However, for certain word categories, further types of information are needed if the annotated corpora are to serve as source, e.g., for the construction of NLP lexica or for various NLP-applications. Among these types of information are the semantic and functional categories of adjectives that occur as premodifiers in nominal phases (NPs) (Raskin and Nirenburg, 1995). In this paper, we focus on the functional categories such as 'deictic', 'numerative', 'epithet', 'classifying', etc. As is well-known from the literature (Halliday, 1994; Engel, 1988), the functional category of an adjectival modifier in an NP predetermines its relative ordering with respect to other modifiers in the NP in question, the possibility of a coordination with other modifiers, and to a certain extent, also the reading in the given communicative context. Consider, e.g. in German,

(1) *Viele junge kommunale Politiker ziehen aufs Land*
'Many young municipal politicians move to the country side'.

but

**Viele kommunale junge Politiker ziehen aufs Land*
'Many municipal young politicians move to the country side'.

(2) *Viele ehemalige Politiker ziehen aufs Land*
'Many previous politicians move to the country side.'

but

**Ehemalige viele Politiker ziehen aufs Land*
'Previous many politicians move to the country side.'

Jung 'young' and *kommunal* 'municipal', *viele* 'many' and *ehemalig* 'previous' belong to different functional categories, which makes them unpermutable in the above NPs and implies a specific relative ordering: category(*jung*) $<$ category(*kommunal*) and category(*viele*) $<$ category(*ehemalig*). In contrast, *jung* 'young' and *dynamisch* 'dynamic' belong to the same category; they can be permuted in an NP without an impact on the grammaticality of the example:

(3) *Viele junge, dynamische Politiker ziehen aufs Land*
'Many young, dynamic politicians move to the country side'.

and

Viele dynamische, junge Politiker ziehen aufs Land
'Many dynamic, young politicians move to the country side'.

They can also appear in a coordination:

(4) *Viele junge und dynamische Politiker ziehen aufs Land*
'Many young and dynamic politicians move to the country side'.

Viele dynamische und junge Politiker ziehen aufs Land
'Many dynamic and young politicians move to the country side'.

while, e.g., *viele* and *kommunal* cannot:

(5) **Viele junge und kommunale Politiker ziehen aufs Land*
'Many young and municipal Stuttgart politicians move to the country side'.

In such applications as natural language generation and machine translation, it is important to have the function of the adjectives specified in the lexicon. However, as yet, no large lexica are available that would contain this information. Therefore, an automatic corpus-based annotation of functional information seems the most suitable option.

In what follows, we present a bootstrapping approach to the functional annotation of German adjectives in corpora. The next section presents a short outline of the theoretical assumptions we make with respect to the function of adjectival modifiers and their occurrence in NPs and coordination contexts, before in Section 3. the preparatory stage

and the annotation algorithms are specified. Section 4. contains then the description of the experiments we carried out in order to evaluate our approach, and Section 5. contains the discussion of these experiments. In Section 6., we give some references to work that is related to ours. In Section 7., finally, we draw some conclusions and outline the directions we intend to take in this area in the future.

2. The Grammatical Prerequisits

Grammarians often relate the default ordering of adjectival modifiers to their semantic or functional categories; see, among others, (Dixon, 1982; Engel, 1988; Dixon, 1991; Frawley, 1992; Halliday, 1994). (Vendler, 1968) motivates it by the order of the transformations for the derivation of the NP in question. (Quirk et al., 1985) state that the position of an adjective in an NP depends on how inherent this adjective's meaning is: adjectives with a more inherent meaning are placed closer to the noun than those with a less inherent meaning. (Seiler, 1978) and (Helbig and Buscha, 1999) argue that the order is determined by the scope of the individual adjectival modifiers in an NP. For an overview of the literature on the topic, see, e.g., (Raskin and Nirenburg, 1995).

As mentioned above, we follow the argumentation that the order of adjectives in an NP is determined by their functional categories. In this section, we first outline the range of functions of adjectival modifiers known from the literature especially for German, present then the function-dependent default ordering, and discuss, finally, the results of an empirical study carried out to verify the theoretical postulates and thus to prepare the grounds for the automatic functional category annotation procedure.

2.1. Ranges of Functions of Adjectival Modifiers

In the literature, different ranges of functional categories of adjectival premodifiers have been discussed. For instance, (Halliday, 1994), proposes for English the following categories of the elements in an NP that precede the noun:

(i) deictic: *this*, *those*, *my*, *whose*,...;

(ii) numerative: *many*, *second*, *preceding*, ...;

(iii) epithet: *old*, *blue*, *pretty*, ...;

(iv) classifier: *electric*, *catholic*, *vegetarian*, *Spanish*, ...

In (Engel, 1988), a slightly different range of categories is given for German adjectival premodifiers:

(i) quantitative: *viele* 'many', *einige* 'some', *wenige* 'few', ...

(ii) referential: *erst* 'first', *heutige* 'today's', *diesseitige* 'from-this-side', ...

(iii) qualificative: *schön* 'beautiful', *alt* 'old', *gehoben* 'upper', ...

(iv) classifying: *regional* 'regional', *staatlich* 'state', *katholisch* 'catholic', ...

(v) origin: *Stuttgarter* 'from-Stuttgart', *spanisch* 'Spanish', *marsianisch* 'from-Mars', ...

The function of a modifier may vary with the context of the NP in question or even be ambiguous (Halliday, 1994; Tucker, 1995). Thus, Ger. *zweit* 'second' belong to the referential category in the NP *zweiter Versuch* 'second attempt'; in *zweiter Preis* 'second price', it belongs to the classifying category. *Fast* in *fast train* can be considered as qualificative or as classifying (if *fast train* means 'train classified as express').

Two modifiers are considered to belong to the same category if they can appear together in a coordination or can be permutated in an NP:

(6) a. Ger. *eine rote oder weiße Rose*
'a red or a white rose'

b. *dritter oder vierter Versuch*
'third or fourth attempt'

c. *elektrische oder mechanische Schreibmaschine*
'an electric or mechanic typewriter'

but not

(7) a. $^{??}$*eine rote und langstielige Rose*
'a red and long-stemmed rose'

b. **rote und holländische Rosen*
'red and Dutch roses'

c. **eine schöne oder elektrische Schreibmaschine*
'a beautiful or electric typewriter'

The credibility of the coordination test is limited, however. Consider

(8) $^{??}$ *Eine schöne und rote Rose*
'a beautiful and red rose'

where *schön* 'beautiful' and *rot* 'red' both belong to the qualitative category, but still do not permit a coordination easily.

Adjectival modifier function taxonomies are certainly language-specific (Frawley, 1992). Nonetheless, as the taxonomies suggested by Halliday and Engel show, they may overlap to a major extent. Often, the difference is more of a terminological than of a semantic nature. In our work, we adopt Engel's taxonomy.

2.2. The Default Ordering of Adjectival Modifiers

Engel (Engel, 1988) suggests the following default ordering of modifier functions:
quantitative $<$ referential $<$ qualificative $<$ classifying $<$ origin

Cf, e.g.:

quant.	referent.	qual.	class.	origin
viele	ehemalige	junge	kommunale	Stuttgarter
'many'	'previous'	'young'	'municipal'	'Stuttgart'

as in

(9) *Viele ehemalige junge kommunale Stuttgarter Politiker ziehen aufs Land*
'Many previous young municipal Stuttgart politicians move to the country side'.

According to Engel, a violation of this default ordering leads to ungrammatical NPs. (1–3) in the Introduction illustrate this violation.

2.3. Empirical Evidence for the Theoretical Claims

In the first stage of our work, we sought empirical evidence for the theoretical claims with respect to the functional category motivated ordering and the functional category motivated coordination restrictions. Although, in general, these claims have been buttressed by our study, counterexamples were found in the corpus with respect to both of them.

2.3.1. Default Ordering: Counterexamples

Especially adjectives of the category 'origin' tended to occur before classifying or qualificative modifiers instead of being placed immediately left to the noun–as would be required by the default ordering. For instance, *spanisch* 'Spanish' occured in 3.5% of its occurrences in the corpus in other positions; cf., for illustration:

(10) a. (*das*) *spanische höfische Bild*
'(the) Spanish courtly picture'

b. (*der*) *spanische schwarze Humor*
'(the) Spanish black humour'

c. (*der*) *spanischen sozialistischen Partei*
'(the) Spanish socialist party$_{\mathrm{dat}}$'

To be noted is that in such NPs as (*der*) *spanische schwarze Humor* and *deutsche katholische Kirche* 'German catholic church' the noun and the first modifier form a multiword lexeme rather than a freely composed NP (i.e. *schwarzer Humor* 'black humour' and *katholische Kirche* 'catholic church'). That is, the preceding modifiers (*spanisch* 'Spanish'/*deutsch* 'German') function as modifiers of the respective multiword lexeme, not of the noun only. This is also in accordance with (Helbig and Buscha, 1999)'s scope proposal.

2.3.2. Coordination Restrictions: Counterexamples

It is mainly ordinals that occur, contrary to the theoretical claim, in coordinations with modifiers that belong to a different category. For instance, *erst* 'first' appears in the corpus in 9.74% cases of its occurrence in such "heterogeneous" coordinations. Cf., for illustration:

(11) a. (*die*) *erste und wichtigste Aufgabe*
'(the) first and the most important task'

b. (*eines der*) *ersten und augenfälligsten Projekte*
'one of the first and conspicuous projects'

c. (*die*) *oberste und erste Pflicht*
'(the) supreme and first duty'

As a rule, in such cases the ordinals have a classifying function, which is hard to capture, however.

2.3.3. Grammaticality of the Counterexamples

An evaluation of the counterexamples found in the corpus revealed that not all of these examples can, in fact, be considered as providing counter evidence for the theoretical claims. The grammaticality of a considerable number of these examples has been questioned by several speakers of German; cf., for instance:

(12) a. *(*die*) *ersten und fehlerhaften Informationen*
'(the) first and erroneous informations'

b. $^{??}$*jüngster und erster Präsident*
'youngest and first president'

c. $^{??}$(*die*) *oberste und erste Pflicht*
'(the) supreme and first duty'

3. The Approach

The empirical study of the relative ordering of adjectival modifiers in NPs and of adjectival modifier coordinations in the corpus showed that the theoretical claims made with respect to the interdependency between functional categories and ordering respectively coordination context restrictions are not always proved right. However, deviances from these claims encountered are not numerous enough to question these claims. Therefore, in our approach to the automatic annotation of adjectival modifiers in NPs with functional information outlined below, we make use of them.

The basic idea underlying the approach can be summarized as follows:

1. take a small set of samples for each functional category as point of departure;
2. look in the corpus for coordinations in which one of the elements is in the starting set (and whose functional category is thus known) and the other element is not yet annotated and annotate it with the category of the first element;

   alternatively:

   look in the corpus for all NP-contexts in which one of the elements is in the starting set, assign to its left and right neighbors all categories that these can may have according to the default ordering;
3. attempt to further constrict the range of categories of all modifiers that are still assigned more than one category;
4. add the unambiguously annotated modifers to the set of samples and repeat the annotation procedure;
5. terminate if all adjectival modifiers have been annotated a unique functional category or no further constrictions are possible.

Note that we do not take the punctuation rule into account, which states that adjectival modifiers of the same category are separated by a comma, while modifiers of different categories are not separated. This is because this rule is considered to be unreliable in practice. Furthermore, we do not use such hints as that classifying modifiers do not appear in comparative and superlative forms. See, however, Section 7.

3.1. The Preparatory Stage

The preparatory stage consists of three phases: (i) preprocessing the corpus, (ii) pre-annotation of modifiers whose category is *a priori* known, and (iii) compilation of the sets of modifiers from which the annotation algorithms start.

3.1.1. Preprocessing the Corpus

To have the largest possible corpus at the lowest possible cost, we start with a corpus that is not annotated with POS. When preprocessing the corpus, first token sequences are identified in which one or several tokens with an attributive adjectival suffix (*-e*, *-es*, *-en*, *-er*, or *-em*) are written in small letters and are followed by a capitalized token assumed to be a noun.[1] The tokens with an attributive suffix may be separated by a blank, a comma or have the conjunction *und* 'and' or the disjunction *oder* 'or' in between: cf.:

(13) a. (*das*) *erste richtige Beispiel*
'(the) first correct example'

b. *rote, blaue und grüne oder schwarze Hosen*
'red, blue and green or black pants'

Note that this strategy does not capture certain marginal NP-types; e.g.:

(a) NPs with an irregular adjectival suffix; e.g., *-a*: (*eine*) *lila Tasche* '(a) purple bag', *rosa Haare* 'pink hair', etc.;

(b) NPs with adjectival modifiers that start with a capital.

However, NPs of type (a) are very rare and can more reliably be annotated manually. NPs of type (b) are, first of all, modifiers at the beginning of sentences and attributive uses of proper nouns; cf. *Sorgenloses* 'free of care' in *Sorgenloses Leben – das ist das, was ich will!* lit. 'Free-of-care life—this is what I want' and *Franfurter* 'Frankfurt' in *Frankfurter Würstchen* 'Frankfurt sausages'. The first type appears very seldom in the corpus and can thus be neglected; for the second type, other annotation strategies proved to be more appropriate (Klatt, forthcoming).

After the token sequence identification, wrongly selected sequences are searched for (cf., e.g., *eine schöne Bescherung* 'a nice mess', where *eine* 'a' is despite its suffix obviously not an adjective but an article). This is done by using a morphological analysis program.

3.1.2. Pre-Annotation

In the pre-annotation phase, the following tasks are carried out:

- Adjectival modifiers of the category 'quantitative' are manually searched for and annotated. This is because the set of these modifiers is very small (*einige* 'some', *wenige* 'few', *viele* 'many', *mehrere* 'several') and would not justify the attempt of an automatic annotation.
- In (Engel, 1988), ordinals are by default considered to be referential. Therefore, we use a morphological analysis program to identify ordinals in order to annotate them accordingly in a separate procedure.
- Engel considers attributive readings of verb participles to be qualitative. This enables us to annotate participles with the qualitative function tag before the actual annotation algoritm is run.

3.1.3. Compiling the Starting Sets

Once the corpus is preprocessed and the pre-annotation is done, the starting sample sets for the annotation algorithms are compiled: for each category, a starting set of samples is manually chosen. The number of samples in each set is not fixed. In the experiments we carried out to evaluate our approach the size of sets varied from one to four (cf. Tables 3 and 5 below).

3.2. The Annotation Algorithms

The annotation program consists of two algorithms that can be executed in sequence or independently of each other. The first algorithm processes coordination contexts only. The second algorithm processes NP-contexts in general.

3.2.1. The Coordination Context Algorithm

The coordination context algorithm makes use of the knowledge that two adjectival modifiers that appear together in a conjunction or disjunction belong to the same functional category. As mentioned above, it loops over the set of modifiers whose category is already known (at the beginning, this is the starting set) looking for coordinations in which one of the elements is member of this set and the other element is not yet annotated. The element not yet annotated is assigned the same category as carried by the element already annotated.

The algorithm can be summarized as follows:

1. For each starting set in the starting set configuration do:
   (a) Mark each element in the set as `starting element` and as `processed`.
   (b) Retrieve all coordinations in which one of the `starting elements` occurs;
   for the not yet annotated elements in the coordinations do
   – mark each of them as `preprocessed`;
   – annotate each of them with the same category as assigned to its already annotated respective neighbor;
   – make a frequency distribution of them.
   (c) determine the element in the above frequency distribution with the highest frequency that is not marked as `processed` and mark this element as the next iteration `candidate` of the functional category in question.
2. Take the next iteration `candidate` with the highest frequency of the sets of all categories and mark it as `processed`. Stop, if no next iteration `candidate`

[1] Recall that in German nouns are capitalized.

can be found in any of the newly annotated elements of one of the categories.

3. Find all new corresponding coordination neighbors, add these elements to the set of `preprocessed` elements for the given category and make a new frequency distribution.

4. Determine the next iteration `candidate` for the given category as done in step 1c.

5. Continue with step 2.

Note that the coordination context algorithm does not loop over one of the categories a predetermined number of times and passes on then to the next category in order to repeat the same procedure. Rather, the switch from category to category is determined solely on the basis of the frequency distribution: the most frequent modifier not yet annotated is automaticaly chosen for annotation—independently of the category that has been assigned before. This strategy has two major advantages:

- it takes into account that the distribution of the modifiers in the corpus over the functional categories is extremely unbalanced: the set of 'quantitatives' counts only a few members while the set of 'qualitatives' is very large.

- it helps avoid an effect of "over-annotation" in the course of which the choice of an element that has already been selected as next iteration `candidate` for a specific category as next iteration `candidate` for a different category would lead to a revision of the annotation of all other already annotated elements involved in coordinations with this element.

Especially the second advantage contributes to the quality of our annotation approach. However, obviously enough, this algorithm assigns only one functional category to each adjective. That is, a multiple category assignment that is desirable in certain contexts must be pursued by another algorithm. This is done by the NP-context algorithm discussed in the next subsection.

Table 1 shows a few iterations of the coordination context algorithm with the starting sets of Experiment 1 in Section 4.. Here and henceforth the functional categories are numbered as follows:

1	2	3	4	5
↓	↓	↓	↓	↓
quant.	referent.	qualificat.	class.	origin

In the first iteration, the most frequent "next iteration candidate" of category 1 is *solch* 'such'with a frequency of 10, the most frequent of category 2 is *letzt* 'last' with a frequency of 71, and so on. The candidate of category 4 *wirtschaftlich* 'economic' possesses the highest frequency; therefore it is chosen for annotation and taken as "next iteration starting element" (see Step 2 in the algorithm outline). After adding all elements that occur in a coordination with *wirtschaftlich* to the candidate list, in iteration 2 the next element for annotation (and thus also the starting element) is chosen. This is done as described above for Iteration 1.

It.	cat.1	cat.2	cat.3	cat.4	cat.5
1	solch (10)	letzt (71)	klein (195)	wirtschaftlich (350)	französisch (93)
2	solch (10)	letzt (71)	klein (195)	sozial (295)	französisch (93)
3	solch (10)	letzt (71)	klein (195)	kulturell (208)	französisch (93)
4	solch (10)	letzt (71)	klein (195)	gesellschaftlich (119)	französisch (93)
5	solch (10)	letzt (71)	mittler (370)	gesellschaftlich (119)	französisch (93)
6	solch (10)	letzt (71)	alt (84)	gesellschaftlich (119)	französisch (93)
7	solch (10)	letzt (71)	alt (84)	ökonomisch (105)	französisch (93)
8	solch (10)	letzt (71)	alt (84)	ökologisch (118)	französisch (93)
9	solch (10)	letzt (71)	alt (84)	militärisch (74)	französisch (93)
10	solch (10)	letzt (71)	alt (84)	militärisch (74)	amerikanisch (95)

Table 1: An excerpt of the first iterations of the coordination context algorithm

3.3. The NP-Context Algorithm

The NP-context algorithm is based on the functional category motivated relative ordering of adjectival modifiers in an NP as proposed by Engel (see Section 2.).

In contrast to the coordination-context algorithm, which always ensures a non-ambiguous determination of the category of an adjective, the NP-context algorithm is more of an auxiliary nature. It helps to (i) identify cases where an adjective can be assigned multiple categories, (ii) make hypotheses with respect to categories of adjectival modifiers that do not appear in coordinations, (iii) verify the category assignment of the coordination-context algorithm.

The NP-context algorithm allows for a non-ambiguous determination of the category only in the case of a "comprehensive" NP, i.e., when all positions of an NP (from 'quantitative' to 'origin' are instantiated. Otherwise, relative statements of the kind as in the following case are possible:

> Given the NP (*der*) *schöne, junge, grüne Baum* '(the) beautiful, young, green tree', from which we know that *jung* 'young' is qualitative, we can conclude that *schön* may belong to one of the following three categories: quantitative, referential, or also qualitative, and that *grün* is either qualitative or classifying.

In other words, the following rules underlie the NP-context algorithm:
Given an adjective in an NP whose category X is known:

- assign to all left neighbors of this adjective the categories Y with $Y = 1, 2, \ldots, X$ (i.e., all categories with the number $\leq X$)

- assign to all right neighbors of this adjective the categories Z with $Z = X, X+1, \ldots, 5$ (i.e., all categories with the number $\geq X$

The NP-context algorithm varies slightly depending on the task it is used for—the verification of the categories assigned by the coordination-context algorithm or putting forward hypotheses with respect to the category of adjectives. When being used for the first task, it looks as follows:

1. for all adjectives that received a category tag during the coordination-context algorithm do
   - overtake this tag for all instances of these adjectives in the NP-contexts
2. do for each `candidate` that has been annotated a category
   - for each of the five categories C do
     - assign tentatively C to `candidate`
     - evaluate the NP-context of `candidate` as follows:
       (a) if the other modifiers in the context do not possess category tags, mark the context as unsuitable for the verification procedure
       (b) else, if with respect to the numerical category labels (see above) there is a decreasing pair of adjacent labels (i.e. of neighbor adjectives), mark this NP-context as rejecting C as category of `candidate`, otherwise mark the NP-context as accepting C as category of `candidate`
3. Choose the category whose choice received the highest number of confirmative coordination contexts

Table 2 shows the result of the verification of the category of a few adjectives. The first column contains the adjective whose category is verified. The second column contains the numerical category labels; with a '+' the category prognosticated by the coordination-context algorithm is marked.[2] In the third column, the number of confirmations of the corresponding category by NP-contexts is indicated (i.e. in the case of *neu* 'new', 6083 NP-contexts confirm category 3 ('qualificative') of *neu*, 5048 confirm category 4 ('classifying'), etc.). In the fourth column, the number of NP-contexts is specified that do not provide any evidence for the corresponding category. And in the fifth column the number of NP-contexts is indicated that negate the corresponding function. For four adjectives in Table 2 (*neu* 'new', *groß* 'big', *finanziell* 'financial', and *bosnisch* 'Bosnian') the NP-context algorithm confirmed the category suggested by the coordination-context algorithm; for two adjectives different categories were suggested (for *deutsch* 'German' 4 (classifying) instead of 5 (origin) and for *politisch* 'political' 5 instead of 4).

In the current version of the NP-context algorithm, for adjectival modifiers of category 4 or 5, the correct category is quite often listed as the second best choice. To avoid an incorrect annotation, further measures need to be taken (see also Section 7.).

[2] In all six cases, the coordination-context algorithm assignment was correct.

Table 2: Examples of categorial classification by the NP-context algorithm

4. Experiments with the Coordination Algorithm

To evaluate the performance of the algorithms suggested in the previous section, we carried out experiments in two phases, three experiments each phase. The phases varied with respect to the size of the corpora used; the experiments in each phase varied with respect to the size of the starter sets.

In what follows, the experiments with the coordination algorithm only are discussed.

4.1. The Data

The experiments of the first phase were run on the *Stuttgarter-Zeitung* (STZ) corpus, which contains 36 Mio tokens; the experiments of the second phase were run on the corpus that consisted of the STZ-corpus and the *Frankfurter Rundschau* (FR) corpus with 40 Mio tokens; cf. Table 3. The first row in Table 3 shows the number of adjectival modifier coordinations and the number of premodifier NPs without coordinations in the STZ-corpus and in the STZ+FR-corpus; the second row shows the number of different adjectives that occur in all of these constructions in the respective corpus.

	STZ		STZ+FR	
	coord	NP	coord	NP
# contexts	18648	67757	36985	120673
# diff. adjectives	5894	10035	8003	12993

Table 3: Composition of the adjectival premodifier contexts in our corpora

		number of adjectival mods.						
exp	type	2	3	4	5	6	7	$\sum$
1-3	coord	17228	1238	149	31	2		18648
1-3	NP	66692	1059	6				67757
4-6	coord	34035	2598	298	47	6	1	36985
4-6	NP	118886	1772	15				120673

Table 4: Statistics on the size of the adjectival groups in STZ and STZ+FR

This gives us a ratio of 6.7 between the number of NPs and the number of different adjectives (i.e., the average number of NPs in which a specific adjective occurs) for the STZ-corpus and a ratio of 10.0 for the STZ+FR-corpus. Not surprisingly, larger corpora show a higher adjective repetition rate than small corpora do.

Table 4 contains the statistics on the size of modifier coordinations and the number of adjectival modifiers in NPs in general across both of our corpora. Adjectival modifier groups of size 3 or greater were thus very seldom.

Table 5 contains the data on the composition of both corpora with respect to ordinals and participles of which we assume to know *a priori* to which category they belong: ordinals to the category 2 ('referential') and participles to the category 3 ('qualitative'); see Section 2.

The starter sets consisted for the experiments 1 and 4 of one sample per category: an adjectival modifier of the corresponding category with a high frequency in the STZ-corpus. For the experiments 2 and 5, two, respectively three, high frequency samples for each category were added to starter sets. For the experiments 3 and 6, the starter sets were further extended by an additional modifier which has been assigned a wrong category in the experiments before. Table 6 shows the composition of the starter sets used for the experiments.

Apart from these "regular" members of the starter sets, to the starter sets of category 2 all ordinals and to the starter sets of category 3 all participles available in the respective corpus were added.

To have reliable data for the evaluation of the performance of the annotation program, we let an independent expert annotate 1000 adjectives with functional category

Table 7: Results of the experiments 1 to 3

information. The manually annotated data were then compared with the output of our program to estimate the precision figures (see below).

4.2. Phase 1 Experiments

In the experiments 1 to 3, we were able to assign a functional category to 93,6% of the adjectival modifiers with all three starter sets. In 379 cases, the program could not assign a category; we discuss these cases in Section 5.. Table 7 summarizes the results of the experiments 1 to 3 ('p' stands for "precision").

Many of the 1000 manually annotated tokens occur only a few times in the corpus (and appear thus in a few coordinations). Low frequency tokens negatively influence the precision rate of the algorithm. The diagrams in Figures 1 to 3 illustrate the number of erroneous annotations in the experiments 1 to 3 in relation to the number of coordinations in which a token chosen as next for annotation appears as element at the moment when *n* tokens from the manually annotated token set have already been annotated. For instance, in Experiment 1, the first time when less than or 100 coordinations are considered to determine the category of a token, 9 of the 1000 members of the test set were annotated correctly, the first time when less than or 75 coordinations are considered, 17 of 1000 received the correct category, the first time when less than or 50 coordinations are considered, 31 tokens received the correct category and one a wrong one. And so on. Note, when less than or 5 coordinations were considered for the first time, only 41 annotations (out of 565) were wrong. This gives us a precision rate of $((565 - 41)/565) \times 100 = 92.74\%$.

Figures 2 and 3 show the annotation statistics for Experiments 2 and 3. Note that in Experiment 2 the precision rate for high frequency adjectives is considerably better than in Experiment 1: when 5 coordination contexts are available for the annotation decision, only 26 mistakes were made (instead of 41 in Experiment 1). Figure 3 shows that by a further extension of the starter set, no reasonable improvement of the results is achieved.

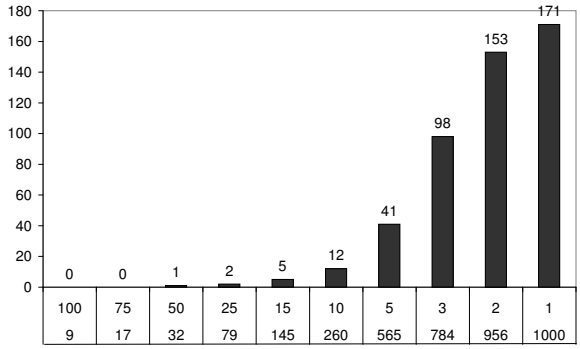

Figure 1: The annotation statistics in Experiment 1

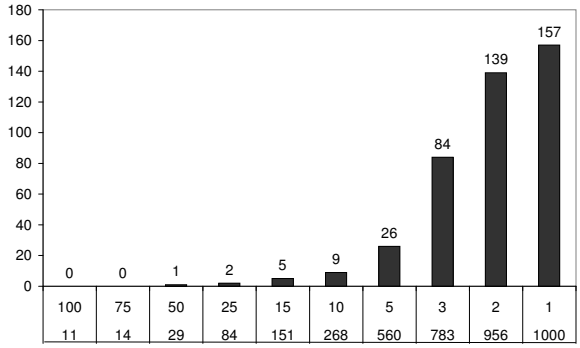

Figure 2: The annotation statistics in Experiment 2

4.3. Phase 2 Experiments

In experiments 4 to 6 we were able to assign with all three starter sets a functional category to 94,1% of the adjectival modifiers, i.e/, to 0.5% more than in the experiments of Phase 1. However, as Table 8 shows, the precision rate decreased slightly. Figures 4 to 6 show the annotation statistics for the Phase 2 experiments.

5. Discussion

In what follows, we first discuss the first 20 iterations of the coordination algorithm in Experiment 1 and Experiment 2, respectively, and present then the overall results of the experiments.

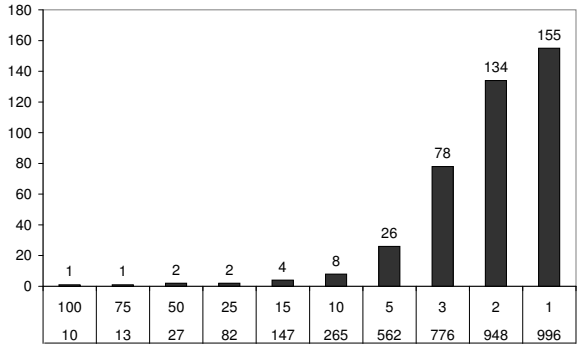

Figure 3: The annotation statistics in Experiment 3

exp.	in total	assigned	¬assigned	p (%)

6	8003	7558	445	84.92%

Table 8: Results of the experiments 4 to 6

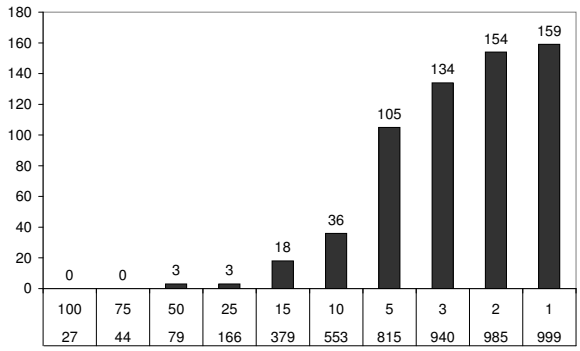

Figure 4: The annotation statistics in Experiment 4

5.1. A Snapshot of the Iterations in Experiments 1 and 2

Table 9 shows the first twenty iterations in Experiment 1, and Table 10 the first twenty iterations in Experiment 2. They look very similar despite the different starting sets in both experiments. Thus, in both nearly the same modifiers are annotated in nearly the same order—except *neu*, which is in Experiment 1 annotated in iteration 14, while in Experiment 2 in iteration 3. At the first glance, one might think that both experiments show the same results. However, as already pointed out above, the bigger starter set in Experiment 2 results in a considerably better precision rates with high and middle frequency adjectives.

5.2. Evaluation of the Experiments

Table 11 shows the distribution of the adjectival modifiers in the six experiments among the five functional categories.

Let us now consider some wrong annotations and some cases where the program was not able to assign a category.

In Table 12, some wrong annotations of category '3' (qualitative) in Experiment 1 are listed. The first column of the table specifies in which iteration of the algorithm the

respective adjective has been assigned a category. 'it freq' (*iteration frequency*) specifies the number of the coordinations with this adjective as element that were available in the corresponding iteration; 'total freq' specifies how many times the adjective occured in coordinations in the corpus in total.

The correct category of *unter* 'under' would have been 2 ('referential'); that of *marktwirtschaftlich* 'free-enterprise' 4 ('classifying'), that of *kommunistisch* 'communist' 4, etc. Note the case of *katholisch* 'catholic'. Its total frequency of 77 is much higher as that of the adjectives processed before. However, it was chosen with an iteration frequency of only 5, i.e., only 5 coordinations have been considered to determine its category. The consequence is that the following adjectives (cf. iterations 808-811) also received a wrong annotation.

Table 13 shows the first 10 of the 445 adjectives that have not been assigned a category in Experiment 6.

Consider, e.g., the coordination constructions in which, e.g., *neunziger* 'ninety/nineties' occurs: *achtziger* 'eighty/eighties' COORD *neunziger* (11 times) and *siebziger* 'seventy/seventies' COORD *achtziger* COORD *neunziger* (1 time). That is, we run into a deadlock here:

	adjective	freq
1.	sechziger	248
2.	siebziger	195
3.	fünfziger	147
4.	dreißiger	102
5.	achtziger	93
6.	zwanziger	81
7.	vierziger	61
8.	zehner	21

Figure 7: The taxonomy that underlies the adjective classification by Raskin and Nirenburg

neunziger cannot be assigned a category because all its coordination neighbors did not receive a category either.

6. Related Work

To our knowledge, ours is the first approach to the automatic classification of adjectives with respect to a range of functional categories. In the past, approaches to the classification of adjectives focused on the classification with respect to semantic taxonomies. For instance, (Raskin and Nirenburg, 1995) discuss a manual classification procedure in the framework of the *MikroKosmos*. The taxonomy they refer to is is shown in Figure 7.

Obviously, an automatization of the classification with respect to this taxonomy is still beyond the state of the art in the field. On the other side, (Engel, 1988)'s functional categories seem to suffice to solve, e.g., the problem of word ordering in text generation.

(Hatzivassiloglou and McKeown, 1993) suggest an algorithm for clustering adjectives according to meaning. However, they do not refer to a predetermined (semantic) typology or set of functional categories.

(Hatzivassiloglou and McKeown, 1997) determine the orientation of the adjectives (negative vs. positive). The orientation is a useful lexical information since it has an impact on the use of adjectives in coordinations: only adjectives with the same orientation appear easily in conjunctions; cf. $^{??}$*stupid and pretty* but *stupid but pretty*. So far, we do not annotate orientation information.

(Shaw and Hatzivassiloglou, 1999)'s work explicitly addresses the problem of the relative ordering of adjectives. In contrast to ours, their approach suggests a pairwise relative ordering of concrete adjectives, not of functional or semantic categories.

7. Conclusions and Future Work

We presented two simple algorithms for the classification of adjectives with respect to a range of functional categories. One of these algorithms, the *coordination context* algorithm, has been discussed in detail. The precision rate achieved by this algorithm is encouraging. It is better for high frequency adjectives than for low frequency adjectives.

Our approach can be considered as a first step into the right direction. In order to achieve better results, we intend to extend our approach along two lines:

- incorporation of additional linguistic clues (e.g., that classifier modifiers do not appear in comparative and superlative forms, that modifiers of the same category can be separated by a comma while those of different categories cannot, etc.);
- combination of our strategies with strategies for the recognition of certain semantic categories (e.g., of city and region names, of human properties, etc.)

The middle-range goal of our project is to compile a lexicon for NLP that contains besides the standard lexical and semantic information functional information.

Abstract

We present a simple, one-pass word alignment algorithm for parallel text. Our algorithm utilizes synchronous parsing and takes advantage of existing syntactic annotations. In our experiments the performance of this model is comparable to more complicated iterative methods. We discuss the challenges and potential benefits of using this model to train syntactic parsers for new languages.

1 Introduction

Word alignment is an exercise commonly assigned to students learning a foreign language. Given a pair of sentences that are translations of each other, the students are asked to draw lines between words that mean the same thing.

In the context of multi-lingual natural language processing, word alignment (more simply, *alignment*) is also a necessary step for many applications. For instance, it is required in the parameter estimation step for training statistical translation models (Al-Onaizan et al., 1999; Brown et al., 1990; Melamed, 2000). Alignments are also useful for foreign language resource acquisition. Yarowsky and Ngai (2001) use an alignment to project part-of-speech (POS) tags from English to Chinese, and use the resulting noisy corpus to train a reliable Chinese POS tagger. Their result suggests that is worthwhile to consider more ambitious endeavors in resource acquisition.

Creating a syntactic treebank (e.g., the Penn Treebank Project (Marcus et al., 1993)) is time-consuming and expensive. As a consequence, state-of-the-art stochastic parsers which rely on such treebanks exist only in languages such as English for which they are available. If syntactic annotation could be projected from English to a language for which no treebank has been developed, then the treebank bottleneck may be overcome (Cabezas et al., 2001).

In principle, the success of treebank acquisition in this manner depends on a few key assumptions. The first assumption is that syntactic relationships in one language can be directly projected to another language using an accurate alignment. This theory is explored in Hwa et al. (2002b). A second assumption is that we have access to a reliable English parser and a word aligner. Although high-quality English parsers are available, high-quality aligners are more difficult to come by. Most alignment research has out of necessity concentrated on unsupervised methods. Even the best results are much worse than alignments created by humans. Therefore, this paper focuses on producing alignments that are tailored to the aims of syntactic projection. In particular, we propose a novel alignment model that, given an English sentence, its dependency parse tree, and its translation, simultaneously generates alignments and a dependency tree for the translation.

Our alignment model aims to improve alignment accuracy while maintaining sensitivity to constraints imposed by the syntactic transfer task. We hypothesize that the incorporation of syntactic knowledge into the alignment model will result in higher quality alignments. Moreover, by generating alignments and parse trees simultaneously, the alignment algorithm avoids irreconcilable errors in the projected trees such as crossing dependencies. Thus, our two objectives complement each other.

To verify these hypotheses, we have performed a suite of experiments, evaluating our algorithm on the quality of the resulting alignments and projected parse trees for English and Chinese sentence pairs. Our initial experiments demonstrate that our approach produces alignments and dependency trees whose quality is comparable to those produced by current state-of-the art systems.

We acknowledge that the strong assumptions we have stated for the success of treebank acquisition do not always hold true (Hwa et al., 2002a; Hwa et al., 2002b). Therefore, it will be necessary to devise a training algorithm that learns syntax even in the face of substantial noise introduced by failures in these assumptions. Although this last point is beyond the scope of this paper, we will allude to potential syntactic transfer approaches that are possible with our system, but infeasible under other approaches.

2 Background

Synchronous parsing appears to be the best model for syntactic projection. Synchronous parsing models the translation process as dual sentence generation in which a word and its translation in the other sentence are generated in lockstep. Translation pairs of both words and phrases are generated in a manner consistent with the syntax of their respective languages, but in a way that expresses the same relationship to the rest of the sentence. Thus, alignment and syntax are produced simultaneously and induce mutual constraints on each other. This model is ideal for the pursuit of our objectives, because it captures our complementary goals in an elegant theoretical framework.

Synchronous parsing requires both parses to adhere to the constraints of a given monolingual parsing model. If we assume context-free grammars, then each parse must be context-free. If we assume dependency grammars, then each parse must observe the planarity and connectivity con-

straints typical of such grammars (e.g. Sleator and Temperley (1993)).

In contrast, many alignment models (Melamed, 2000; Brown et al., 1990) rely on a bag-of-words model. This model presupposes no structural constraints on either input sentence beyond its linear order. To see why this type of model is problematic for syntactic transfer, consider what happens when syntax subsequently interacts with its output. Projecting dependencies across such an alignment may result in a dependency tree that violates planarity and connectivity constraints (Figure 1).

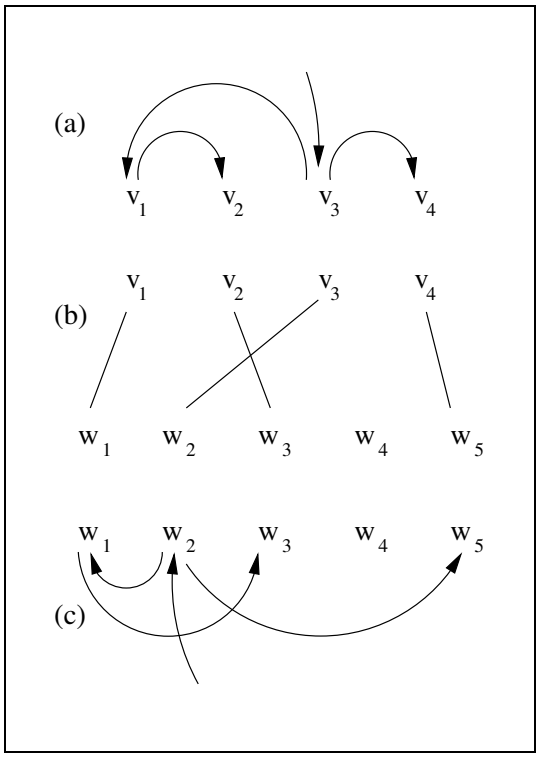

Figure 1: Violation of dependency grammar constraints caused by projecting a dependency parse across a bag-of-words alignment. Combining the syntax of (a) with the alignment of (b) produces the syntax of (c). In this example, the link (w_1, w_3) crosses the link (w_2, w_5) violating the planarity constraint. The word w_4 is unconnected, violating the connectivity constraint.

Once the fundamental assumptions of the syntactic model have been breached, there is no clear way to recover. For this reason, we would prefer not to use bag-of-words alignment models, although in many respects they remain state-of-the-art for alignment.

A canonical example of synchronous parsing is the Stochastic Inversion Transduction Grammar (SITV) (Wu, 1995). The SITV model imposes the constraints of context-free grammars on the synchronous parsing environment. However, we regard context-free grammars as problematic for our task, because recent statistical parsing models (Charniak, 2000; Collins, 1999; Ratnaparkhi, 1999) owe much of their success to ideas inherent to dependency parsing. We therefore adopt an algorithm described in Alshawi and Douglas (2000).[1] Their algorithm constructs synchronous dependency parses in the context of a domain-specific speech-to-speech translation system. In their system, synchronous parsing only enforces a contiguity constraint on phrasal translations. The actual syntax of the sentence is not assumed to be known. Nevertheless, their model is a synchronous parser for dependency syntax, and we adopt it for our purposes.

3 Our Modified Alignment Algorithm

We introduce parse trees as an optional input to the algorithm of Alshawi and Douglas (2000). We require that output dependency trees conform to dependency trees that are provided as input. If no parse tree is provided, our algorithm behaves identically to that of Alshawi and Douglas (2000).

3.1 Definitions

Our input is a parallel corpus that has been segmented into sentence pairs. We represent a sentence pair as the pair of word sequences ($V = v_1...v_m$, $W = w_1...w_n$). The algorithm iterates over the sentence pairs producing alignments.

We define a dependency parse as a rooted tree in which all words of the sentence appear once, and each node in the tree is such a word (Figure 2). An in-order traversal of the tree produces the sentence. A word is said to be *modified* by any words that appear as its children in the tree; conversely, the parent of a word is known as its *headword*. A word is said to *dominate* the span of all words that are descended from it in the tree, and is likewise known as the *headword* of that span.[2] Subject to these constraints, the dependency parse of V is expressed as a function $p_V : \{1...m\} \rightarrow \{0...m\}$ which defines the headword of each word in the dependency graph. The expression $p_V(i) = 0$ indicates that word v_i is the root node of the graph (the headword of the sentence). The dependency parse of W, $p_W : \{1...n\} \rightarrow \{0...n\}$ is defined in the same way.

An alignment is expressed as a function $a : \{1...m\} \rightarrow \{0...n\}$ in which $a(i) = j$ indicates that word v_i of V is aligned with word w_j of W. The case in which $a(i) = 0$ denotes *null alignment* (i.e. the word v_i does not correspond to any word in W). Under the constraints of synchronous parsing, we require that if $a(i) \neq 0$, then $p_W(a(i)) = a(p_V(i))$. In other words, the headword of a word's translation is the translation of the word's headword (Figure 3). We also require that the analogous condition hold for the inverse alignment map $a^{-1} : \{1...n\} \rightarrow \{0...m\}$.

3.2 Algorithm Details

Our algorithm (Appendix) is a bottom-up dynamic programming procedure. It is initialized by considering all

[1] An alternative to dependency grammar is the richer formalism of Synchronized Tree-Adjoining Grammar (TAG) (Shieber and Schabes, 1990). However, Synchronized TAG raises issues of computational complexity and has not yet been exploited in a stochastic setting.

[2] Elsewhere, the terms *connectivity* and *planarity* are used to define these constraints.

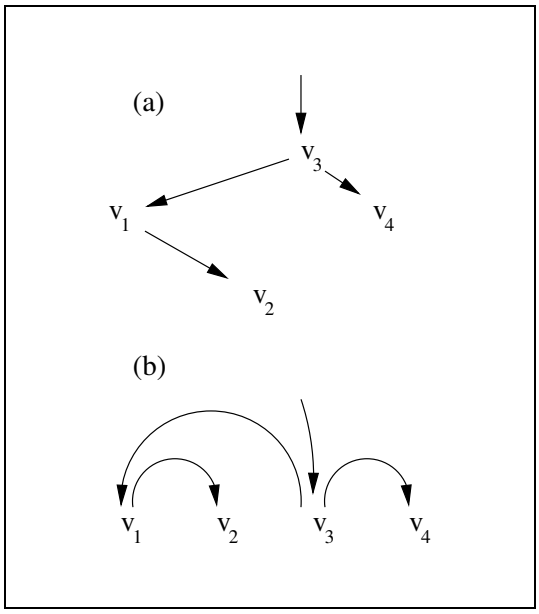

Figure 2: A dependency parse. In (a) the sentence is depicted in a tree form that makes the dominance and headword relationships clear (v_3 is the headword of the sentence). In (b) the same tree is depicted in more familiar sentence form, with the links drawn above the words.

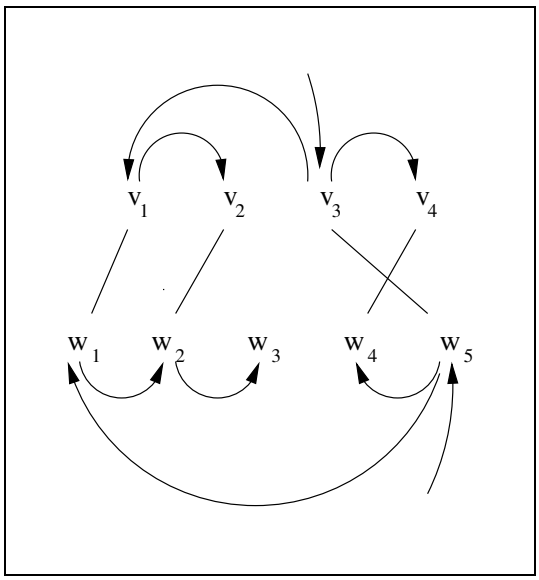

Figure 3: Synchronous dependency parses. Notice that all dependency links are symmetric across the alignment. In addition, the unaligned word w_3 is connected in the parse of W.

possible alignments of one word to another word or to null. Alshawi and Douglas (2000) considered alignments of two words to one or no words, but we found in our evaluations that restricting the initialization step to one word produced better results. In fact, Melamed (2000) argues in favor of exclusively one-to-one alignments. However, we may later explore in more detail the effects of initializing from multiword alignments.

As in Alshawi and Douglas (2000) each possible one-to-one alignment is scored using the ϕ^2 metric (Gale and Church., 1991), which is used to compute the correlation between $v_i \in V$ and $w_j \in W$ over all sentence pairs (V, W) in the corpus. Sentence co-occurrence counts are not the only possible data set with which we can use this metric. Therefore, we denote this type of initialization by ϕ^2_A to distinguish from a case we consider in Section 4.7, in which we use ϕ^2 initialized from counts of Giza++ alignment links. The latter case is denoted by ϕ^2_G.

To compute alignments of larger spans, the algorithm combines adjacent sub-alignments. During this step, one sub-alignment becomes a modifier phrase. Interpreting this in terms of dependency parsing, the aligned headwords of the modifier phrase become modifiers of the aligned headwords of the other phrase. At each step, the score of the alignment is computed. Following Alshawi and Douglas (2000) we simply add the score of the sub-alignments. Thus the overall score of any aligned subphrase can be computed as follows.

$$\sum_{(i,j):a(i)=j} \phi^2(v_i, w_j)$$

The output of the algorithm is simply the highest-scoring alignment that covers the entire span of both V and W.

3.3 Treatment of Null Alignments

Null alignments present a few practical issues. For experiments involving ϕ^2_A, we adopt the practice of counting a null token in the shorter sentence of each pair.[3] An alternative solution to this problem would involve initialization from a word association model that explicitly handles nulls, such as that of Melamed (2000).

An implication of the synchronous parsing constraint given in Section 3.1 is that null aligned words must be leaf words within their respective dependency graphs. In certain cases this may not lead to the best synchronized parse. We remove this condition. Effectively, we consider each sentence to consist of the same number of tokens, some of which may be null tokens. (usually, this will introduce null tokens into only the shorter sentence, but not necessarily). The null tokens behave like words with regards to the synchronous parsing constraint, but they do not impact phrase contiguity.[4] In only the resulting surface dependency graphs, we remove null tokens by contracting all edges between the null token and its parent and naming the resultant node with the word on the parent node. Recall from graph theory that contraction is an operation whereby an edge is removed and the nodes at its endpoints are conflated. [5] Thus, words that modify a null token are interpreted as modifiers of the the null token's headword. This is illustrated in Figure 4. One important implication of this is that we can only allow a null token to be the headword

[3] Srinivas Bangalore, personal communication.

[4] a null token is considered to be contiguous with any other subphrase – another way to view this is that a null token is an unseen word that may appear at any location in the sentence in order to satisfy contiguity constraints.

[5] see e.g., Gross and Yellen (1999)

of the sentence if it has a single modifier. Otherwise, the result of the graph contraction would not be a rooted tree. We found that this treatment of null alignments resulted in a slight improvement in alignment results.

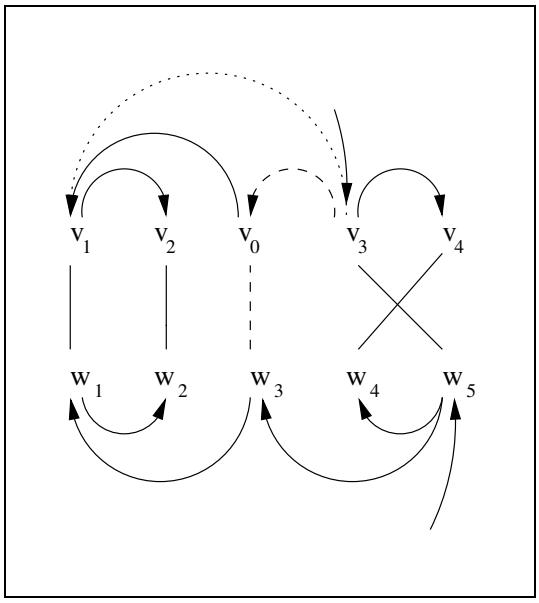

Figure 4: Effect of null words on synchronous parses. In this case, word w_3 has been aligned to the null token v_0. However, v_0 can still dominate other words in the parse of V. Once the structure has been completed, the edge between v_0 and v_3 (indicated by the dashed line) will contract. This will cause the dependency between v_1 and v_0 to become the inferred dependency (indicated by the dotted line) between v_1 and v_3.

3.4 Analysis

In the case that there are no parses available, the computational complexity of the algorithm is $O(m^3n^3)$, but with a parse of V (and an efficient enumeration of the subphrase combinations allowed by the parse) the complexity reduces to $O(m^3n)$. If both parses are available the complexity would be reduced to $O(mn)$.

It is important to note that as it is presented, our algorithm does not search the entire space of possible alignment/tree combinations. Melamed observes that two modifications are required to accomplish this.[6] The first modification entails the addition of four new loop parameters to enumerate the possible headwords of the four monolingual subspans. These additional parameters add a factor of $O(m^2n^2)$. Second, Melamed points out that for a small subset of legal structures, it must be possible to combine subphrases that are not adjacent to one another. The most efficient solution to this problem adds two more parameters, for a total of $O(m^6n^6)$. The best known optimization reduces the total complexity to $O(m^5n^5)$. This is far too complex for a practical implementation, so we chose to use the original $O(m^3n^3)$ algorithm for our evaluations. Thus we recognize that our algorithm does not search the entire space of synchronous parses. It inherently incorporates a greedy heuristic, since for each subphrase, it considers only the most likely headword.

[6] I. Dan Melamed, personal communication.

4 Evaluation

We have performed a suite of experiments to evaluate our alignment algorithm. The qualities of the resulting alignments and dependency parse trees are quantified by comparisons with correct human-annotated parses. We compare the alignment output of our algorithm with that of the basic algorithm described in Alshawi and Douglas (2000) and the well-known IBM statistical model described in Brown et al. (1990) using the freely available implementation (Giza++) described in Al-Onaizan et al. (1999). We also compare the output dependency trees against several baselines and against projected dependency trees created in the manner described in (Hwa et al., 2002a). We found that our model, which combines cross-lingual statistics with syntactic annotation, produces alignments and trees that are are comparable to the best results of other methods.

4.1 Data Set

The language pair we have focused on for this study is English-Chinese. The training corpus consists of around 56,000 sentence pairs from the Hong Kong News parallel corpus. Because the training corpus is solely used for word co-occurrence statistics, no annotation is performed on it.

The development set was constructed by obtaining manual English translations for 47 Chinese sentences of 25 words or less, taken from sections 001-015 of the Chinese Treebank (Xia et al., 2000). A separate test set, consisting of 46 Chinese sentences of 25 words or less, was constructed in a similar fashion.[7] To obtain correct English parses, we used a context-free parser (Collins, 1999) and converted its output to dependency format. To obtain correct Chinese parses, Chinese Treebank trees were converted to dependency format. Both sets of parses were hand-corrected. The correct alignments for the development and test set were created by two native Chinese speakers using annotation software similar to that described in Melamed (1998).

4.2 Metrics for evaluating alignments

As a measure of alignment accuracy, we report Alignment Precision (AP) and Alignment Recall (AR) figures. These are computed by by comparing the alignment links made by the system with the links in the correct alignment. We denote the set of guessed alignment links by G_a and the set of correct alignment links by C_a. Precision is given by $AP = \frac{|C_a \cap G_a|}{|G_a|}$. Recall is given by $AR = \frac{|C_a \cap G_a|}{|C_a|}$. We also compute the F-score (AF), which is given by $AF = \frac{2 \cdot AP \cdot AR}{AP + AR}$. Null alignments are ignored in all computations. Our evaluation metric is similar to that of Och and Ney (2000).

[7] These sentences have already been manually translated into English as part of the NIST MT evaluation preview (See http://www.nist.gov/speech/tests/mt/). The sentences were taken from sections 038, 039, 067, 122, 191, 207, 249.

Synchronous Parsing Method	AP	AR	AF	CTP
sim-Alshawi (ϕ_A^2)	40.6	36.5	38.4	18.5
sim-Alshawi (ϕ_A^2) + English parse	43.8	39.3	41.4	39.9
sim-Alshawi (ϕ_A^2) + English parse + Chinese bigrams	42.9	38.5	40.6	39.4
sim-Alshawi (ϕ_A^2) + both bigrams	41.5	37.3	39.3	16.5
Giza++ initialization (ϕ_G^2)	51.2	45.9	**48.4**	11.6
Giza++ initialization (ϕ_G^2)+ English parse	49.6	44.6	47.0	**44.7**

Baseline Method	AP	AR	AF	CTP
Same Order Alignment	15.7	14.1	14.8	NA
Random Alignment (avg scores)	7.8	7.0	7.4	NA
Forward-chain	NA	NA	NA	37.3
Backward-chain	NA	NA	NA	12.9
Giza++	68.7	40.9	**51.3**	NA
Hwa et al. (2002a)	NA	NA	NA	**44.1**

Table 1: Alignment Results for All Methods.
AP = Alignment Precision. AR = Alignment Recall. AF = Alignment F-Score. CTP = Chinese Tree Precision.
All scores are reported as percentages of 100.
The best scores in each table appear in bold.

4.3 Metrics for evaluating projected parse trees

As a measure of induced dependency tree accuracy, we report unlabeled Chinese Tree Precision (CTP). This is computed by comparing the output dependency tree with the correct dependency trees. We denote the set of guessed dependency links by G_p and the set of correct alignment links by C_p. A small number of words (mostly punctuation) were not linked to any parent word in the correct parse; links containing these words are not included in either C_p or G_p. Precision is given by $CTP = \frac{|C_p \cap G_p|}{|G_p|}$. For dependency trees, $|C_p| = |G_p|$, since each word contributes one link relating it to its headword. Thus, recall is the same as precision for our purposes.

4.4 Baseline Results

We first present the scores of some naïve algorithms as a baseline in order to provide a lower bound for our results. The results of the baseline experiments are included with all other results in Table 1. Our first baseline (Same Order Alignment) simply maps character v_i in the English sentence to character w_i in the Chinese sentence, or w_n in the case of $i > n$. Our second baseline (Random Alignment), randomly aligns word v_i to word w_j subject to the constraint that no words are multiply aligned. We report the average scores over 100 runs of this baseline. The best Random Alignment F-score was 10.0% and the worst was 5.3% with a standard deviation of 0.9%.

For parse trees, we use two simple baselines. In the first (Forward-Chain), each word modifies the word immediately following it, and the last word is the headword of the sentence. For the second baseline (Backward-Chain), each word modifies the word immediately preceding it, and the first word is the headword of the sentence. No alignment was performed for these baselines.

The remaining baselines relate to the Giza++ algorithm. Giza++ produces the best word alignments. For reasons described previously, Giza++ alignments do not combine easily with syntax. However, Hwa et al. (2002a) contains an investigation in which trees output from a projection across Giza++ alignment are modified using several heuristics, and subsequently improved using linguistic knowledge of Chinese. We report the Chinese Tree Precision obtained by this method.

4.5 Synchronous Parsing Results

Our first set of alignments combines the ϕ_A^2 cross-lingual co-occurrence metric described previously with either English parse or no parse trees. In this set, ϕ_A^2 with no parse is nearly identical to the approach described in Alshawi and Douglas (2000) (excepting our treatment of null alignments). Thus, it serves as a useful point of comparison for runs that make use of other information. In Table 1 we refer to it as sim-Alshawi.

What we find is that incorporating parse trees results in a modest improvement over the baseline approach of sim-Alshawi. Why aren't the improvements more substantial? One observation is that using parses in this manner results in only passive interaction with the cross-lingual ϕ_A^2 scores. In other words, the parse filters out certain alignments, but cannot in any other way counteract the biases inherent in the word statistics. Nevertheless, it appears to be modest progress.

4.6 Results of Using Bigrams to Approximate Parses

The results suggest that using parses to constrain the alignment is helpful. It is possible that using both parses would result in a more substantial improvement. However, we have already stated that we are interested in the case of asynchronous resources. Under this scenario, we only have access to one parse. Is there some way that we can approximate syntactic constraints of a sentence without having access to its parse?

The parsers of (Charniak, 2000; Collins, 1999; Ratnaparkhi, 1999) make substantial use of *bilexical dependencies*. Bilexical dependencies capture the idea that linked words in a dependency parse have a statistical affinity for each other: they often appear together in certain contexts. We suspect that bigram statistics could be used as a proxy for actual bilexical dependencies.

We constructed a simple test of this theory: for each English sentence $V = v_1...v_m$ in the development set with parse $p_V : \{1...m\} \rightarrow \{0...m\}$, we first construct the set of all bigrams $B = \{(v_i, v_j) : 1 \leq i < j \leq m\}$. We then partitioned B into two sets: bigrams of linked words, i.e. $L = \{(v_i, v_j) : (v_i, v_j) \in B; p_V(v_i) = v_j \text{ or } p_V(v_j) = v_i\}$ and unlinked words $U = B - L$. We used the Bigram Statistics Package (Pedersen, 2001), to collect bigram statistics over the entire dev/train corpus and compute the average statistical correlation of each set using a variety of metrics (loglikelihood, dice, χ^2, ϕ^2). The results indicated that bigrams in the linked set L were more correlated than those in the unlinked set U under all metrics. We repeated this experiment with the development sentences in Chinese, with similar results. Although this is by no means a conclusive experiment, we took the results as an indication that using bigram statistics as an approximation of a parse might be helpful where no parse was actually available.

To incorporate bigram statistics into our alignment model, we modified the scoring function in the following manner: each time a dependency link is introduced between words and we do not have access to the source parse, we add into the alignment score the bigram score of the two words. The bigram score is based on the ϕ^2 metric computed for bigram correlation. We call this ϕ^2_B. The resulting alignment score can now be given by the following formula.

$$\sum_{(i,j):a(i)=j} \phi^2_A(v_i, w_j) + \sum_{(i,j):i<j, p_W(i)=j \wedge p_W(j)=i} \phi^2_B(w_i, w_j)$$

Our results indicate that using Chinese bigram statistics in conjunction with English parse trees in this manner results in a small decrease in the score along all measures. Nonetheless, there is an intuitively appealing interpretation of using bigrams in this way. The first is that the modification of the scoring function provides competitive interaction between parse information and cross-lingual statistics. The second is that if bigram statistics represent a weak approximation of syntax, then perhaps the iterative refinement of this statistic (e.g. by taking counts only over words that were linked in a previous iteration) would satisfy our objective of syntactic transfer.

4.7 Results of Using Better Word Statistics

Our results show that using parse information and coarse cross-lingual word statistics provides a modest boost over an approach using only the cross-lingual word statistics. We also decided to investigate what happens when we seed our algorithm with better cross-lingual statistics

To test this, we initialize our co-occurrence counts from alignment links output by the Giza++ alignment of our corpus. We still use ϕ^2 to compute the correlation. We call this ϕ^2_G. Predictably, using the better word correlation statistics improves the quality of the alignment output in all cases. In this scenario, adding parse information does not seem to improve the alignment score. However, parse trees induced in this manner achieve a higher precision than any of the other methods. It outscores the baseline algorithms by a significant amount, and produces results comparable to the baseline of Hwa et al. (2002a). It is important to note, however, that the baseline of Hwa et al. (2002a) is achieved only after the application of numerous linguistic rules to the output of the Giza++ alignment. Additionally, the trees themselves may contain errors of the type described in Section 2. In contrast, our tree precision results directly from the application of our synchronous parsing algorithm, and all of the output trees are valid dependency parses.

5 Future Work

We believe that a fundamental advantage of our baseline model is its simplicity. Improving upon it will be considerably easier than improving upon a complex model such as the one described in Brown et al. (1990). Improvements may proceed along several possible paths. One path would involve reformulating the scoring functions in terms of statistical models (e.g. generative models). A natural complement to this path would be the introduction of iteration with the goal of improving the alignments and the accompanying models. In this approach, we could attempt to learn a coarse statistical model of the syntax of the low-density language after each iteration of the alignment. This information could in turn be used as evidence in the next iteration of the alignment model, hopefully improving its performance. Our results have already established a set of statistics that could be used in the initial iteration of such a task. The iterative approach resonates with an idea proposed in Yarowsky and Ngai (2001), regarding the use of learned part-of-speech taggers in subsequent alignment iterations.

An orthogonal approach would be the application of additional linguistic information. Our results indicated that syntactic knowledge can help improve alignment. Additional linguistic knowledge obtained from named-entity analyses, phrasal boundary detection, and part-of-speech tags might also improve alignment.

Although our output dependency trees represent definite progress, trees with such low precision cannot be used directly to train statistical parsers that assume correct training data (Charniak, 2000; Collins, 1999; Ratnaparkhi, 1999). There are two possible methods of improving upon the precision of this training data. The first is the use of noise-resistant training algorithms such as those described in (Yarowsky and Ngai, 2001). The second is the possibility of improving the precision yield by removing obviously bad training examples from the set. Unlike the baseline model, our word alignment model provides an obvious means of doing this. One possibility is to use a score gleaned from the alignment algorithm as a means of ranking dependency links, and removing links whose score is above some threshold. We hope that a dual approach of improving the precision of the training examples, while simultaneously reducing the sensitivity of the training algorithm, will result in the ability to train a reasonably accurate statistical parser for the new language. Our eventual objective

is to train a parser in this manner.

6 Related work

Al-Onaizan et al. (1999), Brown et al. (1990) and Melamed (2000) focus on the description of statistical translation models based on the bag-of-words model. Alignment plays a crucial part in the parameter estimation methods of these models, but they remain problematic for syntactic transfer for reasons described in Section 2. The work of Hwa et al. (2002b) is an investigation into the combination of syntax with the output of this type of model. Och et al. (1999) presents a statistical translation model that performs phrasal translation, but it relies on shallow phrases that are discovered statistically, and makes no use of syntax. Yamada and Knight (2001) create a full-fledged syntax-based translation model. However, their model is unidirectional; it only describes the syntax of one sentence, and makes no provision for the syntax of the other. Wu (1995) presents a complete theory of synchronous parsing using a variant of context-free grammars, and exhibits several positive results, though not for syntax transfer. Alshawi and Douglas (2000) present the synchronous parsing algorithm on which our work is based. Much like the work on translation models, however, this work is interested in alignment primarily as a mechanism for training a machine translation system. Variations on the synchronous parsing algorithm appear in Alshawi et al. (2000a) and Alshawi et al. (2000b), but the algorithm of Alshawi and Douglas (2000) appears to be the most complete.

7 Conclusion

We have described a new approach to alignment that incorporates dependency parses into a synchronous parsing model. Our results indicate that this approach results in alignments whose quality is comparable to those produced by complicated iterative techniques. In addition, our approach demonstrates substantial promise in the task of learning syntactic models for resource-poor languages.

A Algorithm Pseudocode

The following code does not address what constitutes a legal combination of subspans for an alignment. Legal subspans depend on constraints imposed by an input parse, if available. Otherwise, as in Alshawi and Douglas (2000), all possible combinations of subspans are legal. Regardless of what constitutes a legal subspan, the enumeration of spans must be done in a reasonable way. Small spans must be enumerated before larger spans that are constructed from them.

The variables i_V and j_V denote the span $v_{i_V+1}...v_{j_V}$, and p_V denotes a partition of the span such that $i_V \leq p_V \leq j_V$. The variables i_W, j_W, and p_W are defined analogously on W.

Our data structure is a chart α, which contains cells indexed by i_V, j_V, i_W, and j_W. Each cell contains subfields $phrase$, $modifierPhrase$, and $score$.

Finally, we assume the existence of functions assocScore and score. The assocScore function computes the score of directly aligning to short spans of the sentence pair. In this paper, we use variations on the ϕ^2 metric (Gale and Church., 1991) for this. The score function computes the score of combining two sub-alignments, assuming that the second sub-alignment becomes a modifier of the first. In this paper, we use one score function that simply adds the score of sub-alignments, and one that adds bigram correlation to the score of the sub-alignments. In principle, arbitrary scoring functions can be used.

initialize the chart

for all legal combinations of i_V, j_V,i_W, and j_W

$\alpha(i_V, j_V, i_W, j_W) = assocScore(v_{i_V+1}...v_{j_V}, w_{i_W+1}...w_{j_W})$

complete the chart

for all legal combinations of i_V, j_V, p_V, i_W, j_W, and p_W

consider the case in which aligned subphrases are in the same order in both languages.

$phrase = \alpha(i_V, p_V, i_W, p_W)$

$modifierPhrase = \alpha(p_V, j_V, p_W, j_W)$

$score =$score($phrase, modifierPhrase$)

if $score > \alpha(i_V, j_V, i_W, j_W).score$ then

$\alpha(i_V, j_V, i_W, j_W) =$ new subAlignment($phrase, modifierPhrase, score$)

consider the case in which the dominance relationship between these two phrases is reversed.

swap($phrase, modifierPhrase$)

$score =$score($phrase, modifierPhrase$)

if $score > \alpha(i_V, j_V, i_W, j_W).score$ then

$\alpha(i_V, j_V, i_W, j_W) =$ new subAlignment($phrase, modifierPhrase, score$)

consider the case in which aligned subphrases are in the reverse order in each language.

$phrase = \alpha(i_V, p_V, p_W, j_W)$

$modifierPhrase = \alpha(p_V, j_V, i_W, p_W)$

$cost =$cost($phrase, modifierPhrase$)

$score =$score($phrase, modifierPhrase$)

if $score > \alpha(i_V, j_V, i_W, j_W).score$ then

$\alpha(i_V, j_V, i_W, j_W) =$ new subAlignment($phrase, modifierPhrase, score$)

consider the case in which the dominance relationship between these two phrases is reversed.

swap($phrase, modifierPhrase$)

$score =$score($phrase, modifierPhrase$)

if $score > \alpha(i_V, j_V, i_W, j_W).score$ then

$\alpha(i_V, j_V, i_W, j_W) =$ new subAlignment($phrase, modifierPhrase, score$)

Generating A Parsing Lexicon from an LCS-Based Lexicon

Necip Fazıl Ayan and Bonnie J. Dorr

Department of Computer Science
University of Maryland
College Park, 20742, USA
{nfa, bonnie}@umiacs.umd.edu

Abstract

This paper describes a technique for generating parsing lexicons for a principle-based parser (Minipar). Our approach maps lexical entries in a large LCS-based repository of semantically classified verbs to their corresponding syntactic patterns. A by-product of this mapping is a lexicon that is directly usable in the Minipar system. We evaluate the accuracy and coverage of this lexicon using LDOCE syntactic codes as a gold standard. We show that this lexicon is comparable to the hand-generated Minipar lexicon (i.e., similar recall and precision values). In a later experiment, we automate the process of mapping between the LCS-based repository and syntactic patterns. The advantage of automating the process is that the same technique can be applied directly to lexicons we have for other languages, for example, Arabic, Chinese, and Spanish.

1. Introduction

This paper describes a technique for generating parsing lexicons for a principle-based parser (Minipar (Lin, 1993; Lin, 1998)) using a lexicon that is semantically organized according to Lexical-Conceptual Structure (LCS) (Dorr, 1993; Dorr, 2001)—an extended version of the verb classification system proposed by (Levin, 1993).[1] We aim to determine how much syntactic information we can obtain from this resource, which extends Levin's original classification as follows: (1) it contains 50% more verbs and twice as many verb entries (Dorr, 1997)—including new classes to accommodate previously unhandled verbs and phenomena (e.g., clausal complements); (2) it incorporates theta-roles which, in turn, are associated with a thematic hierarchy for generation (Habash and Dorr, 2001); and (3) it provides a higher degree of granularity, i.e., verb classes are sub-divided according to their aspectual characteristics (Olsen et al., 1997).

More specifically, we provide a general technique for projecting this broader-scale semantic (language-independent) lexicon onto syntactic entries, with the ultimate objective of testing the effects of such a lexicon on parser performance. Each verb in our semantic lexicon is associated with a class, an LCS representation, and a thematic grid.[2] These are mapped systematically into syntactic representations. A by-product of this mapping is a lexicon that is directly usable in the Minipar system.

Several recent lexical-acquisition approaches have produced new resources that are ultimately useful for syntactic analysis. The approach that is most relevant to ours is that of (Stevenson and Merlo, 2002b; Stevenson and Merlo, 2002a), which involves the derivation of verb classes from syntactic features in corpora. Because their approach is unsupervised, it provides the basis for automatic verb classification for languages not yet seen. This work is instrumental in providing the basis for wide-spread applicability of our technique (mapping verb classes to a syntactic parsing lexicon), as verb classifications become increasingly available for new languages over the next several years.

An earlier approach to lexical acquisition is that of (Grishman et al., 1994), an effort resulting in a large resource called Comlex—a repository containing 38K English headwords associated with detailed syntactic patterns. Other researchers (Briscoe and Carroll, 1997; Manning, 1993) have also produce subcategorization patterns from corpora. In each of these cases, data collection is achieved by means of statistical ex-

[1] We focus only on verb entries as they are cross-linguistically the most highly correlated with lexical-semantic divergences.

[2] Although Lexical Conceptual Structure (LCS) is the primary semantic representation used in our verb lexicon, it is not described in detail here (but see (Dorr, 1993; Dorr, 2001). For the purpose of this paper, we rely primarily on the thematic grid representation, which is derived from the LCS. Still we refer to the lexicon as "LCS-based" as we store all of these components together in one large repository: http://www.umiacs.umd.edu/~bonnie/LCS_Database_Documentation.html.

traction from corpora; there is no semantic basis and neither is intended to be used for multiple languages.

The approaches of (Carroll and Grover, 1989) and (Egedi and Martin, 1994) involve acquisition English lexicons from entries in LDOCE and *Oxford Advanced Learner's Dictionary* (OALD), respectively. The work of (Brent, 1993) produces a lexicon from a grammar—the reverse of what we aim to do. All of these approaches are specific to English. By contrast, our goal is to have a unified repository that is transferable to other languages—and from which our parsing (and ultimately generation) grammars may be derived.

For evaluation purposes, we developed a mapping from the codes of Longman's Dictionary of Contemporary English (LDOCE (Procter, 1978))—the most comprehensive online dictionary for syntactic categorization—to a set of syntactic patterns. We use these patterns as our gold standard and show that our derived lexicon is comparable to the hand-generated Minipar lexicon (i.e., similar recall and precision values). In a later experiment, we automate the process of mapping between the LCS-based repository and syntactic patterns—with the goal of portability: We currently have LCS lexicons for English, Arabic, Spanish, and Chinese, so our automated approach allows us to produce syntactic lexicons for parsing in each of these languages.

Section 2. presents a brief description of each code set we use in our experiments. In Section 3., we explain how we generated syntactic patterns from three different lexicons. In Section 4., we discuss our experiments and the results. Section 5. describes ongoing work on automating the mapping between LCS-based representations and syntactic patterns. Finally, we discuss our results and some possible future directions.

2. Code Descriptions

In many online dictionaries, verbs are classified according to the arguments and modifiers that can follow them. Most dictionaries use specific codes to identify transitivity, intransitivity, and ditransitivity. These broad categories may be further refined, e.g., to distinguish verbs with NP arguments from those with clausal arguments. The degree of refinement varies widely.

In the following subsections, we will present three different code sets. As shown in Figure 1, the first of these (OALD) serves as a mediating representation in the mapping between Minipar codes and syntactic patterns. The LCS lexicon and LDOCE codes are mapped directly into syntactic patterns, without an intervening representation. The patterns resulting from the LDOCE are taken as the gold standard, serving as the basis of comparison between the Minipar- and LCS-based lexicons.

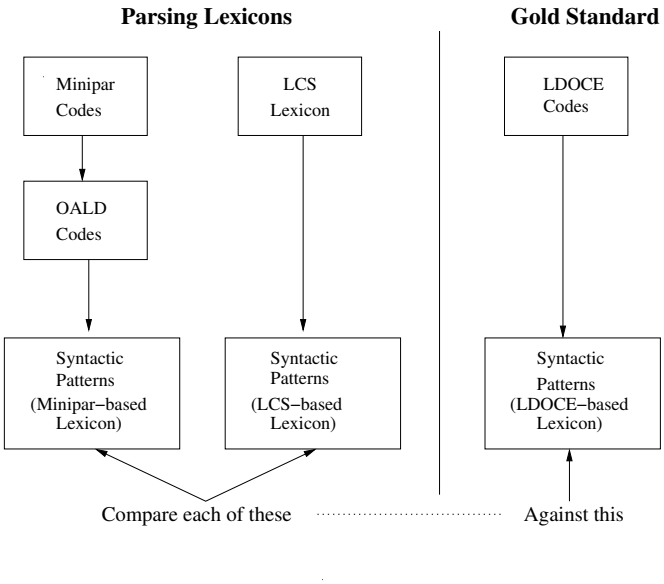

Figure 1: A Comparison between Minipar- and LCS-based Lexicons using LDOCE as the Gold Standard

2.1. OALD Codes

This code set is used in Oxford Advanced Learner's Dictionary, a.k.a OALD (Mitten, 1992). The verbs are categorized into 5 main groups: Intransitive verbs, transitive verbs, ditransitive verbs, complex transitive verbs, and linking verbs. Each code is of the form $Sa_1[.a_2]$ where S is the first letter of the verb categorization ($S \in \{I, T, D, C, L\}$ for the corresponding groups), and $a_1, a_2, \ldots$ are the argument types. If a code contains more than one argument, each argument is listed serially. Possible argument types are n for nouns, f for finite clauses (*that* clauses), g for "-ing" clauses, t for infinitive clauses, w for finite clauses beginning with "-wh", i for bare infinitive clauses, a for adjective phrases, p for prepositions and pr for prepositional phrases.

For example, Tn refers to the verbs followed by a noun ('She read the book'), $Tn.pr$ refers to the verbs followed by a noun and a prepositional phrase ('He opened the door with a latch'), and $Dn.n$ refers to the verbs followed by two nouns ('She taught the children French'). The number of codes in OALD code set is 32 and the codes are listed in Table 1.

OALD codes are simplistic in that they do not include modifiers. In addition, they also do not explicitly specify which prepositions can be used in the PPs.

2.2. Minipar Codes

The Minipar coding scheme is an adaptation of the OALD codes. Minipar extends OALD codes by pro-

Categorization	OALD Codes
Intransitive verbs	{I, Ip, Ipr, In/pr, It}
Transitive verbs	{Tn, Tn.pr, Tn.p, Tf, Tw, Tt, Tg, Tn.t, Tn.g, Tn.i}
Complex Transitive verbs	{Cn.a, Cn.n, Cn.n/a, Cn.t, Cn.g, Cn.i}
Ditransitive verbs	{Dn.n, Dn.pr, Dn.f, Dn.t, Dn.w, Dpr.f, Dpr.w, Dpr.t}
Linking verbs	{La, Ln}

Table 1: OALD Code Set: The Basis of Minipar Codes

viding a facility for specifying prepositions, but only 8 verbs are encoded with these prepositional codes in the official Minipar distribution. In these cases, the codes containing pr are refined to be $pr.prep$, where $prep$ is the head of the PP argument.[3] In addition, Minipar codes are refined in the following ways:

1. Optional arguments are allowed, e.g., $T[n].pr$ describes verbs followed by an optional noun and a PP. This is equivalent to the combination of the OALD codes $Tn.pr$ and Ipr.

2. Two or more codes may be combined, e.g., *Tfgt* describes verbs followed by a clause that is finite, infinitive, or gerundive ("-ing").

3. Prepositions may be specified in prepositional phrases. Some of the codes containing pr as an argument are converted into $pr.prep$ in order to declare that the prepositional phrase can begin with only the specified preposition $prep$.

The set of Minipar codes contain 66 items. We will not list them here since they are very similar to the ones in Table 1, with the modifications described above.

2.3. LDOCE Codes

LDOCE has a more detailed code set than that of OALD (and hence Minipar). The codes include both arguments and modifiers. Moreover, prepositions are richly specified throughout the lexicon. The syntax of the codes is either *CN* or *CN-Prep*, where *C* corresponds to the verb sub-categorization (as in the generic OALD codes) and N is a number, which corresponds to different sets of arguments that can follow the verb. For example, T1-ON refers to verbs that are followed by a noun and a PP with the head *on*. The number of codes included in this set is 179. The meaning of each is described in Table 2.

Number	Arguments
1	one or more nouns
2	bare infinitive clause
3	infinitive clause
4	-ing form
5	-that clause
6	clauses with a wh- word
7	adjective
8	past participle
9	descriptive word or phrase

Table 2: LDOCE Number Description

3. Our Approach

Our goal is evaluate the accuracy and coverage of a parsing lexicon where each verb is classified according to the arguments it takes. We use syntactic patterns as the basis of the comparison between our parsing lexicon and the original lexicon used in Minipar.

Syntactic patterns simply list the type of the arguments one by one, including the subject. Formally, a syntactic pattern is $a_1, a_2, \ldots$ where a_i is an element of NP, AP, PP, FIN, INF, BARE, ING, WH, PREP, corresponding to noun phrases, adjective phrases, prepositional phrases, clauses beginning with "that", infinitive clauses, bare infinitive clauses, "-ing" clauses, "-wh" clauses and prepositions, respectively. Prepositional phrases may be made more specific by including the heads, which is done by PP.$prep$ where $prep$ is the head of the prepositional phrase. The first item in the syntactic pattern gives the type of the subject.

Our initial attempts at comparing the Minipar- and LCS-based lexicons involved the use of the OALD code set instead of syntactic patterns. This approach has two problems, which are closely related. First, using the class number and thematic grids as the basis of mapping from the LCS lexicon to OALD codes is a difficult task because of the high degree of ambiguity. For example, it is hard to choose among four OALD codes (Ln, La, Tn or Ia) for the thematic grid _th_pred, regardless of the Levin class. In general, the grid-to-OALD mapping is so ambiguous that maintaining consistency over the whole LCS lexicon is virtually impossible.

Secondly, even if we are able to find the correct OALD codes, it is not worth the effort because all that is needed for the parsing lexicon is the type and number of arguments that can follow the verb. For example, $Cn.n$ (as in *"appoint him king"*) and $Dn.n$ (as in *"give him a book"*) both correspond to two

[3] This extension is used only for the preposition *as* for the verbs *absolve, accept, acclaim, brand, designate, disguise, fancy,* and *reckon*.

NPs, but the second NP is a direct object in the former case and an indirect object in the latter. Since the parser relies ultimately on syntactic patterns, not codes, we can eliminate this redundancy by mapping any verb in either of these two categories directly into the [NP.NP.NP] pattern. Thus, using syntactic patterns is sufficient for our purposes.

Our experiments revealed additional flexibility in using syntactic patterns. Unlike the OALD codes (which contain at most two arguments or modifiers), the thematic grids consist of up to 4 modifiers. Mapping onto syntactic patterns instead of onto OALD codes allows us to use all arguments in the thematic grids. For example, [NP.NP.PP.from.PP.to] is an example of transitive verb with two prepositional phrases, one beginning with *from* and the other beginning with *to*, as in *"She drove the kids from home to school."*

In the following subsections, we will examine the mapping into these syntactic patterns from: (1) the LCS lexicon; (2) the Minipar codes; and (3) the LDOCE codes.

3.1. Mapping from the LCS Lexicon to Syntactic Patterns

The LCS lexicon consists of verbs grouped into classes based on an adapted version of verb classes (Levin, 1993) along with the thematic grid representations (see (Dorr, 1993; Dorr, 2001)). We automatically assigned syntactic patterns for each verb in the LCS lexicon using its semantic class number and thematic grid. The syntactic patterns we used in our mapping specify prepositions for entries that require them. For example, the grid _ag_th_instr(with) is mapped onto [NP.NP.PP.with] instead of a generic pattern [NP.NP.PP].

More generally, thematic grids contain a list of arguments and modifiers, and they can be obligatory (indicated by an underscore before the role) or optional(indicated by a comma before the role). The arguments can be one of AG, EXP, TH, SRC, GOAL, INFO, PERC, PRED, LOC, POSS, TIME, and PROP. The logical modifiers can be one of MOD-POSS, BEN, INSTR, PURP, MOD-LOC, MANNER, MOD-PRED, MOD-PERC and MOD-PROP. If the argument or the modifier is followed by parenthesis, the corresponding element is a prepositional phrase and its head must be the one specified between the parentheses (if there is nothing between parentheses, PP can begin with any preposition).

Our purpose is to find the set of syntactic patterns for each verb in LCS lexicon using its Levin class and thematic grid. Since each verb can be in many classes and we aim at assigning syntactic patterns based on the semantic classes and thematic grids, there are three possible mapping methodologies:

1. Assign one or more patterns to each class.
2. Assign one or more patterns to each thematic grid.
3. Assign one or more patterns to each pair of class and thematic grid.

The first methodology fails for some classes because the distribution of syntactic patterns over a specific class is not uniform. In other words, attempting to assign only a set of patterns to each class introduces errors because some classes are associated with more than one syntactic frame. For example, class 51.1.d includes three thematic grids: (1) _th,src; (2) _th,src(from); and (3) _th,src(),goal(). We can either assign all patterns for all of these thematic grids to this class or we can choose the most common one. However, both of these approaches introduce errors: The first will generate redundant patterns and the second will assign incorrect patterns to some verbs. (This occurs because, within a class, thematic grids may vary with respect to their optional arguments or the prepositional head associated with arguments or modifiers.)

The second methodology also fails to provide an appropriate mapping. The problem is that some thematic grids correspond to different syntactic patterns in different classes. For example, the thematic grid _th_prop corresponds to 3 different syntactic patterns: (1) [NP.NP] in class 024 and 55.2.a; (2) [NP.ING] in classes 066, 52.b, and 55.2.b; and (3) [NP.INF] in class 005. Although the thematic grid is the same in all of these classes, the syntactic patterns are different.

The final methodology circumvents the two issues presented above (i.e., more than one grid per class and more than one syntactic frame per thematic grid) as follows: If a thematic grid contains an optional argument, we create two mappings for that grid, one in which the optional argument is treated as if it were not there and one in which the argument is obligatory. For example, _ag_th,goal() is mapped onto two patterns [NP.NP] and [NP.NP.PP]. If the number of optional arguments is X, then the maximum number of syntactic patterns for that grid is 2^X (or perhaps smaller than 2^X since some of the patterns may be identical).

Using this methodology, we found the correct mapping for each class and thematic grid pair by examining the verbs in that class and considering all possible syntactic patterns for that pair. This is a many-to-many mapping, i.e. one pattern can be used for different

OALD Code	Syntactic Patterns
I	[NP]
Tn	[NP.NP]
T[n].pr	[NP.NP] and [NP.NP.PP]
Cn.a	[NP.NP.AP]
Cn.n	[NP.NP.NP]
Cn.n/a	[NP.NP.PP.as]
Cn.i	[NP.NP.BARE]
Dn.n	[NP.NP.NP]

T5	[NP.FIN]
D1	[NP.NP.NP]
D3	[NP.NP.INF]
V4	[NP.NP.ING]

Table 4: Mapping From LDOCE to Syntactic Patterns

pairs and each pair may be associated with more than one pattern. Each verb in each class is assigned the corresponding syntactic patterns according to its thematic grid. Finally, for each verb, we combined all patterns in all classes containing this particular verb in order to generate the lexicon. We will refer to the resulting lexicon as the LCS-based lexicon in Section 4..

3.2. Mapping from Minipar Codes To Syntactic Patterns

Minipar codes are converted straightforwardly into syntactic patterns using the code specification in (Mitten, 1992). An excerpt of the mapping is given in Table 3. This mapping is one-to-many as exemplified by the code $T[n].pr$. Moreover, the set of syntactic patterns extracted from Minipar does not include some patterns such as [NP.PP] (and related patterns) because Minipar does not include modifiers in its code set.

As a result of this mapping, we produced a new lexicon from Minipar entries, where each verb is listed along with the set of syntactic patterns. We will refer to this lexicon as the Minipar-based lexicon in Section 4..

3.3. Mapping from LDOCE Codes to Syntactic Patterns

Similar to the mapping from Minipar to the syntactic patterns, we converted LDOCE codes to syntactic patterns using the code specification in (Procter, 1978). An excerpt of the mapping is given in Table 4.

Each LDOCE code was mapped manually to one or more patterns. LDOCE codes are more refined than the generic OALD codes, but mapping each to syntactic patterns provides an equivalent mediating representation for comparison. For example, LDOCE codes D1-AT and T1-AT are mapped onto [NP.NP.PP.at] by our mapping technique. Again, this is a many-to-many mapping but only a small set of LDOCE codes map to more than one syntactic pattern.

As a result of this mapping, we produced a new lexicon from LDOCE entries, similar to Minipar lexicon. We will refer to this lexicon as the LDOCE-based lexicon in Section 4..

4. Experiments and Results

To measure the effectiveness of our mapping from LCS entries to syntactic patterns, we compared the precision and recall our derived LCS-based syntactic patterns with the precision and recall of Minipar-based syntactic patterns, using LDOCE-based syntactic patterns as our "gold standard".

Each of the three lexicons contains verbs along with their associated syntactic patterns. For experimental purposes, we convert these into pairs. Formally, if a verb v is listed with the patterns $p_1, p_2, \ldots$, we create pairs (v, p_1), (v, p_2) and so on. In addition, we have made the following adjustments to the lexicons, where L is the lexicon under consideration (Minipar or LCS):

1. Given that the number of verbs in each of the two lexicons is different and that neither one completely covers the other, we take only those verbs that occur in both L and LDOCE, for each L, while measuring precision and recall.

2. In the LDOCE- and Minipar-based lexicons, the number of arguments is never greater than 2. Thus, for a fair comparison, we converted the LCS-based lexicon into the same format. For this purpose, we simply omit the arguments after the second one if the pattern contains more than two arguments/modifiers.

3. The prepositions are not specified in Minipar-based lexicon. Thus, we ignore the heads of the prepositions in LCS-based lexicon, i.e., if the pattern includes [PP.$prep$] we take it as a [PP].

Precision and recall are based on the following inputs:

A = Number of pairs in L occurring in LDOCE
B = Number of pairs in L NOT occurring in LDOCE
C = Number of pairs in LDOCE NOT occurring in L

That is, given a syntactic pattern encoded lexicon L, we compute:

(1) The *precision* of $L = \frac{A}{A+B}$;
(2) The *recall* of $L = \frac{A}{A+C}$.

Verbs fetched completely	3002	1875
Precision	80%	81%
Recall	68%	67%

Table 6: Experiments on Minipar-based Lexicon

We compare two results: one where L is the Minipar-based lexicon and one where L is the LCS-based lexicon. Table 5 gives the number of verbs used in the LCS-based lexicon and the LDOCE-based lexicon, showing the precision and recall. The row showing the number of verbs fetched completely gives the number of verbs in the LCS lexicon which contains all the patterns in the LDOCE entry for the same verb. Both the precision and the recall for LCS-based lexicon with the manually-crafted mapping is 61%.

We did the same experiment for the Minipar-based lexicon in two different ways, first with all the verbs in the Minipar lexicon and then with only the verbs occurring in both the LCS and Minipar lexicons. The second approach is useful for a direct comparison between the Minipar- and LCS-based lexicons. As before, we used the LDOCE-based lexicon as our gold standard. The results are shown in Table 6. The definitions of entries are the same as in Table 5.

The number of Minipar verbs in Minipar occurring in the LCS lexicon is different from the total number of LCS verbs because some LCS verbs (266 of them) do not appear in Minipar lexicon. The results indicate that the Minipar-based lexicon yields much better precision, with an improvement of nearly 25% over the LCS-based lexicon. The recall is low because Minipar does not take modifiers into account most of the time. This results in missing nearly all patterns with PPs, such as [NP.PP] and [NP.NP.PP]. However, the recall achieved is 6% more than the recall for the LCS-based lexicon.

Verbs in LDOCE Lexicon	5648

Verbs fetched completely	1265
Precision	91%
Recall	50%

Table 7: Experiment on Intersection Lexicon

Finally, we conducted an experiment to see how the intersection of the Minipar and LCS lexicons compares to the LDOCE-based lexicon. For this experiment, we included only the verbs and patterns occurring in both lexicons. The results are shown in Table 7 in a format similar to previous tables.

The number of common verbs differs from the previous ones because we omit the verbs which do not have any patterns across the two lexicons. The results are not surprising: High precision is achieved because only those patterns that occur in both lexicons are included in the intersection lexicon; thus, the total number of pairs is reduced significantly. For the same reason, the recall is significantly reduced.

The highest precision is achieved by the intersection of two lexicons, but at the expense of recall. We found that the precision was higher for Minipar than for the LCS lexicon, but when we examined this in more detail, we found that this was almost entirely due to "double counting" of entries with optional modifiers in the LCS-based lexicon. For example, the single LCS-based grid _ag_th,instr(with) corresponds to two syntactic patterns, [NP.NP] and [NP.NP.PP], while LDOCE views these as the single pattern [NP.NP]. Specifically, 53% of the non-matching LCS-based patterns are [NP.NP.PP]—and 93% of these co-occur with [NP.NP]. Similarly, 13% of the non-matching LCS-based patterns are pattern [NP.PP]—and 80% of these co-occur with [NP].

This is a significant finding, as it reveals that our precision is spuriously low in our comparison with the "gold standard." In effect, we should be counting the LCS-based pattern [NP.NP.PP]/[NP.NP] to be a match against the LDOCE-based pattern [NP.NP]—which is a fairer comparison since neither LDOCE nor Minipar takes modifiers into account. (We henceforth refer to LCS-based the co-occurring patterns

	Minipar Lexicon (All verbs in Minipar Lexicon)	Minipar Lexicon (Common verbs with LCS Lexicon)	LCS Lexicon	Intersection of Minipar and LCS Lexicons
Precision	80%	81%	61%	91%
Enhanced Precision	81%	82%	80%	91%
Recall	68%	67%	61%	50%

Table 8: Precision and Recall Summary: Minipar- and LCS-based Lexicons

[NP.NP.PP]/[NP.NP] and [NP.PP]/[NP] as overlapping pairs.) To observe the degree of the impact of optional modifiers, we computed another precision value for the LCS-based lexicon by counting overlapping patterns once instead of twice. With this methodology, we achieved 80% (enhanced) precision. This precision value is nearly same as the value achieved with the current Minipar lexicon. Table 8 summarizes all results in terms of precision and recall.

The enhanced precision is an important and accurate indicator of the effectiveness of our approach, given that overlapping patterns arise because of (optional) modifiers. When we ignore those modifiers during our mapping process, we achieve nearly the same precision and recall with the current Minipar lexicon, which also ignores the modifiers in its code set. Moreover, overlapping patterns in our LCS-based lexicon do not affect the performance of the parser, other than to induce a more sophisticated handling of modifiers (which presumably would increase the precision numbers, if we had access to a "gold standard" that includes modifiers). For example, Minipar attaches modifiers at the clausal level instead of at the verbal level even in cases where the modifier is obviously verbal—as it would be in the LCS-based version of the parse in the sentence *She rolled the dough [PP into cookie shapes]*.

5. Ongoing Work: Automatic Generation of Syntactic Patterns

The lexicon derived from the hand-crafted mapping between the LCS lexicon and the syntactic patterns is comparable to the current Minipar lexicon. However, the mapping required a great deal of human effort, since each semantic verb class must be examined by hand in order to identify appropriate syntactic patterns. The process is error-prone, laborious, and time-intensive (approximately 3-4 person-months). Moreover, it requires that the mapping be done again by a human every time the LCS lexicon is updated.

In a recent experiment, we developed an automated mapping (in 2 person-weeks) that takes into account both semantic roles and some additional features stored in the LCS database, without reference to the class number. The mapping is based primarily on the thematic role, however in some situations the thematic roles themselves are not sufficient to determine the type of the argument. In such cases, the correct form is assigned using featural information associated with that specific verb in the LCS database.

Table 10 summarizes the automated mapping rules. The thematic role "prop" is an example of a case where featural information is necessary (e.g., (cform inf)), as there are five different patterns to choose from for this thematic role. Similarly, whether a "pred" role is an NP or AP is determined by featural information. For example, this role becomes an AP for the verb $behave$ in class 29.6.a while it is mapped onto an NP for the verb $carry$ in class 54.2. In the cases where the syntactic pattern is ambiguous and there is no specification for the verbs, default values are used for the mapping: BARE for "prop", AP for "pred" and NP for "perc".

Syntactic patterns for each thematic grid are computed by combining the results of the mapping from each thematic role in the grid to a syntactic pattern, one after another. If the grid includes optional roles, every possibility is explored and the syntactic patterns for each of them is included in the whole list of patterns for that grid. For example, the syntactic patterns for _ag_th,instr(with) include the patterns for both _ag_th and _ag_th_instr(with), which are [NP.NP] and [NP.NP.PP.with].

Note that this approach eliminates the need for using the same syntactic patterns for all verbs in a specific class: Verbs in the same class can be assigned different syntactic patterns with the help of additional features in the database. Thus, we need not rely on the semantic class number at all during this mapping. We can easily update the resulting lexicons when there is any change on the semantic classes or thematic grids of some verbs.

This experiment resulted in a parsing lexicon that has virtually the same precision/recall as that of the manually generated LCS-based lexicon above. (See Table 9.) As in the case of the manually generated mappings, the enhanced precision is 80%, which is

Verbs in LDOCE Lexicon	5648

only 1-2% lower than that of the current Minipar-based lexicon.

Our approach demonstrates that examination of thematic-role and featural information in the LCS-based lexicon is sufficient for executing this mapping automatically. Automating our approach gives us the flexibility of re-running the program if the structure of the database changes (e.g., an LCS representation is modified or class membership changes) and of porting to a new language with minimal effort.

6. Discussion

In all experiments reported above, both the LCS- and Minipar-based lexicons yield low recall values. Upon further investigation, we found that LDOCE is too specific in assigning codes to verbs. Most of the patterns associated with the verbs are rare—cases not considered in the LCS- and Minipar-based lexicons. Because of that, we believe that the recall values will improve if we take only a subset of LDOCE-based lexicon, e.g., those associated with the most frequent verb-pattern pairs in a large corpus. This is a future research direction considered in the next section.

The knowledgeable reader may question the mapping of a Levin-style lexicon into syntactic codes, given that Levin's original proposal is to investigate verb meaning through examination of syntactic patterns, or *alternations*, in the first place. As alluded to in Section 1., there are several ways in which this database has become more than just a "semantified" version of a syntactic framework; we elaborate on this further here.

Levin's original framework omitted a large number of verbs—and verb senses for existing Levin verbs—which we added to the database by semi-automatic techniques. Her original framework contained 3024 verbs in 192 classes numbering between 9.1 and 57—a total of 4186 verb entries. These were grouped together primarily by means of syntactic alternations. Our augmented database contains 4432 verbs in 492 classes with more specific numbering (e.g., "51.3.2.a.ii") including additional class numbers for new classes that Levin did not include in her work (between 000 and 026)—a total of 9844 verb entries. These were categorized according to semantic information (using WordNet synsets coupled with syntactic filtering) (Dorr, 1997)—not syntactic alternations.

An example of an entry that we added to the database is the verb *oblige*. We have assigned a semantic representation and thematic grid to this verb, creating a new class 002—which we call *Coerce Verbs*—corresponding to verbs whose underlying meaning corresponds to "force to act". Because Levin's repository omits verbs taking clausal complements, several other verbs with a similar meaning fell into this class (e.g., *coerce*, *compel*, *persuade*) including some that were already included in the original system, but not in this class (e.g., *ask*). Thus, the LCS Database contains 50% more verbs and twice as many verb entries since the original framework of Levin. The result is that we can now parse constructions such as *She compelled him to eat* and *She asked him to eat*, which would not have been analyzable had we compiled our parsing lexicon on the basis of Levin's

classes alone.

Levin's original proposal also does not contain semantic representations or thematic grids. When we built the LCS database, we examined each verb class carefully by hand to determine the underlying components of meaning unifying the members of that class. For example, the LCS representation that we generated for verbs in the *put* class includes components of meaning corresponding to "spatial placement in some manner," thus covering *dangle*, *hang*, *suspend*, etc.

From these hand-generated LCS representations, we derived our thematic grids—the same ones that are mapped onto our syntactic patterns. For example, position 1 (the highest leftmost argument in the LCS) is always mapped into the agent role of the thematic grid. The grids are organized into a thematic hierarchy that provides the basis for determining argument assignments, thus enhancing the generation process in ways that could not have been done previously with Levin's classes alone—e.g., producing constructions like *John sent a book to Paul* instead of constructions like *The book sent John to Paul*. Although the value of the thematic hierarchy seems most relevant to generation, the overall semantic/thematic hierarchical organization enables the automatic construction of lexicons that are equally suitable for both parsing and generation, thus reducing our overall lexical acquisition effort for both processes.

Beyond the above considerations, the granularity of the original Levin framework also was not adequate for our interlingual MT and lexical acquisition efforts. Our augmented form of this repository has brought about a more refined classification in which we are able to accommodate aspectual distinctions. We encode knowledge about aspectual features (e.g., *telicity*) in our LCS representations, thus sub-dividing the classes into more specific sub-classes. The tests used for this sub-division are purely *semantic* in nature, not syntactic. An example is the Dowty-style test "*He was X-ing* entails *He has X-ed*" (Dowty, 1979), where X is atelic (as in *run*) only if this entailment is considered valid by a human—and telic otherwise (as in *win*).

The inclusion of this type of knowledge allows us to refine Levin's classification significantly. An example is Class 35.6—*Ferret Verbs*: In Levin's original framework, this class conflated verbs occurring in different aspectual categories. Using the semantic tests above, we found that, in fact, these verbs should be divided as follows (Olsen et al., 1997):

Ferret Verbs: nose ferret tease (telic); seek (atelic)

The implication of this division for parsing is that the verbal arguments are constrained in a way that was not available to us in the original Levin-style classification—thus easing the job of the parser in choosing attachment points:

Telic:

∗He ferreted the truth from him.

He ferreted the truth out of him

Atelic:

He sought the truth from him.

∗He sought the truth out of him

Finally, Levin makes no claims as to the applicability of the English classes to other languages. Orienting our LCS database more toward semantic (aspectual) features rather than syntactic alternations has brought us closer to an interlingual representation that has now been demonstrably ported (quickly) to multiple languages including Arabic, Chinese, and Spanish. For example, telicity has been shown to be a crucial deciding feature in translating between divergence languages (Olsen et al., 1998), as in the translation of English *run across* as Spanish *cruzar corriendo*.

To summarize, our work is intended to: (1) Investigate the realization of a parsing lexicon from an LCS database that has developed from extensive semantic enhancements to an existing framework of verb classes and (2) Automate this technique so that it is directly applicable to LCS databases in other languages.

7. Future Work and Conclusions

Our ongoing work involves the following:

1. Using a subset of LDOCE-based lexicon by taking only the most frequent verb-pattern pairs in a big corpus: We expect that this approach will produce more realistic recall values.

2. Creating parsing lexicons for different languages: Once we have an automated mapping from the semantic lexicon to the set of syntactic patterns, we can use this method to create parsing lexicons from semantic lexicons that we already have available in other languages (Chinese, Spanish and Arabic).

3. Integration of these parsing lexicons in ongoing machine translation work (Habash and Dorr, 2001): We will feed the created lexicons into a parser and examine how successful the lexicons are. The same lexicons will also be used in our current clustering project.

Some of the ideas mentioned above are explored in detail in (Ayan and Dorr, 2002).

We conclude that it is possible to produce a parsing lexicon by projecting from LCS-based lexical entries—achieving precision and recall on a par with

a syntactic lexicon (Minipar) encoded by hand specifically for English. The consequence of this result is that, as semantic lexicons become increasingly available for multiple languages (ours are now available in English, Chinese, and Arabic), we are able to produce parsing lexicons automatically for each language.

Abstract

We discuss work in progress in the semi-automatic generation of *thematic lexicons* by means of *term categorization*, a novel task employing techniques from information retrieval (IR) and machine learning (ML). Specifically, we view the generation of such lexicons as an iterative process of learning previously unknown associations between terms and *themes* (i.e. disciplines, or fields of activity). The process is iterative, in that it generates, for each c_i in a set $C = \{c_1, \ldots, c_m\}$ of themes, a sequence $L_0^i \subseteq L_1^i \subseteq \ldots \subseteq L_n^i$ of lexicons, bootstrapping from an initial lexicon L_0^i and a set of text corpora $\Theta = \{\theta_0, \ldots, \theta_{n-1}\}$ given as input. The method is inspired by *text categorization*, the discipline concerned with labelling natural language texts with labels from a predefined set of themes, or categories. However, while text categorization deals with documents represented as vectors in a space of terms, we formulate the task of term categorization as one in which terms are (dually) represented as vectors in a space of documents, and in which terms (instead of documents) are labelled with themes. As a learning device, we adopt *boosting*, since (a) it has demonstrated state-of-the-art effectiveness in a variety of text categorization applications, and (b) it naturally allows for a form of "data cleaning", thereby making the process of generating a thematic lexicon an iteration of generate-and-test steps.

1. Introduction

The generation of *thematic lexicons* (i.e. lexicons consisting of specialized terms, all pertaining to a given theme or discipline) is a task of increased applicative interest, since such lexicons are of the utmost importance in a variety of tasks pertaining to natural language processing and information access.

One of these tasks is to support text search and other information retrieval applications in the context of thematic, "vertical" portals (aka *vortals*)[1]. Vortals are a recent phenomenon in the World Wide Web, and have grown out of the users' needs for directories, services and information resources that are both rich in information and specific to their interests. This has led to Web sites that specialize in aggregating market-specific, "vertical" content and information. Actually, the evolution from the generic portals of the previous generation (such as Yahoo!) to today's vertical portals is just natural, and is no different from the evolution that the publishing industry has witnessed decades ago with the creation of specialized magazines, targeting specific categories of readers with specific needs. To read about the newest developments in ski construction technology, skiers read specialty magazines about skiing, and not generic newspapers, and skiing magazines is also where advertisers striving to target skiers place their ads in order to be the most effective. Vertical portals are the future of commerce and information seeking on the Internet, and supporting sophisticated information access capabilities by means of thematic lexical resources is thus of the utmost importance.

Unfortunately, the generation of thematic lexicons is expensive, since it requires the intervention of specialized manpower, i.e. lexicographers and domain experts working together. Besides being expensive, such a manual approach does not allow for fast response to rapidly emerging needs. In an era of frantic technical progress new disciplines emerge quickly, while others disappear as quickly; and in an era of evolving consumer needs, the same goes for new market niches. There is thus a need of cheaper and faster methods for answering application needs than manual lexicon generation. Also, as noted in (Riloff and Shepherd, 1999), the manual approach is prone to errors of omission, in that a lexicographer may easily overlook infrequent, non-obvious terms that are nonetheless important for many tasks.

Many applications also require that the lexicons be not only thematic, but also tailored to the specific data tackled in the application. For instance, in query expansion (automatic (Peat and Willett, 1991) or interactive (Sebastiani, 1999)) for information retrieval systems addressing thematic document collections, terms synonymous or quasi-synonymous to the query terms are added to the query in order to retrieve more documents. In this case, the added terms should occur in the document collection, otherwise they are useless, and the relevant terms which occur in the document collection should potentially be added. That is, for this application the ideal thematic lexicon should contain all and only the technical terms present in the document

[1]See e.g. `http://www.verticalportals.com/`

collection under consideration, and should thus be generated directly from this latter.

1.1. Our proposal

In this paper we propose a methodology for the semi-automatic generation of thematic lexicons from a corpus of texts. This methodology relies on *term categorization*, a novel task that employs a combination of techniques from information retrieval (IR) and machine learning (ML). Specifically, we view the generation of such lexicons as an iterative process of learning previously unknown associations between terms and *themes* (i.e. disciplines, or fields of activity)[2]. The process is iterative, in that it generates, for each c_i in a set $C = \{c_1, \ldots, c_m\}$ of predefined themes, a sequence $L_0^i \subseteq L_1^i \subseteq \ldots \subseteq L_n^i$ of lexicons, bootstrapping from a lexicon L_0^i given as input. Associations between terms and themes are learnt from a sequence $\Theta = \{\theta_0, \ldots, \theta_{n-1}\}$ of sets of documents (hereafter called *corpora*); this allows to enlarge the lexicon as new corpora from which to learn become available. At iteration y, the process builds the lexicons $L_{y+1} = \{L_{y+1}^1, \ldots, L_{y+1}^m\}$ for all the themes $C = \{c_1, \ldots, c_m\}$ in parallel, from the same corpus θ_y. The only requirement on θ_y is that at least some of the terms in each of the lexicons in $L_y = \{L_y^1, \ldots, L_y^m\}$ should occur in it (if none among the terms in a lexicon L_y^j occurs in θ_y, then no new term is added to L_y^j in iteration y).

The method we propose is inspired by *text categorization*, the activity of automatically building, by means of machine learning techniques, *automatic text classifiers*, i.e. programs capable of labelling natural language texts with (zero, one, or several) thematic categories from a predefined set $C = \{c_1, \ldots, c_m\}$ (Sebastiani, 2002). The construction of an automatic text classifier requires the availability of a corpus $\psi = \{\langle d_1, C_1\rangle, \ldots, \langle d_h, C_h\rangle\}$ of preclassified documents, where a pair $\langle d_j, C_j\rangle$ indicates that document d_j belongs to all and only the categories in $C_j \subseteq C$. A general inductive process (called the *learner*) automatically builds a classifier for the set C by learning the characteristics of C from a *training set* $Tr = \{\langle d_1, C_1\rangle, \ldots, \langle d_g, C_g\rangle\} \subset \psi$ of documents. Once a classifier has been built, its effectiveness (i.e. its capability to take the right categorization decisions) may be tested by applying it to the *test set* $Te = \{\langle d_{g+1}, C_{g+1}\rangle, \ldots, \langle d_h, C_h\rangle\} = \psi - Tr$ and checking the degree of correspondence between the decisions of the automatic classifier and those encoded in the corpus.

While the purpose of text categorization is that of classifying documents represented as vectors in a space of terms, the purpose of term categorization, as we formulate it, is (dually) that of classifying terms represented as vectors in a space of documents. In this task terms are thus items that may belong, and must thus be assigned, to (zero, one, or several) themes belonging to a predefined set. In other words, starting from a set Γ_y^i of preclassified terms, a new set of terms Γ_{y+1}^i is classified, and the terms in Γ_{y+1}^i which are deemed to belong to c_i are added to L_y^i to yield L_{y+1}^i. The set Γ_y^i is composed of lexicon L_y^i, acting as the set of "positive examples", plus a set of terms known not to belong to c_i, acting as the set of "negative examples".

For input to the learning device and to the term classifiers that this will eventually build, we use "bag of documents" representations for terms (Salton and McGill, 1983, pages 78–81), dual to the "bag of terms" representations commonly used in text categorization.

As the learning device we adopt ADABOOST.MH^{KR} (Sebastiani et al., 2000), a more efficient variant of the ADABOOST.MH^{R} algorithm proposed in (Schapire and Singer, 2000). Both algorithms are an implementation of *boosting*, a method for supervised learning which has successfully been applied to many different domains and which has proven one of the best performers in text categorization applications so far. Boosting is based on the idea of relying on the collective judgment of a committee of classifiers that are trained sequentially; in training the k-th classifier special emphasis is placed on the correct categorization of the training examples which have proven harder for (i.e. have been misclassified more frequently by) the previously trained classifiers.

We have chosen a boosting approach not only because of its state-of-the-art effectiveness, but also because it naturally allows for a form of "data cleaning", which is useful in case a lexicographer wants to check the results and edit the newly generated lexicon. That is, in our term categorization context it allows the lexicographer to easily inspect the classified terms for possible misclassifications, since at each iteration y the algorithm, apart from generating the new lexicon L_{y+1}^i, ranks the terms in L_y^i in terms of their "hardness", i.e. how successful have been the generated classifiers at correctly recognizing their label. Since the highest ranked terms are the ones with the highest probability of having been misclassified in the previous iteration (Abney et al., 1999), the lexicographer can examine this list starting from the top and stopping where desired, removing the misclassified examples. The process of generating a thematic lexicon then becomes an iteration of generate-and-test steps.

This paper is organized as follows. In Section 2. we describe how we represent terms by means of a "bag of documents" representation.. For reasons of space we do not describe ADABOOST.MH^{KR}, the boosting algorithm we employ for term classification; see the extended paper for details (Lavelli et al., 2002). Section 3.1. discusses how to combine the indexing tools introduced in Section 2. with the boosting algorithm, and describes the role of the lexicographer in the iterative generate-and-test cycle. Section 3.2. describes the results of our preliminary experiments. In Section 4. we review related work on the automated generation of lexical resources, and spell out the differences between our and existing approaches. Section 5. concludes, pointing to avenues for improvement.

[2] We want to point out that our use of the word "term" is somehow different from the one often used in natural language processing and terminology extraction (Kageura and Umino, 1996), where it often denotes a *sequence* of lexical units expressing a concept of the domain of interest. Here we use this word in a neutral sense, i.e. without making any commitment as to its consisting of a single word or a sequence of words.

2. Representing terms in a space of documents

2.1. Text indexing

In text categorization applications, the process of building internal representations of texts is called *text indexing*. In text indexing, a document d_j is usually represented as a vector of term *weights* $\vec{d_j} = \langle w_{1j}, \ldots, w_{rj} \rangle$, where r is the cardinality of the *dictionary* and $0 \leq w_{kj} \leq 1$ represents, loosely speaking, the contribution of t_k to the specification of the semantics of d_j. Usually, the dictionary is equated with the set of *terms* that occur at least once in at least α documents of Tr (with α a predefined threshold, typically ranging between 1 and 5).

Different approaches to text indexing may result from different choices (i) as to what a term is and (ii) as to how term weights should be computed. A frequent choice for (i) is to use single words (minus stop words, which are usually removed prior to indexing) or their stems, although some researchers additionally consider noun phrases (Lewis, 1992) or "bigrams" (Caropreso et al., 2001). Different "weighting" functions may be used for tackling issue (ii), either of a probabilistic or of a statistical nature; a frequent choice is the *normalized* $tfidf$ function (see e.g. (Salton and Buckley, 1988)), which provides the inspiration for our "term indexing" methodology spelled out in Section 2.2..

2.2. Abstract indexing and term indexing

Text indexing may be viewed as a particular instance of *abstract indexing*, a task in which abstract objects are represented by means of abstract features, and whose underlying metaphor is, by and large, that the semantics of an object corresponds to the *bag of features* that "occur" in it[3]. In order to illustrate abstract indexing, let us define a *token* τ to be a specific occurrence of a given feature $f(\tau)$ in a given object $o(\tau)$, let T be the set of all tokens occurring in any of a set of objects O, and let F be the set of features of which the tokens in T are instances. Let us define the *feature frequency* $ff(f_k, o_j)$ of a feature f_k in an object o_j as

$$ff(f_k, o_j) = |\{\tau \in T \mid f(\tau) = f_k \ \wedge \ o(\tau) = o_j\}| \quad (1)$$

We next define the *inverted object frequency* $iof(f_k)$ of a feature f_k as

$$iof(f_k) = \quad (2)$$
$$= \log \frac{|O|}{|\{o_j \in O \mid \exists \tau \in T : f(\tau) = f_k \ \wedge \ o(\tau) = o_j\}|}$$

and the *weight* $w(f_k, o_j)$ of feature f_k in object o_j as

$$w_{kj} = w(f_k, o_j) = \quad (3)$$
$$= \frac{ff(f_k, o_j) \cdot iof(f_k)}{\sqrt{\sum_{s=1}^{|F|} (ff(f_s, o_j) \cdot iof(f_s))^2}}$$

We may consider the $w(f_k, o_j)$ function of Equation (3) as an *abstract indexing function*; that is, different instances of this function are obtained by specifying different choices for the set of objects O and set of features F.

The well-known text indexing function $tfidf$, mentioned in Section 2.1., is obtained by equating O with the training set of documents and F with the dictionary; T, the set of occurrences of elements of F in the elements of O, thus becomes the set of term occurrences.

Dually, a term indexing function may be obtained by switching the roles of F and O, i.e. equating F with the training set of documents and O with the dictionary; T, the set of occurrences of elements of F in the elements of O, is thus again the set of term occurrences (Schäuble and Knaus, 1992; Sheridan et al., 1997).

It is interesting to discuss the kind of intuitions that Equations (1), (2) and (3) embody in the dual cases of text indexing and term indexing:

- Equation (1) suggests that when a feature occurs multiple times in an object, the feature characterizes the object to a higher degree. In text indexing, this indicates that the more often a term occurs in a document, the more it is representative of its content. In term indexing, this indicates that the more often a term occurs in a document, the more the document is representative of the content of the term.
- Equation (2) suggests that the fewer the objects a feature occurs in, the more representative it is of the content of the objects in which it occurs. In text indexing, this means that terms that occur in too many documents are not very useful for identifying the content of documents. In term indexing, this means that the more terms a document contains (i.e. the longer it is), the less useful it is for characterizing the semantics of a term it contains.
- The intuition ("length normalization") that supports Equation (3) is that weights computed by means of $ff(f_k, o_j) \cdot iof(f_k)$ need to be normalized in order to prevent "longer objects" (i.e. ones in which many features occur) to emerge (e.g. to be scored higher in document-document similarity computations) just because of their length and not because of their content. In text indexing, this means that longer documents need to be deemphasized. In term indexing, this means instead that terms that occur in many documents need to be deemphasized[4].

It is also interesting to note that any program or data structure that implements $tfidf$ for text indexing may be used straightaway, with no modification, for term indexing: one needs only to feed the program with the terms in place of the documents and viceversa.

[3] "Bag" is used here in its set-theoretic meaning, as a synonym of *multiset*, i.e. a set in which the same element may occur several times. In text indexing, adopting a "bag of words" model means assuming that the number of times that a given word occurs in the same document is semantically significant. "Set of words" models, in which this number is assumed not significant, are thus particular instances of bag of words models.

[4] Incidentally, it is interesting to note that in switching from text indexing to term indexing, Equations (2) and (3) switch their roles: the intuition that terms occurring in many documents should be deemphasized is implemented in Equation (2) in text indexing and Equation (3) in term indexing, while the intuition that longer documents need to be deemphasized is implemented in Equation (3) in text indexing and Equation (2) in term indexing.

3. Generating thematic lexicons by bootstrapping and learning

3.1. Operational methodology

We are now ready to describe the overall process that we will follow for the generation of thematic lexicons. The process is iterative: we here describe the y-th iteration. We start from a set of thematic lexicons $L_y = \{L_y^1, \ldots, L_y^m\}$, one for each theme in $C = \{c_1, \ldots, c_m\}$, and from a corpus θ_y. We index the terms that occur in θ_y by means of the term indexing technique described in Section 2.2.; this yields, for each term t_k, a representation consisting of a vector of weighted documents, the length of the vector being $r = |\theta_y|$.

By using $L_y = \{L_y^1, \ldots, L_y^m\}$ as a training set, we then generate m classifiers $\Phi_y = \{\Phi_y^1, \ldots, \Phi_y^m\}$ by applying the ADABOOST.MH^{KR} algorithm. While generating the classifiers, ADABOOST.MH^{KR} also produces, for each theme c_i, a ranking of the terms in L_y^i in terms of how hard it was for the generated classifiers to classify them correctly, which basically corresponds to their probability of being misclassified examples. The lexicographer can then, if desired, inspect L_y and remove the misclassified examples, if any (possibly rerunning, especially if these latter were a substantial number, ADABOOST.MH^{KR} on the "cleaned" version of L_y). At this point, the terms occurring in θ_y that ADABOOST.MH^{KR} has classified under c_i are added (possibly, after being checked by the lexicographer) to L_y^i, yielding L_{y+1}^i. Iteration $y+1$ can then take place, and the process is repeated again.

Note that an alternative approach is to involve the lexicographer only after the last iteration, and not after each iteration. For instance, Riloff and Shepherd (Riloff and Shepherd, 1999) perform several iterations, at each of which they add to the training set (without human intervention) the new items that have been attributed to the category with the highest confidence. After the last iteration, a lexicographer inspects the list of added terms and decides which one to remove, if any. This latter approach has the advantage of requiring the intervention of the lexicographer only once, but has the disadvantage that spurious terms added to lexicon at early iterations can cause, if not promptly removed, new spurious ones to be added in the next iterations, thereby generating a domino effect.

3.2. Experimental methodology

The process we have described in Section 3.1. is the one that we would apply in an operational setting. In an experimental setting, instead, we are also interested in evaluating the effectiveness of our approach on a benchmark. The difference with the process outlined in Section 3.1. is that at the beginning of the process the lexicon L_y is split into a training set and a test set; the classifiers are learnt from the training set, and are then tested on the test set by checking how good they are at extracting the terms in the test set from the corpus θ_y. Of course, in order to guarantee a fair evaluation, the terms that never occur in θ_y are removed from the test set, since there is no way that the algorithm (or any other algorithm that extracts terms from a corpus) could possibly guess them.

Category c_i		expert judgments	
		YES	**NO**
classifier judgments	**YES**	TP_i	FP_i
	NO	FN_i	TN_i

Table 1: The contingency table for category c_i. Here, FP_i (*false positives wrt* c_i) is the number of test terms incorrectly classified under c_i; TN_i (*true negatives wrt* c_i), TP_i (*true positives wrt* c_i) and FN_i (*false negatives wrt* c_i) are defined accordingly.

We will comply with standard text categorization practice in evaluating term categorization effectiveness by a combination of *precision* (π), the percentage of positive categorization decisions that turn out to be correct, and *recall* (ρ), the percentage of positive, correct categorization decisions that are actually taken. Since most classifiers can be tuned to emphasize one at the expense of the other, only combinations of the two are usually considered significant. Following common practice, as a measure combining the two we will adopt their harmonic mean, i.e. $F_1 = \frac{2\pi\rho}{\pi+\rho}$. Effectiveness will be computed with reference to the contingency table illustrated in Table 1. When effectiveness is computed for several categories, the results for individual categories must be averaged in some way; we will do this both by *microaveraging* ("categories count proportionally to the number of their positive training examples"), i.e.

$$\pi^{\mu} = \frac{TP}{TP+FP} = \frac{\sum_{i=1}^{m} TP_i}{\sum_{i=1}^{|\mathcal{C}|}(TP_i+FP_i)}$$

$$\rho^{\mu} = \frac{TP}{TP+FN} = \frac{\sum_{i=1}^{m} TP_i}{\sum_{i=1}^{m}(TP_i+FN_i)}$$

and by *macroaveraging* ("all categories count the same"), i.e.

$$\pi^{M} = \frac{\sum_{i=1}^{|\mathcal{C}|} \pi_i}{m} \qquad \rho^{M} = \frac{\sum_{i=1}^{m} \rho_i}{m}$$

Here, "μ" and "M" indicate microaveraging and macroaveraging, respectively, while the other symbols are as defined in Table 1. Microaveraging rewards classifiers that behave well on *frequent categories* (i.e. categories with many positive test examples), while classifiers that perform well also on infrequent categories are emphasized by macroaveraging. Whether one or the other should be adopted obviously depends on the application.

3.3. Our experimental setting

We now describe the resources we have used in our experiments.

3.3.1. The corpora

As the corpora $\Theta = \{\theta_1, \ldots, \theta_n\}$, we have used various subsets of the Reuters Corpus Volume I (RCVI), a corpus of documents recently made available by Reuters[5] for text categorization experimentation and consisting of about 810,000 news stories. Note that, although the texts of RCVI

[5] http://www.reuters.com/

are labelled by thematic categories, we have not made use of such labels (not it would have made much sense to use them, given that these categories are different from the ones we are working with); the reasons we have chosen this corpus instead of other corpora of unlabelled texts are inessential.

3.3.2. The lexicons

As the thematic lexicons we have used subsets of an extension of WordNet, that we now describe.

WordNet (Fellbaum, 1998) is a large, widely available, non-thematic, monolingual, machine-readable dictionary in which sets of synonymous words are grouped into synonym sets (or *synsets*) organized into a directed acyclic graph. In this work, we will always refer to WordNet version 1.6.

In WordNet only a few synsets are labelled with thematic categories, mainly contained in the glosses. This limitation is overcome in WordNetDomains, an extension of WordNet described in (Magnini and Cavaglià, 2000) in which each synset has been labelled with one or more from a set of 164 thematic categories, called *domains*[6]. The 164 domains of WordNetDomains are a subset of the categories belonging to the classification scheme of Dewey Decimal Classification (DDC (Mai Chan et al., 1996)); example domains are ZOOLOGY, SPORT, and BASKETBALL.

These 164 domains have been chosen from the much larger set of DDC categories since they are the most popular labels used in dictionaries for sense discrimination purposes. Domains have long been used in lexicography (where they are sometimes called *subject field codes* (Procter, 1978)) to mark technical usages of words. Although they convey useful information for sense discrimination, they typically tag only a small portion of a dictionary. WordNetDomains extends instead the coverage of domain labels to an entire, existing lexical database, i.e. WordNet.

A domain may include synsets of different syntactic categories: for instance, the MEDICINE domain groups together senses from Nouns, such as `doctor#1` (the first among several senses of the word "doctor") and `hospital#1`, and from Verbs, such as `operate#7`. A domain may include senses from different WordNet subhierarchies. For example, SPORT contains senses such as `athlete#1`, which descends from `life_form#1`; `game_equipment#1`, from `physical_object#1`; `sport#1`, from `act#2`; and `playing_field#1`, from `location#1`. Note that domains may group senses of the same word into thematic clusters, with the side effect of reducing word polysemy in WordNet.

The annotation methodology used in (Magnini and Cavaglià, 2000) for creating WordNetDomains was mainly manual, and based on lexico-semantic criteria which take advantage from the already existing conceptual relations in WordNet. First, a small number of high level synsets were manually annotated with their correct domains. Then, an automatic procedure exploiting some of the WordNet relations (i.e. hyponymy, troponymy, meronymy, antonymy and pertain-to) was used in order to extend these assignments to all the synsets reachable through inheritance. For example, this procedure automatically marked the synset {`beak, bill, neb, nib`} with the code ZOOLOGY, starting from the fact that the synset {`bird`} was itself tagged with ZOOLOGY, and following a "part-of" relation (one of the meronymic relations present in WordNet). In some cases the inheritance procedure had to be manually blocked, inserting an "exception" in order to prevent a wrong propagation. For instance, if blocking had not been used, the term `barber_chair#1`, being a "part-of" `barbershop#1`, which is annotated with COMMERCE, would have inherited COMMERCE, which is unsuitable.

For the purpose of the experiments reported in this paper, we have used a simplified variant of WordNetDomains, called WordNetDomains(42). This was obtained from WordNetDomains by considering only 42 highly relevant labels, and tagging by a given domain c_i also the synsets that, in WordNetDomains, were tagged by the domains immediately related to c_i in a hierarchical sense (that is, the parent domain of c_i and all the children domains of c_i). For instance, the domain SPORT is retained into WordNetDomains(42), and labels both the synsets that it originally labelled in WordNetDomains, plus the ones that in WordNetDomains were labelled under its children categories (e.g. VOLLEY, BASKETBALL, ...) or under its parent category (FREE-TIME). Since FREE-TIME has another child (PLAY) which is also retained in WordNetDomains(42), the synsets originally labelled by FREE-TIME will now be labelled also by PLAY, and will thus have multiple labels. However, that a synset may have multiple labels is true in general, i.e. these labels need not have any particular relation in the hierarchy.

This restriction to the 42 most significant categories allows to obtain a good compromise between the conflicting needs of avoiding data sparseness and preventing the loss of relevant semantic information. These 42 categories belong to 5 groups, where the categories in a given group are all the children of the same WordNetDomains category, which is however not retained into WordNetDomains(42); for example, one group is formed by SPORT and PLAY, which are both children of FREE-TIME (not included into WordNetDomains(42)).

3.3.3. The experiment

We have run several experiments for different choices of the subset of RCVI chosen as corpus of text θ_y, and for different choices of the subsets of WordNetDomains(42) chosen as training set Tr_y and test set Te_y. We first describe how we have run a generic experiment, and then go on to describe the sequence of different experiments we have run. For the moment being we have run experiments consisting of one iteration only of the bootstrapping process. In future experiments we also plan to allow for multiple iterations, in which the system learns new terms also from previously learnt ones.

In our experiments we considered only nouns, thereby discarding words tagged by other syntactic categories. We plan to also consider words other than nouns in future ex-

[6] From the point of view of our term categorization task, the fact that more than one domain may be attached to the same synset means that ours is a *multi-label* categorization task (Sebastiani, 2002, Section 2.2).

periments.

For each experiment, we discarded all documents that did not contain any term from the training lexicon Tr_y, since they do not contribute in representing the meaning of training documents, and thus could not possibly be of any help in building the classifiers. Next, we discarded all "empty" training terms, i.e. training terms that were not contained in any document of θ_y, since they could not possibly contribute to learning the classifiers. Also empty test terms were discarded, since no algorithm that extracts terms from corpora could possibly extract them. Quite obviously, we also do not use the terms that occur in θ_y but belong neither to the training set Tr_y nor to the test set Te_y.

We then lemmatized all remaining documents and annotated the lemmas with part-of-speech tags, both by means of the TREETAGGER package (Schmid, 1994); we also used the WordNet morphological analyzer in order to resolve ambiguities and lemmatization mistakes. After tagging, we applied a filter in order to identify the words actually contained in WordNet, including multiwords, and then we discarded all terms but nouns. The final set of terms that resulted from this process was randomly divided into a training set Tr_y (consisting of two thirds of the entire set) and a test set Te_y (one third). As negative training examples of category c_i we chose all the training terms that are not positive examples of c_i.

Note that in this entire process we have not considered the grouping of terms into synsets; that is, the lexical units of interest in our application are the terms, and not the synsets. The reason is that RCVI is not a sense-tagged corpus, and for any term occurrence τ it is not clear to which synset τ refers to.

3.3.4. The results

Our experimental results on this task are still very preliminary, and are reported in Table 2.

Instead of tackling the entire RCVI corpus head on, for the moment being we have run only small experiments on limited subsets of it (up to 8% of its total size), with the purpose of getting a feel for which are the dimensions of the problem that need investigation; for the same reason, for the moment being we have used only a small number of boosting iterations (500). In Table 2, the first three lines concern experiments on the news stories produced on a single day (08.11.1996); the next three lines use the news stories produced in a single week (08.11.1996 to 14.11.1996), and the last six lines use the news stories produced in an entire month (01.11.1996 to 30.11.1996). Only training and test terms occurring in at least x documents were considered; the experiments reported in the same block of lines differ for the choice of the x parameter.

There are two main conclusions we can draw from these still preliminary experiments. The first conclusion is that F_1 values are still low, at least if compared to the F_1 values that have been obtained in *text* categorization research on the same corpus (Ault and Yang, 2001); a lot of work is still needed in tuning this approach in order to obtain significant categorization performance. The low values of F_1 are mostly the result of low recall values, while precision tends to be much higher, often well above the 70% mark. Note that the low absolute performance might also be explained, at least partially, with the imperfect quality of the WordNetDomains(42) resource, which was generated by a combination of automatic and manual procedures and did no undergo extensive checking afterwards.

The second conclusion is that results show a constant and definite improvement when higher values of x are used, despite the fact that higher levels of x mean a higher number of labels per term, i.e. more polysemy. This is not surprising, since when a term occurs e.g. in one document only, this means that only one entry in the vector that represents the term is non-null (i.e. significant). This is in sharp contrast with text categorization, in which the number of non-null entries in the vector representing a document equals the number of distinct terms contained in the document, and is usually at least in the hundreds. This alone might suffice to justify the difference in performance between term categorization and text categorization.

However, one reason the actual F_1 scores are low is that this is a hard task, and the evaluation standards we have adopted are considerably tough. This is discussed in the next paragraph.

No baseline? Note that we present no baseline, either published or new, against which to compare our results, for the simple fact that term categorization as we conceive it here is a novel task, and there are as yet no previous results or known approaches to the problem to compare with.

Only (Riloff and Shepherd, 1999; Roark and Charniak, 1998) have approached the problem of extending an existing thematic lexicon with new terms drawn from a text corpus. However, there are key differences between their evaluation methodology and ours, which makes comparisons difficult and unreliable. First, their "training" terms have not been chosen randomly our of a thematic dictionary, but have been carefully selected through a manual process by the authors themselves. For instance, (Riloff and Shepherd, 1999) choose words that are "frequent in the domain" and that are "(relatively) unambiguous". Of course, their approach makes the task easier, since it allows the "best" terms to be selected for training. Second, (Riloff and Shepherd, 1999; Roark and Charniak, 1998) extract the terms from texts that are known to be about the theme, which makes the task easier than ours; conversely, by using generic texts, we avoid the costly process of labelling the documents by thematic categories, and we are able to generate thematic lexicons for multiple themes at once *from the same unlabelled text corpus*. Third, their evaluation methodology is manual, i.e. subjective, in the sense that the authors themselves manually checked the results of their experiments, judging, for each returned term, how reasonable the inclusion of the term in the lexicon is[7]. This sharply contrasts with our evaluation methodology, which is completely automatic (since we measure the proficiency

[7] For instance, (Riloff and Shepherd, 1999) judged a word classified into a category correct also if they judged that "the word refers to a part of a member of the category", thereby judging the words `cartridge` and `clips` to belong to the domain WEAPONS. This looks to us a loose notion of category membership, and anyway points to the pitfalls of "subjective" evaluation methodologies.

# of docs	# of training terms	# of test terms	# of labels per term	minimum # of docs per term	Precision micro	Recall micro	F_1 micro	Precision macro	Recall macro	F_1 macro

Table 2: Preliminary results obtained on the automated lexicon generation task (see Section 3.3. for details).

of our system at discovering terms about the theme, by the capability of the system to replicate the lexicon generation work of a lexicographer), can be replicated by other researchers, and is unaffected by possible experimenter's bias. Fourth, checking one's results for "reasonableness", as (Riloff and Shepherd, 1999; Roark and Charniak, 1998) do, means that one can only ("subjectively") measure precision (i.e. whether the terms spotted by the algorithm do in fact belong to the theme), but not recall (i.e. whether the terms belonging to the theme have actually been spotted by the algorithm). Again, this is in sharp contrast with our methodology, which ("objectively") measures precision, recall, and a combination of them. Also, note that in terms of precision, i.e. the measure that (Riloff and Shepherd, 1999; Roark and Charniak, 1998) subjectively compute, our algorithm fares pretty well, mostly scoring higher than 70% even in these very preliminary experiments.

4. Related work

4.1. Automated generation of lexical resources

The automated generation of lexicons from text corpora has a long history, dating back at the very least to the seminal works of Lesk, Salton and Sparck Jones (Lesk, 1969; Salton, 1971; Sparck Jones, 1971), and has been the subject of active research throughout the last 30 years, both within the information retrieval community (Crouch and Yang, 1992; Jing and Croft, 1994; Qiu and Frei, 1993; Ruge, 1992; Schütze and Pedersen, 1997) and the NLP community (Grefenstette, 1994; Hirschman et al., 1988; Riloff and Shepherd, 1999; Roark and Charniak, 1998; Tokunaga et al., 1995). Most of the lexicons built by these works come in the form of *cluster-based thesauri*, i.e. networks of groups of synonymous or quasi-synonymous words, in which edges connecting the nodes represent semantic contiguity. Most of these approaches follow the basic pattern of (i) measuring the degree of pairwise similarity between the words extracted from a corpus of texts, and (ii) clustering these words based on the computed similarity values. When the lexical resources being built are of a *thematic* nature, the thematic nature of a word is usually established by checking whether its frequency within thematic documents is higher than its frequency in generic documents (Chen et al., 1996; Riloff and Shepherd, 1999; Schatz et al., 1996; Sebastiani, 1999) (this property is often called *salience* (Yarowsky, 1992)).

In the approach described above, the key decision is how to tackle step (i), and there are two main approaches to this. In the first approach the similarity between two words is usually computed in terms of their degree of co-occurrence and co-absence within the same document (Crouch, 1990; Crouch and Yang, 1992; Qiu and Frei, 1993; Schäuble and Knaus, 1992; Sheridan and Ballerini, 1996; Sheridan et al., 1997); variants of this approach are obtained by restricting the context of co-occurrence from the document to the paragraph, or to the sentence (Schütze, 1992; Schütze and Pedersen, 1997), or to smaller linguistic units (Riloff and Shepherd, 1999; Roark and Charniak, 1998). In the second approach this similarity is computed from head-modifier structures, by relying on the assumption that frequent modifiers of the same word are semantically similar (Grefenstette, 1992; Ruge, 1992; Strzalkowski, 1995). The latter approach can also deal with indirect co-occurrence[8], but the former is conceptually simpler, since it does not even need any parsing step.

This literature (apart from (Riloff and Shepherd, 1999; Roark and Charniak, 1998), which are discussed below) has thus taken an *unsupervised* learning approach, which can be summarized in the recipe "from a set of documents about theme t and a set of generic documents (i.e. mostly not about t), extract the words that mostly characterize t". Our work is different, in that its underlying *supervised* learning approach requires a starting kernel of terms about t, but does not require that the corpus of documents from which

[8]We say that words w_1 and w_2 *co-occur directly* when they both occur in the same document (or other linguistic context), while we say that they *co-occur indirectly* when, for some other word w_3, w_1 and w_3 co-occur directly and w_2 and w_3 co-occur directly. Perfect synonymy is not revealed by direct co-occurrence, since users tend to consistently use either one or the other synonym but not both, while it is obviously revealed by indirect co-occurrence. However, this latter also tends to reveal many more "spurious" associations than direct co-occurrence.

the terms are extracted be labelled. This makes our supervised technique particularly suitable for *extending* a previously existing thematic lexical resource, while the previously known unsupervised techniques tend to be more useful for generating one from scratch. This suggests an interesting methodology of (i) generating a thematic lexical resource by some unsupervised technique, and then (ii) extending it by our supervised technique. An intermediate approach between these two is the one adopted in (Riloff and Shepherd, 1999; Roark and Charniak, 1998), which also requires a starting kernel of terms about t, but also requires a set of documents about theme t from which the new terms are extracted.

As anyone involved in applications of supervised machine learning knows, labelled resources are often a bottleneck for learning algorithms, since labelling items by hand is expensive. Concerning this, note that our technique is advantageous, since it requires an initial set of labelled terms *only in the first bootstrapping iteration*. Once a lexical resource has been extended with new terms, extending it further only requires a new *unlabelled* corpus of documents, but no other labelled resource. This is different from the other techniques described earlier, which require, for extending a lexical resource that has just been built by means of them, a new *labelled* corpus of documents.

A work which is closer in spirit to ours than the abovementioned ones is (Tokunaga et al., 1997), since it deals with using previously classified terms as training examples in order to classify new terms. This work exploits a naive Bayesian model for classification in conjunction with another learning method, chosen among nearest neighbour, "category-based" (by which the authors basically mean a Rocchio method – see e.g. (Sebastiani, 2002, Section 6.7)) and "cluster-based" (which does not use category labels of training examples). However, these latter learning methods and (especially) the nature of their integration with the naive Bayesian model are not specified in mathematical detail, which does not allow us to make a precise comparison between the model of (Tokunaga et al., 1997) and ours. Anyway, our model is more elegant, in that it just assumes a single learning method (for which we have chosen boosting, although we might have chosen any other supervised learning method), and in that it replaces the ad-hoc notion of "co-occurrence" with a theoretically sounder "dual" theory of text indexing, which allows one, among other things, to bring to bear any kind of intuitions on term weighting, or any kind of text indexing theory, that are known from information retrieval.

4.2. Boosting

Boosting has been applied to several learning tasks related to text analysis, including POS-tagging and PP-attachment (Abney et al., 1999), clause splitting (Carreras and Màrquez, 2001b), word segmentation (Shinnou, 2001), word sense disambiguation (Escudero et al., 2000), text categorization (Schapire and Singer, 2000; Schapire et al., 1998; Sebastiani et al., 2000; Taira and Haruno, 2001), e-mail filtering (Carreras and Márquez, 2001a), document routing (Iyer et al., 2000; Kim et al., 2000), and term extraction (Vivaldi et al., 2001). Among these works, the one somehow closest in spirit to ours is (Vivaldi et al., 2001), since it is concerned with extracting medical terms from a corpus of texts. A key difference with our work is that the features by which candidate terms are represented in (Vivaldi et al., 2001) are not simply the documents they occur in, but the results of term extraction algorithms; therefore, our approach is simpler and more general, since it does not require the existence of separate term extraction algorithms.

5. Conclusion

We have reported work in progress on the semi-automatic generation of thematic lexical resources by the combination of (i) a dual interpretation of IR-style text indexing theory and (ii) a boosting-based machine learning approach. Our method does not require pre-existing semantic knowledge, and is particularly suited to the situation in which one or more preexisting thematic lexicons need to be extended and no corpora of texts classified according to the themes are available. We have run only initial experiments, which suggest that the approach is viable, although large margins of improvement exist. In order to improve the overall performance we are planning several modifications to our currently adopted strategy.

The first modification consists in performing *feature selection*, as commonly used in text categorization (Sebastiani, 2002, Section 5.4). This will consist in individually scoring (by means of the *information gain* function) all documents in terms of how indicative they are of the occurrence or non-occurrence of the categories we are interested in, and to choose only the best-scoring ones out of a potentially huge corpus of available documents.

The second avenue we intend to follow consists in trying alternative notions of what a document is, by considering as "documents" paragraphs, or sentences, or even smaller, syntactically characterized units (as in (Riloff and Shepherd, 1999; Roark and Charniak, 1998)), rather than full-blown Reuters news stories.

A third modification consists in selecting, as the negative examples of a category c_i, all the training examples that are not positive examples of c_i *and* are at the same time positive examples of (at least one of) the siblings of c_i. This method, known as the *query-zoning method* or as the *method of quasi-positive examples*, is known to yield superior performance with respect to the method we currently use (Dumais and Chen, 2000; Ng et al., 1997).

The last avenue for improvement is the optimization of the parameters of the boosting process. The obvious parameter that needs to be optimized is the number of boosting iterations, which we have kept to a minimum in the reported experiments. A less obvious parameter is the form of the initial distribution on the training examples (that we have not described here for space limitations); by changing it with respect to the default value (the uniform distribution) we will be able to achieve a better compromise between precision and recall (Schapire et al., 1998), which for the moment being have widely different values.

Acknowledgments

We thank Henri Avancini for help with the coding task and Pio Nardiello for assistance with the

ADABOOST.MH^{KR} code. Above all, we thank Roberto Zanoli for help with the coding task and for running the experiments.

Abstract

This paper describes an application of Grammar Learning by Partition Search to noun phrase extraction, an essential task in information extraction and many other NLP applications. Grammar Learning by Partition Search is a general method for automatically constructing grammars for a range of parsing tasks; it constructs an optimised probabilistic context-free grammar by searching a space of nonterminal set partitions, looking for a partition that maximises parsing performance and minimises grammar size. The idea is that the considerable time and cost involved in building new grammars can be avoided if instead existing grammars can be automatically adapted to new parsing tasks and new domains. This paper presents results for applying Partition Search to the tasks of (i) identifying flat NP chunks, and (ii) identifying all NPs in a text. For NP chunking, Partition Search improves a general baseline result by 12.7%, and a method-specific baseline by 2.2%. For NP identification, Partition Search improves the general baseline by 21.45%, and the method-specific one by 3.48%. Even though the grammars are nonlexicalised, results for NP identification closely match the best existing results for lexicalised approaches.

1. Introduction

Grammar Learning by Partition Search is a computational learning method that constructs probabilistic grammars optimised for a given parsing task. Its main practical application is the adaptation of grammars to new tasks, in particular the adaptation of conventional, "deep" grammars to the shallow parsing tasks involved in many NLP applications. The parsing tasks investigated in this paper are NP identification and NP chunking both of which involve the detection of NP boundaries, a task which is fundamental to information extraction and retrieval, text summarisation, document classification, and other applications.

The ability to automatically adapt an existing grammar to a new parsing task saves time and expense. Furthermore, adapting deep grammars to shallow parsing tasks has a specific advantage. Existing approaches to NP extraction are mostly completely flat. They do not carry out any structural analysis above the level of the chunks and phrases they are meant to detect. Using Partition Search to adapt deep grammars for shallow parsing permits those parts of deeper structural analysis to be retained that are useful for the detection of more shallow components.

The remainder of this paper is organised in two main sections. Section 2. describes Grammar Learning by Partition Search. Section 3. reports experiments and results for NP identification and NP chunking.

2. Learning PCFGs by Partition Search

Partition Search Grammar Learning starts from the idea that new context-free grammars can be created from old simply by modifying the nonterminal sets, *merging* and *splitting* subsets of nonterminals. For example, for certain parsing tasks it is useful to *split* a single verb phrase category into verb phrases that are headed by a modal verb and those that are not, whereas for other parsing tasks, the added grammar complexity is avoidable. In another context, it may not be necessary to distinguish noun phrases in subject position from first objects and second objects, making it possible to *merge* the three categories into one.

The usefulness of such split and merge operations can be objectively measured by their effect on a grammar's size (number of rules and nonterminals) and performance (parsing accuracy on a given task). Grammar Learning by Partition Search automatically tries out different combinations of merge and split operations and therefore can automatically optimise a grammar's size and performance.

2.1. Preliminary definitions

Definition 1 Set Partition

A partition of a nonempty set A is a subset Π of 2^A such that $\emptyset$ is not an element of Π and each element of A is in one and only one set in Π.

The partition of A where all elements are singleton sets is called the *trivial partition* of A.

Definition 2 Probabilistic Context-Free Grammar

A Probabilistic Context-Free Grammar (PCFG) is a 4-tuple (W, N, N^S, R), where W is a set of terminal symbols, N is a set of nonterminal symbols, $N^S = \{(s_1, p(s_1)), \ldots (s_l, p(s_l))\}, \{s_1, \ldots s_l\} \subseteq N$ is a set of start symbols with associated probabilities summing to one, and $R = \{(r_1, p(r_1)), \ldots (r_m, p(r_m))\}$ is a set of rules with associated probabilities. Each rule r_i is of the form $n \rightarrow \alpha$, where n is a nonterminal, and α is a string of terminals and nonterminals. For each nonterminal n, the values of all $p(n \rightarrow \alpha_i)$ sum to one, or: $\sum_{i:(n \rightarrow \alpha_i, p(n \rightarrow \alpha_i)) \in R} p(n \rightarrow \alpha_i) = 1$.

2.2. Generalising and Specialising PCFGs through Nonterminal Set Operations

2.2.1. Nonterminal merging

Consider two PCFGs G and G':

$G = (W, N, N^S, R)$,
$W =$ { NNS, DET, NN, VBD, JJ }
$N =$ { S, NP-SUBJ, VP, NP-OBJ }
$N^S =$ { (S, 1) }
$R =$ { (S -> NP-SUBJ VP, 1),
(NP-SUBJ -> NNS, 0.5),
(NP-SUBJ -> DET NN, 0.5),
(VP -> VBD NP-OBJ, 1),
(NP-OBJ -> NNS, 0.75),
(NP-OBJ -> DET JJ NNS, 0.25) }

$G' = (W, N', N^S, R')$,
$W =$ { NNS, DET, NN, VBD, JJ }
$N' =$ { S, NP, VP }
$N^S =$ { (S, 1) }
$R' =$ { (S -> NP VP, 1),
(NP -> NNS, 0.625),
(NP -> DET NN, 0.25),
(VP -> VBD NP, 1),
(NP -> DET JJ NNS, 0.125) }

Intuitively, to derive G' from G, the two nonterminals NP-SUBJ and NP-OBJ are merged into a single new nonterminal NP. This merge results in two rules from R becoming identical in R': both NP-SUBJ -> NNS and NP-OBJ -> NNS become NP -> NNS. One way of determining the probability of the new rule NP -> NNS is to sum the probabilities of the old rules and renormalise by the number of nonterminals that are being merged[1]. In the above example therefore $p(\text{NP -> NNS}) = (0.5 + 0.75)/2 = 0.625$[2].

An alternative would be to reestimate the new grammar on some corpus, but this is not appropriate in the current context: merge operations are used in a search process (see below), and it would be expensive to reestimate each new candidate grammar derived by a merge. It is better to use any available training data to estimate the original grammar's probabilities, then the probabilities of all derived grammars can simply be calculated as described above without expensive corpus reestimation.

The new grammar G' derived from an old grammar G by merging nonterminals in G is a generalisation of G: the language of G', or $L(G')$, is a superset of the language of G, or $L(G)$. E.g., det jj nns vbd det jj nns is in $L(G')$ but not in $L(G)$. The set of parses assigned to a sentence s by G' differs from the set of parses assigned to s by G. The probabilities of parses for s can change, and so can the probability ranking of the parses, i.e. the most likely parse for s under G may be different from the most likely parse for s under G'. Finally, G' has the same number of rules as G or fewer.

[1] Reestimating the probabilities on the training corpus would of course produce identical results.

[2] Renormalisation is necessary because the probabilities of all rules expanding the same nonterminal sum to one, therefore the probabilities of all rules expanding a new nonterminal resulting from merging n old nonterminals will sum to n.

2.2.2. Nonterminal splitting

Deriving a new PCFG from an old one by splitting nonterminals in the old PCFG is not quite the exact reverse of deriving a new PCFG by merging nonterminals. The difference lies in determining probabilities for new rules. Consider the following grammars G and G':

$G = (W, N, N^S, R)$,
$W =$ { NNS, DET, NN, VBD, JJ }
$N =$ { S, NP, VP }
$N^S =$ { (S, 1) }
$R =$ { (S -> NP VP, 1),
(NP -> NNS, 0.625),
(NP -> DET NN, 0.25),
(VP -> VBD NP, 1),
(NP -> DET JJ NNS, 0.125) }

$G' = (W, N', N^S, R')$,
$W =$ { NNS, DET, NN, VBD, JJ }
$N' =$ { S, NP-SUBJ, VP, NP-OBJ }
$N^S =$ { (S, 1) }
$R' =$ { (S -> NP-SUBJ VP, ?),
(S -> NP-OBJ VP, ?),
(NP-SUBJ -> NNS, ?),
(NP-SUBJ -> DET NN, ?),
(NP-SUBJ -> DET JJ NNS, ?) }
(VP -> VBD NP-SUBJ, ?),
(VP -> VBD NP-OBJ, ?),
(NP-OBJ -> NNS, ?),
(NP-OBJ -> DET NN, ?),
(NP-OBJ -> DET JJ NNS, ?) }

To derive G' from G, the single nonterminal NP is split into two nonterminals NP-SUBJ and NP-OBJ. This split results in several new rules. For example, for the old rule NP -> NNS, there now are two new rules NP-SUBJ -> NNS and NP-OBJ -> NNS. One possibility for determining the new rule probabilities is to redistribute the old probability mass evenly among them, i.e. $p(\text{NP -> NNS}) = p(\text{NP-SUBJ -> NNS}) = p(\text{NP-SUBJ -> NNS})$. However, then there would be no benefit at all from performing such a split: the resulting grammar would be larger, the most likely parses remain unchanged, and for each parse p under G that contains a nonterminal participating in a split operation, there would be at least two equally likely parses under G'.

The new probabilities cannot be calculated directly from G. The redistribution of the probability mass has to be motivated from a knowledge source outside of G. One way to proceed is to estimate the new rule probabilities on the original corpus — provided that it contains the information on the basis of which a split operation was performed in extractable form. For the current example, a corpus in which objects and subjects are annotated could be used to estimate the probabilities of the rules in G', and might yield the following result (which reflects the fact that in English, the NP in a sentence NP VP is usually a subject, whereas the NP in a VP consisting of a verb followed by an NP is an object):

$G' = (W, N', N^S, R')$,
$W =$ { NNS, DET, NN, VBD, JJ }
$N' =$ { S, NP-SUBJ, VP, NP-OBJ }
$N^S =$ { (S, 1) }
$R' =$ {
(S -> NP-SUBJ VP, 1),
(S -> NP-OBJ VP, 0),
(NP-SUBJ -> NNS, 0.5),
(NP-SUBJ -> DET NN, 0.5),
(NP-SUBJ -> DET JJ NNS, 0) }
(VP -> VBD NP-SUBJ, 0),
(VP -> VBD NP-OBJ, 1),
(NP-OBJ -> NNS, 0.75),
(NP-OBJ -> DET NN, 0),
(NP-OBJ -> DET JJ NNS, 0.25) }

With rules of zero probability removed, G' is identical to the original grammar G in the example in the previous section.

2.3. Partition Search

A PCFG together with nonterminal merge and split operations defines a space of derived grammars which can be searched for a new PCFG that optimises some given objective function. The disadvantage of this search space is that it is infinite, and each split operation requires the reestimation of rule probabilities from a training corpus, making it computationally much more expensive than a merge operation.

However, there is a simple way to make the search space finite, and at the same time to make split operations redundant. The resulting method, Grammar Learning by Partition Search, is summarised in this section (Partition Search is described in more detail, including formal definitions and algorithmic details, in Belz (2002)).

2.3.1. PCFG Partitioning

An arbitrary number of merges can be represented by a partition of the set of nonterminals. For the example presented in Section 2.2.1. above, the partition of the nonterminal set N in G that corresponds to the nonterminal set N' in G' is { {S}, {NP-SBJ, NP-OBJ}, {VP} }. The original grammar G together with a partition of its nonterminal set fully specifies the new grammar G': the new rules and probabilities, and the entire new grammar G' can be derived from the partition together with the original grammar G. The process of obtaining a new grammar G', given a base grammar G and a partition of the nonterminal set N of G will be called PCFG Partitioning[3].

2.3.2. Search space

The search space for Grammar Learning by Partition Search can be made finite and searchable entirely by merge operations (grammar partitions).

Making the search space finite: The number of merge operations that can be applied to a nonterminal set is finite, because after some finite number of merges there remains only one nonterminal. On the other hand, the number of split operations that can sensibly be applied to a nonterminal *NT* has an upper bound in the number of different terminals strings dominated by *NT* in a corpus of evidence (e.g. the corpus the PCFG was trained on). For example, when splitting the nonterminal NP into subjects and objects, there would be no point in creating more new nonterminals than the number of different subjects and objects found in the corpus.

Given these (generous) bounds, there is a finite number of distinct grammars derivable from the original grammar by different combinations of merge and split operations. This forms the basic space of candidate solutions for Grammar Learning by Partition Search.

Making the search space searchable by grammar partitioning only: Imposing an upper limit on the number and kind of split operations permitted not only makes the search space finite but also makes it possible to directly derive this *maximally split nonterminal set* (Max Set). Once the Max Set has been defined, the single grammar corresponding to it — the *maximally split Grammar* (Max Grammar) — can be derived and retrained on the training corpus.

The set of points in the search space corresponds to the set of partitions of the Max Set. Search for an optimal grammar can thus be carried out directly in the partition space of the Max Grammar.

Structuring the search space: The finite search space can be given hierarchical structure as shown in Figure 1 for an example of a very simple base nonterminal set {NP, VP, PP}, and a corpus which contains three different NPs, three different VPs and two different PPs.

At the top of the graph is the Max Set. The sets at the next level down (level 7) are created by merging pairs of nonterminals in the Max Set, and so on for subsequent levels. At the bottom is the *maximally merged nonterminal set* (Min Set) consisting of a single nonterminal *NT*. The sets at the level immediately above it can be created by splitting *NT* in different ways. The sets at level 2 are created from those at level 1 by splitting one of their elements. The original nonterminal set ends up somewhere in between the top and bottom (at level 3 in this example).

While this search space definition results in a finite search space and obviates the need for the expensive split operation, the space will still be vast for all but trivial corpora. In Section 3.3. below, alternative ways for defining the Max Set are described that result in much smaller search spaces.

2.3.3. Search task and evaluation function

The input to the Partition Search procedure consists of a base grammar G_0, a base training corpus C, and a task-specific training corpus D^T. G_0 and C are used to create the Max Grammar G. The **search task** can then be defined as follows:

> Given the maximally split PCFG $G = (W, N, N^S, R)$, a data set of sentences D, and a set of target parses D^T for D, find a partition Π_N of N that derives a grammar $G' = (W, \Pi_N, N^{S'}, R')$, such that $|R'|$ is minimised, and $f(G', D, D^T)$ is maximised, where f scores the performance of G' on D as compared to D^T.

[3]The concept of context-free grammar partitioning in this paper is not directly related to that in (Korenjak, 1969; Weng and Stolcke, 1995), and later publications by Weng et al. In these previous approaches, a non-probabilistic CFG's *set of rules* is partitioned into subsets of rules. The partition is drawn along a specific nonterminal NT, which serves as an interface through which the subsets of rules (hence, subgrammars) can communicate after partition (one grammar calling the other).

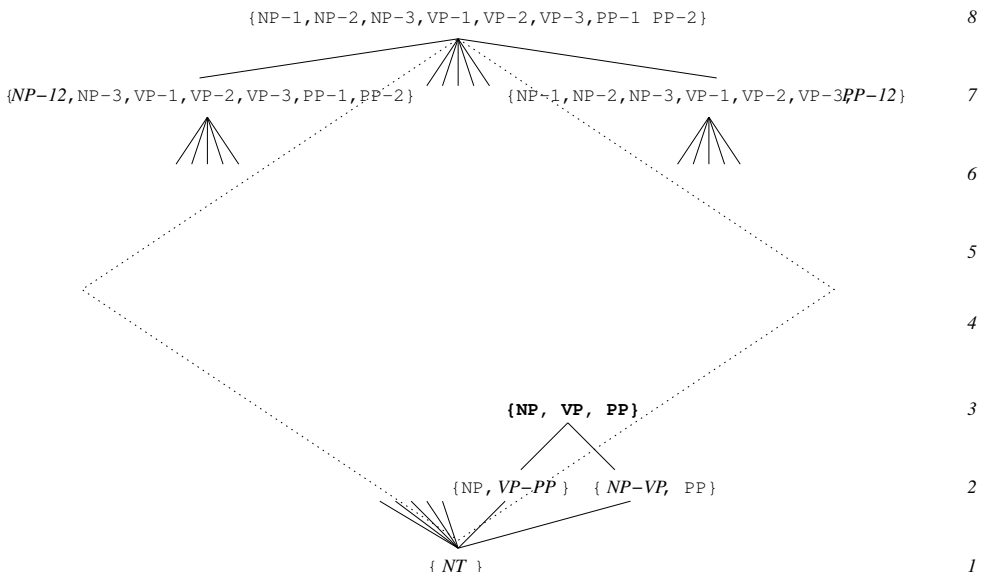

Figure 1: Simple example of a partition search space.

The size of the nonterminal set and hence of the grammar decreases from the top to the bottom of the search space. Therefore, if the partition space is searched top-down, grammar size is minimised automatically and does not need to be assessed explicitly.

In the current implementation, the **evaluation function** f simply calculates the F-Score achieved by a candidate grammar on D as compared to D^T. The F-Score is obtained by combining the standard PARSEVAL evaluation metrics *Precision* and *Recall*[4] as follows: $2 \times Precision \times Recall/(Precision + Recall)$.

An existing parser[5] was used to obtain Viterbi parses. If the parser failed to find a complete parse for a sentence, a simple grammar extension method was used to obtain partial parses instead (based on Schmid and Schulte im Walde (2000, p. 728)).

2.3.4. Search algorithm

Since each point in the search space can be accessed directly by applying the corresponding nonterminal set partition to the Max Grammar, the search space can be searched in any direction by any search method using partitions to represent candidate grammars.

In the current implementation, a variant of beam search is used to search the partition space top down. A list of the n current best candidate partitions is maintained (initialised to the Max Set). For each of the n current best partitions a random subset of size b of its children in the hierarchy is generated and evaluated. From the union of current best partitions and the newly generated candidate partitions, the n best elements are selected and form the new current best set. This process is iterated until either no new partitions can be generated that are better than their parents, or the lowest level of the partition tree is reached. In each iteration the size of the nonterminal set (partition) decreases by one.

The size of the search space grows exponentially with the size i of the Max Set. However, the complexity of the Partition Search algorithm is only $O(nbi)$, because only up to $n \times b$ partitions are evaluated in each of up to i iterations[6].

3. Learning NP Extraction Grammars

3.1. Data and Parsing Tasks

Sections 15–18 of WSJC were used for deriving the base grammar and as the base training corpus, and different randomly selected subsets of Section 1 from the same corpus were used as task-specific training corpora during search. Section 20 was used for final performance tests.

Results are reported in this paper for the following two parsing tasks. In **NP identification** the task is to identify in the input sentence all noun phrases[7], nested and otherwise, that are given in the corresponding WSJC parse. **NP chunking** was first defined by (Abney, 1991), and involves the identification of flat noun phrase chunks. Target parses were derived from WSJC parses by an existing conversion procedure[8].

The Brill Tagger was used for POS tagging testing data, and achieved an average accuracy of 97.5% (as evaluated by `evalb`).

3.2. Base grammar

A simple treebank grammar[9] was derived from Sections 15–18 of the WSJ corpus by the following procedure:

1. Iteratively edit the corpus by deleting (i) brackets and labels that correspond to empty category expansions; (ii) brackets

[4] I used the `evalb` program by Sekine and Collins (`http://cs.nyu.edu/cs/projects/proteus/evalb/`) to obtain Precision and Recall figures.

[5] LoPar (Schmid, 2000) in its non-head-lexicalised mode. Available from `http://www.ims.uni-stuttgart.de/projekte/gramotron/SOFTWARE/LoPar-en.html`.

[6] As before, n is the number of current best candidate solutions, b is the width of the beam, and i is the size of the Max Set.

[7] Corresponding to the WSJC categories `NP, NX, WHNP` and `NAC`.

[8] Devised by Erik Tjong Kim Sang for the TMR project *Learning Computational Grammars*.

[9] The term was coined by Charniak (1996).

and labels containing a single constituent that is not labelled with a POS-tag; (iii) cross-indexation tags; (iv) brackets that become empty through a deletion.

2. Convert each remaining bracketting in the corpus into the corresponding production rule.
3. Collect sets of terminals W, nonterminals N and start symbols N^S from the corpus. Probabilities p for rules $n \rightarrow \alpha$ are calculated from the rule frequencies C by Maximum Likelihood Estimation: $p(n \rightarrow \alpha) = \frac{C(n \rightarrow \alpha)}{\sum_i C(n \rightarrow \alpha^i)}$.

This procedure creates the base grammar *BARE* which has $10,118$ rules and 147 nonterminals.

3.3. Restricting the search space further

The simple method described in Section 2.3.2. for defining the maximally split nonterminal set (Max Set) tends to result in vast search spaces. Using parent node (PN) information to create the Max Set is much more restrictive and linguistically motivated. The Max Grammar *PN* used in the experiments reported below can be seen as making use of *Local Structural Context* (Belz, 2001): the independence assumptions inherent in PCFGs are weakened by making the rules' expansion probabilities dependent on part of their immediate structural context (here, its parent node). To obtain the grammar *PN*, the base grammar's nonterminal set is maximally split on the basis of the *parent node* under which rules are found in the base training corpus[10]. Several previous investigations have demonstrated improvement in parsing results due to the inclusion of parent node information (Charniak and Carroll, 1994; Johnson, 1998; Verdú-Mas et al., 2000).

Another possibility is to use the base grammar *BARE* itself as the Max Grammar. This is a very restrictive search space definition and amounts to an attempt to optimise the base grammar in terms of its size and its performance on a given task without adding any information. Results are given below for both *BARE* and *PN* as Max Grammars.

In the current implementation of the algorithm, the search space is reduced further by avoiding duplicate partitions, and by only allowing merges of nonterminals that have the same phrase prefix `NP-*, VP-*` etc.

The Max Grammars end up having sets of nonterminals that differ from the bracket labels used in the WSJC: while the phrase categories (e.g. `NP`) are the same, the tags (e.g. `*-S, *-3`) on the phrase category labels may differ. In the evaluation, all labels starting with the same phrase category prefix are considered equivalent.

3.4. NP chunking results

Baseline Results. Base grammar *BARE* (see Section 3.2. achieves an F-Score of 88.25 on the NP chunking task. This baseline result compares as follows with existing results:

	NP chunking
Chunk Tag Baseline	79.99
Grammar *BARE*	88.25
Current Best: nonlexicalised	90.12
lexicalised	93.25 (93.86)

The chunk tag baseline F-Score is the standard baseline for the NP chunking task and is obtained by tagging each POS tag in a sentence with the label of the phrase that it most frequently appears in, and converting these phrase tags into labelled brackettings (Nerbonne et al., 2001, p. 102). The best nonlexicalised result was achieved with the decision-tree learner C5.0 (Tjong Kim Sang et al., 2000), and the current overall best result for NP chunking is for memory-based learning and a lexicalised chunker (Tjong Kim Sang et al., 2000)[11].

Table 1 shows results for Partition Search applied to the NP chunking task. The first column shows the Max Grammar used in a given batch of experiments. The second column indicates the type of result, where the Max Grammar result is the F-Score, grammar size and number of nonterminals of the Max Grammar itself, and the remaining results are the average and single best results achieved by Partition Search. The third and fourth columns show the number of iterations and evaluations carried out before search stopped. Columns 5–8 show details of the final solution grammars: column 5 shows the evaluation score on the training data, column 6 the overall F-Score on the testing data, column 7 the size, and the last column gives the number of nonterminals.

The best result (boldface) was an F-Score of 90.24% (compared to the base result of 88.25%), and 95 nonterminals (147 in the base grammar), while the number of rules increased from 10,118 to 11,972. This result improves the general baseline by 12.7% and the performance by grammar *BARE* by 2.2%. It also outperforms the best existing result of 90.12% for nonlexicalised NP chunking by a small margin.

3.5. NP identification results

Baseline Results. Base grammar *BARE* achieves an F-Score of 79.29 on the NP identification task. This baseline result compares as follows with existing results:

	NP identification
Chunk Tag Baseline	67.56
Grammar *BARE*	79.29
Current Best: nonlexicalised	80.15
lexicalised	83.79

All results in this table (except for that for grammar *BARE*) are reported in Nerbonne et al. (2001, p. 103). The task definition used there was slightly different in that it omitted two minor NP categories (WSJC brackets labelled `NAC` and `NX`). The slightly different task definition has only a very small effect on F-Scores, so the above results are comparable. The chunk tag baseline F-Score was again obtained by tagging each POS tag in a sentence with the label of the phrase that it most frequently appears in. The best lexicalised result was achieved with a cascade of memory-based learners. The same paper also included two results for nonlexicalised NP identification.

Table 2 (same format as Table 1) contains results for Partition Search and the NP identification task. The smallest nonterminal set had 63 nonterminals (147 in the base

[10] The parent node of a phrase is the category of the phrase that immediately contains it.

[11] Nerbonne et al. (2001) report a slightly better result of 93.86 achieved by combining seven different learning systems.

Max Grammar		Iter.	Eval.	F-Score (subset)	F-Score (WSJC S 1)	Size (rules)	Nonterms
BARE	Max Grammar result:				88.25	10,118	147
	Average:	116.8	2,749.6	89.64	88.57	7,849.6	32.2
	Best (size):	119	2,806	89.79	88.51	7,541	30
	Best (F-score):	114	2,674	87.93	88.70	7,777	35
PN	Max Grammar result:				89.86	16,480	970
	Average:	526	13,007.75	94.85	89.83	14,538.25	446
	Best (size and F-score):	**877**	**21,822**	**93.85**	**90.24**	**11,972**	**95**

grammar). The best result (boldface) was an F-Score of 82.05% (base result was 79.29%), while the number of rules increased from 10,118 to 15,305. This improves the general baseline by 21.45% and grammar *BARE* by 3.48%. It also outperforms the other two results for nonlexicalised NP chunking by a significant margin, and even comes close to the best lexicalised result (83.79%).

3.6. General comments

Partition Search is able to reduce grammar size by merging groups of nonterminals (hence groups of rules) that do not need to be distinguished for a given task. It is able to improve parsing performance firstly by grammar generalisation (partitioned grammars parse a superset of the sentences parsed by the base grammar), and secondly by reranking parse probabilities (the most likely parse for a sentence under a partitioned grammar can differ from its most likely parse under the base grammar).

The margins of improvement over baseline results were bigger for the NP identification task than for NP chunking. The results reported here for NP chunking are no match for the best lexicalised results, whereas the results for NP identification come close to the best lexicalised results. This indicates that the two characteristics that most distinguish the grammars used here from other approaches — some non-shallow structural analysis and parent node information — are more helpful for NP identification.

Preliminary tests revealed that results were surprisingly constant over different combinations of variable parameter values, although training subset size of less then 50 meant unpredictable results for the complete WSJC Section 1. For a random subset of size 50 and above, there is an almost complete correspondence between subset F-Score and Section 1 F-Score, i.e. higher subset F-Score almost always means higher Section 1 F-Score.

The results presented in the previous section also show what happens if Partition Search is used as a grammar compression method (when existing grammars are used as Max Grammars). In Table 1, for example, when applied to the base grammar *BARE* (four top rows), it maximally reduces the number of nonterminals from 147 to 30 and the number of rules from $10,118$ to $7,541$, while *improving* the overall F-Score. The size reductions on the *PN* grammar are even bigger: 970 nonterminals down to 95, and $16,480$ rules down to $11,972$, again with a slight improvement in the F-Score (even though on average, the F-Score remained about the same). Unlike other grammar compression methods (Charniak, 1996; Krotov et al., 2000), Partition Search achieves lossless compression, in the sense that the compressed grammars are guaranteed to be able to parse all of the sentences parsed by the original grammar.

Compared to other approaches using parent node information (Charniak and Carroll, 1994; Johnson, 1998; Verdú-Mas et al., 2000), the approach presented here has the advantage of being able to select a subset of all parent node information on the basis of its usefulness for a given parsing task. This saves on grammar complexity, hence parsing cost.

3.7. Nonterminal distinctions preserved/eliminated

The base grammar *BARE* has 26 different phrase category prefixes (S, NP, etc.). The additional tags encoding grammatical function and parent node information results in much larger numbers of nonterminals. One of the aims

of partition search is to reduce this number, preserving only useful distinctions. This section looks at nonterminal distinctions that were preserved and eliminated for each task and grammar.

3.7.1. Base grammar *BARE* (functional tags only)

Twelve of the 26 phrase categories are not annotated with functional tags in the WSJC. The remaining 14 phrase categories have between 2 and 28 grammatical function subcategories[12].

In the *BARE* grammar, more nonterminals were merged on average in the NP chunking task (32.2 remaining) than in the NP identification task (37.6 remaining). This is as might be expected since the NP identification task looks the more complex.

Results for NP chunking show a very strong tendency to merge the subcategories of all phrase categories except for two: NP and PP. With only the rare exception, the distinction between different grammatical functions is eliminated for the other 12 out of 14 phrase categories. By contrast, for NP, between 2 and 5 different categories remain (average 2.8), and for PP, between 2 and 4 remain (average 3.6). This implies that for NP chunking only the different grammatical functions of NPs and PPs are useful.

Results for NP identification show a tendency to perserve distinctions among the subcategories of SBAR, NP and PP and to a lesser extent among those of ADVP and ADJP. Other distinctions tend to be eliminated. All subcategories of `SBARQ`, `NX`, `NAC`, `INTJ` and `FRAG` are always merged, `UCP` and `SINV` nearly always.

3.7.2. Grammar *PN* (parent node tags)

The *PN* grammar has 970 phrase subcategories for the 26 basic phrase categories of which only those with the largest numbers of subcategories are examined here: NP (173), PP (173), ADVP (118), S (76), and VP (62).

Surprisingly, far fewer nonterminals were merged on average in the NP chunking task (446 remaining) than in the NP identification task (only 119.4 remaining).

In both tasks, although more so in the NP chunking task, the strongest tendency was that far more NP subcategories were preserved than any other.

In the NP identification task, the different NAC and NX subcategories were always merged into a single one, whereas in the NP chunking task, at least 4 different NAC and 3 different NX subcategories remained.

In both tasks equally, ADVP and PP distinctions were mostly eliminated. The same goes for VP distinctions although VPs with parent node S, SBAR and VP had a higher tendency to remain unmerged.

These results indicate that by far the most important parent node information for both NP identification and chunking are the parent nodes of the NPs themselves. More detailed analysis of merge sets would be needed to see what exactly this means.

[12] `ADJP`: 6, `ADVP`: 18, `FRAG`: 2, `INTJ`: 2, `NAC`: 4, `NP`: 23, `NX`: 2, `PP`: 28, `S`: 14, `SBAR`: 20, `SBARQ`: 3, `SINV`: 2, `UCP`: 8, `VP`: 3.

4. Conclusions and Further Research

Grammar Learning by Partition Search was shown to be an efficient method for constructing PCFGs optimised for a given parsing task. In the nonlexicalised applications reported in this paper, the performance of the base grammar was improved by up to 3.48%. This corresponds to an improvement of up to 21.45% over the standard baseline. The result for NP chunking is slightly better than the best existing result for nonlexicalised NP chunking, whereas the result for NP identification closely matches the best existing result for lexicalised NP identification.

Partition Search can also be used to simply reduce grammar size, if an existing grammar is used as the Max Grammar. In the experiments reported in this paper, Partition Search reduced the size of nonterminal sets by up to 93.5%, and the size of rule sets by up to 27.4%. Compared to other grammar compression techniques, it has the advantage of being lossless.

Further research will look at additionally incorporating lexicalisation, other search methods, and other variable parameter combinations.

Abstract

This study presents an integration of Simple Recurrent Networks to extract grammatical knowledge and Vector-Based Semantic Analysis to acquire semantic information from large corpora. Starting from a large, untagged sample of English text, we use Simple Recurrent Networks to extract morpho-syntactic vectors in an unsupervised way. These vectors are then used in place of random vectors to perform Vector-Space Semantic Analysis. In this way, we obtain rich lexical representations in the form of high-dimensional vectors that integrate morpho-syntactic and semantic information about words. Apart from incorporating data from the different levels, we argue how these vectors can be used to account for the particularities of each different word token of a given word type. The amount of lexical knowledge acquired by the technique is evaluated both by statistical analyses comparing the information contained in the vectors with existing 'hand-crafted' lexical resources such as CELEX and WordNet, and by performance in language proficiency tests. We conclude by outlining the cognitive implications of this model and its potential use in the bootstrapping of lexical resources

1. Introduction

Collecting word-use statistics from large text corpora has proven to be a viable method for automatically acquiring knowledge about the structural properties of language. The perhaps most well-known example is the work of George Zipf, who, in his famous *Zipf's laws* (Zipf, 1949), demonstrated that there exist fundamental statistical regularities in language. Although the useability of statistics for extracting structural information has been widely recognized, there has been, and still is, much scepticism regarding the possibility of extracting semantic information from word-use statistics. We believe that part of the reason for this scepticism is the conception of meaning as something external to language — as something *out there* in the world, or as something *in here* in the mind of a language user. However, if we instead adopt what we may call a "Wittgensteinian" perspective, in which we do not demand any rigid definitions of word meanings, but rather characterize them in terms of their use and their "family resemblance" (Wittgenstein, 1953), we may argue that word-use statistics provide us with exactly the right kind of data to facilitate semantic knowledge acquisition. The idea, first explicitly stated in Harris (1968), is that the meaning of a word is related to its distributional pattern in language. This means that if two words frequently occur in similar context, we may assume that they have similar meanings. This assumption is known as "the Distributional Hypothesis," and it is the ultimate rationale for statistical approaches to semantic knowledge acquisition, such as Simple Recurrent Networks or Vector-Based Semantic Analysis.

1.1. Simple Recurrent Networks

Simple Recurrent Networks (SRN; Elman, 1990) are a class of Artificial Neural Networks consisting of the three traditional 'input', 'hidden' and 'output' layers of units, to which one additional layer of 'context' units is added. The basic architecture of an SRN is shown in Figure 1. The outputs of the 'context' units are connected to the inputs of the 'hidden' layer as if they formed and additional 'input' layer. However instead of receiving their activation from outside, the activations of the 'context' layer at time step n are a copy of the activations of the 'hidden' layer at time step $n-1$. This is achieved by adding simple, one-to-one 'copy-back' connections from the 'hidden' layer into the 'context' layer. In contrast to all the other connections in the network, these are special in that they are not trained (their weights are fixed at 1), and in that they perform a raw copy operation from a hidden unit into a context unit, that is to say, they employ the identity function as the activation function. Networks of this kind combine the advantages of recurrent networks, their capability of maintaining a history of past events, with the simplicity of multilayer perceptrons as they can be trained by the backpropagation algorithm.

Elman (1993) trained an SRN on predicting the next word in a sequence of words, using sentences generated by an artificial grammar, with a very limited vocabulary (24 words). He showed that a network of this class, when trained on a word prediction task and given the right training strategy (see (Rohde and Plaut, 2001) for further discussion of this issue), acquired various grammatical properties such as verbal inflection , plural inflection of nouns, argumental structure of verbs or grammatical category. More-

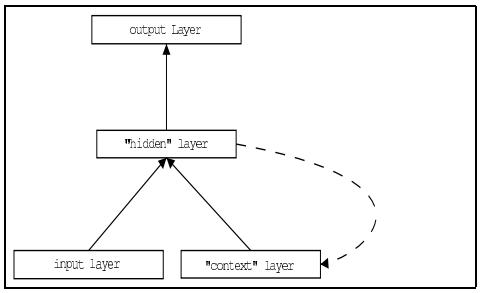

Figure 1: Modular architecture of a Simple Recurrent Network. The boxes correspond to layers of units. The solid arrows represent sets of trainable 'all-to-all' connections between the units in two layers. The dashed arrow stands a for fixed 'one-to-one' not trainable connection between two layers. These connections have the function of copying the activation of the hidden units into the context units at every time step.

over, the activations of the hidden units of the network provided detailed, token-specific characterizations of the morpho-syntactic properties of a word. Moscoso del Prado and Baayen (2001) showed how this method can be extended to deal with the large vocabulary sizes of realistic corpora. They trained a network akin to those of (Rohde and Plaut, 1999; Elman, 1993) on a word prediction task, using moderately large corpora of written English and Dutch (approximately 700,000 tokens of English and 4,500,000 of Dutch). The hidden units again provided rich representations of the morpho-syntactic properties of the words, containing information ranging from grammatical category, to subtle inflectional details such as verbal inflection or adjective gender. Moreover, the network had also captured some semantic properties of words, namely semantic properties that can be inferred from syntactic properties such as argumental structure.

1.2. Vector-Based Semantic Analysis

While SRN's appear to be more sensitive towards syntactic features, vector-space models have been used for over a decade to acquire and represent semantic information about words, documents and other linguistic units. This is done by collecting co-occurrence information in a words-by-contexts matrix F where each row F_w represents a unique word and each column F_c represents a context, which can either be a multi-word segment such as a document or another word. Latent Semantic Analysis/Indexing (LSA/LSI; Deerwester et al., 1990; Landauer and Dumais, 1997) uses document-based co-occurrence statistics, while Hyperspace Analogue to Language (HAL; Lund et al., 1995) and Schutze (1992) use word-based statistics. The cells of the matrix indicate the (weighted and/or normalized) frequency of ocurrence in, or co-occurrence with, the co-occurrence context (i.e. documents or words). Vector-space models generally also use some form of dimension reduction to reduce the computational strains of dealing with the rather ungainly co-occurrence matrix. LSA uses Singular Value Decomposition (SVD) and HAL uses a "column variance method," which consists in discarding the columns with lowest variance. This reduces the dimensionality of the co-occurrence matrix to a fraction of its original size. linguistic units are thus represented in the final reduced matrix by semantic vectors of n dimensionality. LSA is reported to be optimal at $n = 300$ (Landauer and Dumais, 1997), HAL at $n = 200$ (Lund et al., 1995), while Schutze (1992) use $n = 20$. A different approach to create the vector-space is Random Indexing (Kanerva et al., 2000; Karlgren and Sahlgren, 2001), which avoids the inefficient and inflexible dimensionality reduction phase by using high-dimensional sparse, random *index vectors* to accumulate a words-by-contexts matrix in which words are represented by high-dimensional (i.e. n is in the order of thousands) *context vectors*.

Vector-space methodology has been empirically validated in a number of experiments as a viable technique for the automatic extraction of semantic information from raw, unstructured text data. For example, Landauer and Dumais (1997) report a result on a standardized vocabulary test (TOEFL; Test of English as a Foreign Language) that is comparable to the average performance of foreign (non-English speaking) applicants to U.S. colleges (64.4% vs. 64.5% correct answers to the TOEFL). Sahlgren (2001), showed that similar performance (64.5% – 67%) may be obtained by using distributed representations in the Random Indexing technique that eliminates the need for the computationally expensive SVD, and he also demonstrated that the performance may be further enhanced (72% correct answers) by taking advantage of explicit linguistic information (morphology). Further empirical evidence can be found in, for example, (Lund and Burgess, 1996), who used semantic vectors to model reaction times from lexical priming studies, and from (Landauer and Dumais, 1997), who used LSA for evaluating the quality of content of student essays on given topics. Thus, it appears to be beyond doubt that the vector-space methodology really is able to form high-quality semantic representations by using such a simple souce of information as plain co-occurrence statistics. In the remainder of this paper, we will use the label *Vector-Based Semantic Analysis* to denote the practice of using co-occurrence information to construct vectors representing linguistic units in a high-dimensional semantic space.

2. Goal of the paper

In this study, we integrate two techniques to automatically obtain distributed lexical representations from corpora encoding morpho-syntactic and semantic information simultaneously. A hybrid technique such as the one that we describe here has several advantages. First, it requires a minimum of preexisting lexical resources, as it depends only on raw corpora. There is no need for taggers or parsers which, for many languages, may be unavailable.

Second, in contrast to other approaches that exploit word co-occurrences, our method keeps computational costs under control, as we avoid having to deal with huge co-occurrence matrices and we do not need to apply dimensional reduction techniques such as Singular Value Decomposition or Principal Component Analysis. The use of such dimensional reduction techniques imposes important limi-

tations on the extension of existing resources, as the addition of a new item would requires that a new reduced similarity space is calculated. In contrast, both SRN and the VBSA technique allow for the direct inclusion of new data. Another important advantage of our approach is that lexical representations become dynamic in nature: each token of a given type will have a slightly different representation.

We produce explicit measures of reliability that are directly associated to each distance calculated by our method. This is particularly useful for extending existing lexical resources such as computational thesauri.

In what follows, we introduce the corpus employed in the experiment, together with the SRN and VBSA techniques that we used. We then evaluate the grammatical knowledge encoded in the distributed representations obtained by the model. We subsequently evaluate the semantic knowledge contained in the system by means of scores on language proficiency tests (TOEFL), comparison with synonyms in WordNet, and a comparison of the properties of morphological variants. We conclude by discussing the possible application of this technique to bootstrap lexical resources from untagged corpora and the cognitive implications of these results.

3. The Experiment

3.1. Corpus

For the training of the SRN network, we used the texts corresponding to the first 20% of the British National Corpus; by first we mean that we selected the files following the order of directories, and we included the first two directories in the corpus. This corresponds to roughly 20 million tokens. To allow for comparison with the results from (Sahlgren, 2001), which were based on a 10 million word corpus, only the first half of this subset was used in the application of the VSBA technique.

Only a naive preprocessing stage was performed on the original SGML files. This included removing all SGML labels from the corpus, converting all words to lower case, substituting all numerical tokens for a $[num]$ token and separating hyphenated compound words into three different tokens ($first\ word + [hyphen] + second\ word$). All tokens containing non alphabetic characters different from the common punctuation marks were removed from the corpus. Finally, to reduce the vocabulary size, all tokens that were below a frequency threshold of two, were substituted by an $[unknown]$ token.

3.2. Design and training of the SRN

The Simple Recurrent Network followed the basic design shown in Figure 1. We used a network with 300 units in the input and output layers, and 150 units in the hidden and context layers. To allow for representation of a very large number of tokens, we used the semi-localist approach described in (Moscoso del Prado and Baayen, 2001) with a code of three random active units per word. On the one hand, this approach is close to a traditional style one-bit-per-word localistic representation in that the vectors of two different words will be nearly orthogonal. The small deviation from full orthogonality between representations has an effect similar to the introduction of a small amount of random noise, which actually speeds up the learning process. On other the hand, using semi-distributed input/output representations allows us to represent a huge number of types (a maximum of $\binom{300}{3} = 4,455,100$ types), while keeping the size of the network moderately small.

The sentences of the corpus were grouped into 'examples' of five consecutive sentences. At each time step, a word was presented to the input layer and the network would be trained to predict the following word in the output units. The corpus sentences were presented word by word in the order in which they appear. After every five sentences (a full 'example'), the activation of the context units was reset to 0.5. Imposing limitations on the network's memory on the initial stages of training is a pre-requisite for the networks to learn long distance syntactic relations (Elman, 1993; cf., Rohde and Plaut, 2001; Rohde and Plaut, 1999). We implemented this 'starting small' strategy by introducing a small amount of random noise (0.15) in the output of the hidden units, and by gradually reducing to zero during training. At the same time that the random noise in the context units was being reduced, we also gradually reduced the learning rate, starting with a learning rate of 0.1 and finished training with a learning rate of 0.4. Throughout training, we used a momentum of 0.9.

Although the experiments in (Elman, 1993) used the traditional backpropagation algorithm, using the mean square error as the error measure to minimize, following (Rohde and Plaut, 1999) we substituted the training algorithm for a modified momentum descent using cross-entropy as our error measure,

$$\sum_i \left[t_i \log \left(\frac{t_i}{o_i} \right) + (1 - t_i) \log \left(\frac{1 - t_i}{1 - o_i} \right) \right] \qquad (1)$$

Modified momentum descent enables stable learning with very aggressive learning rates as the ones we use. The network was trained on the whole corpus of 20 million for one epoch using the *Light Efficient Network Simulator* (LENS; Rohde, 1999).

3.3. Application of VBSA technique

Once the SRN had been trained, we proceeded to apply the Vector Based Semantic Analysis technique. Sahlgren (2001) used what he called 'random labels'. These were sparse 1800 element vectors, in which, for a given word type, only a small set of randomly chosen elements would be active (± 1.0), while the rest would be inactive. Once these initial labels had been created, the corpus was processed in the following way. For each token in the corpus, the labels of the s immediately preceding or following tokens were added to the vector of the word (all vectors were initialized to a set of 0's). The addition would be weighted giving more importance to the closer word in the window. Words outside a frequency range of $(3 - 14,000)$ are not included in these sums. This range excludes both the very frequent types, typically function words, and the least frequent types, about which there is not enough information to provide reliable counts. Optimal results are obtained with a window size ($s = 3$), that is, by taking into account the three preceeding and following words to a given token.

In order to reduce sparsity, Sahlgren used a lemmatizer to unify tokens representing inflectional variants of the same root. Sahlgren had also observed that the inclusion of explicit syntactic information extracted by a parser did not improve the results, but led to lower performance. We believe that this can be partly due to the *static* character of the syntactic information that was used. We therefore use a *dynamic* coding of syntactic information, which is more sensitive to the subtle changes in grammatical properties of each different instance of a word.

In our study, we substituted the knowledge-free random labels of (Sahlgren, 2001) by the dynamic context-sensitive representations of the individual tokens as coded in the patterns of activations of our SRN. Thus each type is represented by a slightly different vector for each different grammatical context in which it appears. To obtain these representation, we presented the text to the SRN and used the activation of the hidden units to provide the dynamic labels for VBSA

We then used a symmetric window of three words to the left and right of every word. We fed the text again through the neural network in test mode (no weight updating), and we summed the activation of the hidden units of the network for each of the words in the context window that fall within a frequency range of 8 and $30,000$ in the original corpus (the one that was used for the training of the neural network). In this way we excluded low frequency words about which the network might be extremely uncertain, and extremely high frequency function words. We used as weighting schema $w = 2^{1-d}$, were w is the weight for a certain position in the window, and d is the distance in tokens from that position to the center of the window. For instance, the label of the word following the target would be added with a weight $w = 2^{1-1} = 1$ and the label of the word occupying the leftmost position in the window would have a weight $w = 2^{1-3} = 0.25$. When a word in the window was out of the frequency range, its weight was set to 0.0. Punctuation marks were not included in window positions.

4. Results

4.1. Overview of semantics by nearest neighbors

We begin our analysis by inspecting the five nearest neighbors for a given word. Some examples can be found in Table 4.1. To calculate the distances between words, we use normalized cosines (Schone and Jurafsky, 2001). Traditionally, high dimensional lexical vectors have been compared using metrics such as the cosine of the angle between the vectors or the classical Euclidean distance metric or the city-block distance metric. However, using a fixed metric on the components of the vectors induces undesirable effects pertaining to the centrality of representations. More frequent words tend to appear in a much wider range of contexts. When the vectors are calculated as an average of all the tokens of a given type, the vectors or more frequent words will tend to occupy more central positions in the representational space. They will tend to be nearer to all other words, thus introducing an amount of relativity in the distance values. In fact, we believe that this relativity actually reflects people's understanding of word meaning. For example, if we considered the most similar words to a frequent word such as "bird", we would find words as "pigeon" to be very related in meaning. A word such as "penguin" would be considered a more distantly related word. However, if we examined the nearest neighbors of "penguin", we would probably find "bird" among them, although the standard distance measure would still be high. A way to overcome this problem is to place word distances inside a normal distribution, taking into account the distribution of distances of both words. Consider the classical cosine distance between two vectors $\mathbf{v}$ and $\mathbf{w}$:

$$d_{\cos}(\mathbf{v}, \mathbf{w}) = 1 - \frac{\mathbf{v} \cdot \mathbf{w}}{||\mathbf{v}|| \, ||\mathbf{w}||}. \quad (2)$$

For each vector $\mathbf{x} \in \{\mathbf{v}, \mathbf{w}\}$ we calculate the mean ($\mu_{\mathbf{x}}$) and standard deviation ($\sigma_{\mathbf{x}}$) of its cosine distance to 500 randomly chosen vectors of other words. This provides us with an estimate of the mean and standard deviation of the distances between $\mathbf{x}$ and all other words. We can now define the normalized cosine distance between two vectors $\mathbf{v}$ and $\mathbf{w}$ as:

$$d_{norm}(\mathbf{v}, \mathbf{w}) = \max_{\mathbf{x} \in \{\mathbf{v}, \mathbf{w}\}} \left(\frac{d_{\cos}(\mathbf{v}, \mathbf{w}) - \mu_{\mathbf{x}}}{\sigma_{\mathbf{x}}} \right). \quad (3)$$

To speed up this process, the cosine distance means and standard deviation for all words were pre-calculated in advance and stored as part of the representation. The use of normalized cosine distance has the effect of allowing for direct comparisons of the distances between words. In our previous example the distance between "bird" and "penguin", according to a non-normalized metric would suffer from the eccentricity of "penguin"; with the normalization, as the value of the distance would be normalized with respect to "penguin" (the maximum), it would render a value similar to the distance between "bird" and "pigeon".

4.2. Grammatical knowledge

Moscoso del Prado and Baayen (2001) showed that the hidden unit representations of SRN's similar to the one we used here contain information about morpho-syntactic characteristics of the words. In the present technique this information is implicitly available in the input labels for the VBSA technique. The VBSA component however, does not guarantee the preservation of such syntactic information. We therefore need to ascertain whether the grammatical knowledge contained in the SRN vectors is preserved after the application of VBSA.

Note that in Table 4.1., the nearest neighbors of a given word tend to have similar grammatical attributes. For example, plural nouns have other plural nouns as nearest neighbors, e.g., "foreigners" - "others", "outsiders", etc., and verbs tend to have other verbs as nearest neighbors, e.g., "render" - "expose", "reveal", etc. Although the nearest neighbors in Table 4.1. clearly suggest that morpho-syntactic information is coded in the representations, we need to ascertain how much morpho-syntactic information is present and, more importantly, how easily it might be made more explicit. We do this using the techniques proposed in (Moscoso del Prado and Baayen, 2001), that is we employ a machine learning technique using our vectors

Word	Nearest neighbors
hall	centre, theatre, chapel, landscape*, library
half	period, quarter, phase, basis, breeze*
foreigners	others, people, doctors, outsiders, unnecessary*
legislation	orders, contracts, plans, losses, governments
positive	splendid, vital, poetic, similar*, bad
slightly	somewhat, distinctly, little, fake*, supposedly
subjects	issues, films, tasks, substances, materials
taxes	debts, rents, imports, investors, money
render	expose, reveal, extend, ignoring*, develop
re-	anti-, non-, pro-, ex-, pseudo-
omitted	ignored, despised, irrelevant, exploited*, theirs*
Bach	Newton, Webb, Fleming, Emma, Dante

Table 1: Sample of 5 nearest neighbors to some words according to normalized cosine distance. Semantically unrelated words are marked by an asterisk

as input and symbolic grammatical information extracted from the CELEX database (Baayen et al., 1995) as output. A machine learning system is trained to predict the labels from the vectors. The rationale behind this method is very straightforward: If there is a distributed coding of the morpho-syntactic features hidden inside our representation, a standard machine learning technique should be able to detect it.

We begin by assessing whether the grammatical category of a word can be extracted from its vector representation. We randomly selected 500 words that were classified by CELEX as being unambiguously nouns or verbs, that is, they did not have any other possible label. The nouns were sampled evenly between singular an plural nouns, and the verbs were sampled evenly between infinitive, third person singular and gerund forms. Using TiMBL (Daelemans et al., 2000), we trained a memory based learning system on predicting whether a vector corresponded to a noun or a verb. We performed ten-fold cross-validation on the 500 vectors. The systems were trained using 7 nearest neighbors according to a city-block distance metric, the contribution of each component of the vectors weighted by Information Gain Feature Weighting (Quinlan, 1993). To provide a baseline against which to compare the results, we use a second set of files consisting of the same vectors but with random assignment of grammatical category labels to words. The average performance of the system of the Noun-Verb distinction was 68% (randomized averaged 56%). We compared the performance of the system with that of the randomized labels system using a paired two-tailed t-test on the result of each of the runs in the cross-validation, which revealed that the performance of the system was significantly higher than that of the randomized one ($t = 5.63$, $df = 9$, $p = 0.0003$).

We also tested for more subtle inflectional distinctions. We randomly selected 300 words that were unambiguously nouns according to CELEX, sampling evenly from singular and plural nouns. We repeated the test described in the previous paragraph, with the classification task this time being the differentiation between singular and plural. The average performance of the machine learning system was 65% (randomized averaged 48%). A paired two-tailed t-test comparing the results of the systems with the results of systems with the labels randomized revealed again a significant advantage for the non-random system ($t = 5.80$, $df = 9, p = 0.0003$). The same test was performed on a group of 300 randomly chosen unambiguous verbs sampled evenly among infinitive, gerund and third person singular forms, with these labels being the ones the system should learn to predict from the vectors. Performance in differentiating these verbal inflections was of 55% on average while the average of randomized runs was 33%, and significantly above randomized performance accoriding to a paired two-tailed t-test ($t = 4.25$, $df = 9$, $p = 0.0021$).

4.3. Performance in TOEFL synonyms test

Previous studies (Sahlgren, 2001; Landauer and Dumais, 1997) evaluated knowledge about semantic similarity contained in co-occurrence vectors by assessing their performance in a vocabulary test from the Test of English as a Foreign Language (TOEFL). This is a standardized vocabulary test employed by, for instance, American universities, to assess foreign applicants' knowledge of English. In the synonym finding part of the test, participants are asked to select which word is a synonym of another given word, given a choice of four candidates that are generally very related in meaning to the target. In the present experiment, we used the selection of 80 test items described in (Sahlgren, 2001), with the removal of seven test items which contained at least one word that was not present in our representation. This left us with 73 test items consisting of a target word and four possible synonyms. To perform the test, for each test item, we calculated the normalized cosine distance between the target word and each of the candidates, and chose as a synonym the candidate word that showed the smallest cosine distance to the target. The model's performance on the test was 51% of correct responses.

4.3.1. Reliability scores

The results of this test can be improved once we have a measure of the certainty with which the system considers the chosen answer to be a synonym of the target. What we need is a reliability score, according to which, in cases

where the chosen word is not close enough in meaning, i.e., its distance to the target is below a certain probabilistic threshold, the system would refrain from answering. In other words, the system would be allowed to give an answer such as: "I'm not sure about this one". Given that the values of the distances between words in our system, follow a normal distribution $\mathcal{N}(0,1)$, it is quite straightforward to obtain an estimate of the probability of the distance between two words being smaller than a given value, by just using the Normal distribution function $F(x)$. However, while the *general* distribution of distances between any two given words follows $\mathcal{N}(0,1)$, the distribution of the distances from a *particular* word to the other words does not necessarily follow this distribution. In fact they generally do not do so. This difference in the distributions of distances of words is due to effects of prototypicality and probably also word frequency (McDonald and Shillcock, 2001).

To obtain probability scores on how likely it is that a given word is at a certain distance from the target, we need to see the distance of this word *relative* to the distribution of distances from the target word to all other words in the representation. We therefore slightly modify 3, which takes the normalized distance between two words to be the maximum of the cosine distance normalized according to the distribution of distances to the first word, and the cosine distance normalized to the distribution of distances to the second word. We now define the cosine distance between two vectors $\mathbf{v}$ and $\mathbf{w}$ normalized relative to $\mathbf{v}$ as:

$$d^{\mathbf{v}}_{norm} = \frac{d_{\cos}(\mathbf{v},\mathbf{w}) - \mu_{\mathbf{v}}}{\sigma_{\mathbf{v}}}, \qquad (4)$$

which provides us with distances that follow $\mathcal{N}(0,1)$ for each particular word represented by a vector $\mathbf{v}$.

Using 4, we calculated the distance between the target words in the synonym test and the word that the system had selected as most similar, counting only those answers for which the system outputs a probability value below 0.18. The performance on the test increases from 51% to 71%, but the number of items reduced to 45. If we choose probability values below 0.18, the percentage correct continues to rise, but the number of items in the test drops dramatically. Having such a reliability estimator is useful for real-world applications.

4.4. Performance for WordNet synonyms

We can also use the WordNet (Miller, 1990) lexical database to further assess the amount of word similarity knowledge contained in our representations. We randomly selected synonym pairs from each of the four grammatical categories contained in WordNet: nouns, verbs, adjectives and adverbs. We calculated the normalized cosine distance for each of the synonym pairs. As expected, the median distances between synonymous words were clearly smaller than average distance. The median distances were -0.59 for verb synonyms, -0.53 for noun synonyms, -0.49 for adjective synonyms and -0.62 for adverbial synonyms. However, as we have already seen, our vectors contain a great deal of information about morpho-syntactic properties. Hence the fact that synonyms share the same grammatical category could by itself explain the small distances obtained for WordNet synonyms. To check whether this is the case, each synonym pair from our set was coupled with a randomly chosen baseline word of the same grammatical category, and we calculated the distance between one of the synonyms and the baseline word. In this case, as we were interested in the distance of the word relative only to one of the words in the pair, we calculated distances using 4. We compared the series of distances obtained for the true WordNet synonym pairs with the baseline distances by means of two-tailed t-tests. We found that WordNet synonyms were clearly closer in all the cases: nouns ($t = -5.30$, $df = 197$, $p < 0.0001$), verbs ($t = -4.60$, $df = 190$, $p < 0.0001$), adjectives ($t = -3.09$, $df = 195$, $p = 0.0023$) and adverbs ($t = -4.06$, $df = 188$, $p < 0.0001$). This shows that true synonyms were significantly closer in distance space than baseline words.

4.5. Morphology as a measure of meaning

Morphologically related words tend to be related both in form and meaning. This is true both for inflectionally related words, and derivationally related words. As morphological relations tend to reflect regular correspondences to slight changes in the meaning and syntax, they can be used for assessing the amount of semantic knowledge that has been acquired by our system. In what follows, we investigate whether our system is able to recognize inflectional variants of the same word, and whether the vectors of words belonging to the same suffixation class cluster together.

4.5.1. Inflectional morphology

We randomly selected 500 roots that were unambiguously nominal (they did not appear in the CELEX database under any other grammatical category) and for which both the singular and the plural form were present in our dataset. For each of the roots, we calculated the normalized cosine distance between the singular and plural forms. The median of the distance between singular and plural forms was -0.39, which already indicates that inflectional variants of the same noun are represented by similar vectors. As in the case of the WordNet synonyms, it could be argued that this below average distance is completely due to all these word pairs sharing the "noun" property. To ascertain that the observed effect on the distances was at least partly due to real similarities in meaning, each stem r_1 in our set was paired with another stem r_2 also chosen from the original set of 500 nouns. We calculated the normalized cosine distance between the singular form of r_1 and the plural form of r_2. In this way we constructed a data set composed of word pairs plus their normalized cosine distance. A linear mixed effect model (Pinheiro and Bates, 2000) fit to the noun data with normalized cosine distance as dependent variable, the 'stem' (same v. other) as independent variable and the root of the present tense form as random effect, revealed a main effect for stem-sharing pairs ($F(1,499) = 44.42$, $p < 0.0001$). The coefficient of the effect was -0.29 ($\hat{\sigma} = 0.043$). This indicates that the distances between pairs of nouns that share the same stem are in general smaller than the distance between pairs of words that do not share the same root but have the same number. Interestingly, according to a Pearson correlation, 65% of

the variance in the distances is explained by the model.

In the same way, we randomly selected 500 unambiguously verbal roots for which we had the present tense, past tense, gerund and third person singular present tense in our representation. The median normalized cosine distance between the present tense and the other forms of the verb was -0.48, so verbs seem to be clustered together somewhat more tightly than nouns. We repeated the test described above by random pairing of stems, but now we calculated the distances between the present tense form of r_1 and the rest of the inflected forms of r_2. We fit a linear mixed effect model with the normalized cosine distance between the pairs as dependent variable, the pair of inflected forms, i.e., *present-past*, *present-gerund*, or *present-third person singular*, and the 'stem' (same versus different) as independent variables and the root of the first verb as random effect. We found significant, independent effects for type of inflectional pair ($F(1, 2495) = 289.06$, $p < 0.0001$) and stem-sharing ($F(1, 2495) = 109.76$, $p < 0.0001$). The interaction between both independent variables was not significant ($F < 1$). The coefficient for the effect of sharing a root was -0.18 ($\hat{\sigma} = 0.017$), which again indicates that words that share a root have smaller distances than words that do not. It is also interesting to observe that the coefficients for the pairs of inflected forms also provide us with information of how similarly these forms are used in natural language, or, phrased in another way, how similar their meanings are. So, the value of the coefficient for pairs of present tense (uninflected) and past tense forms was -0.48 ($\hat{\sigma} = 0.21$) and the coefficient for pairs composed of a present tense uninflected form and a past tense was -0.38 ($\hat{\sigma} = 0.21$), which suggests that the contexts in which an un-inflected form is used are more similar to the contexts where a past tense form is used than to the contexts of a gerund. The model explained 43% of the variance according to a Pearson correlation.

4.5.2. Derivational morphology

Derivational morphology also captures regular meaning changes, although these changes are often not as regular as the ones that are carried out by inflectional morphology. We tested whether our system captures derivational semantics using the Memory-Based Learning technique that we used for evaluating grammatical knowledge in the system (see section 4.2.). Concentrating on morphological categories, i.e. on words that share the same outer affix. For instance "compositionality" belongs to the morphological category "-ity" and not to the category "-al", although it also contains the suffix "-al". Derivational suffixes generally effect both syntactic and semantic changes. To test whether our vectors reflect semantic regularities, we selected all words ending in the two derivational suffixes "-ist" and "-ness". Both of these suffixes produce nouns, but while the first one generates nouns that are considered agents of actions, the second generates abstract ideas. These affixes generate words with the same grammatical category, but with different semantics. We trained a TiMBL system on predicting the morphological category of the vectors, that is, to predict "-ist" or "-ness". The average performance of the system in predicting these labels in a ten-fold cross-validation was of 78% (compared to an average of 51% obtained when randomizing the affix labels). A paired two-sided t-test between the system performance at each run and the performance of a randomized system on the same run, revealed a significant improvement for the non random system ($t = 10.95$, $df = 9$, $p < 0.0001$).

Although performance was very good for these two nominal affixes, a similar comparison between the adjectival affixes "-able" and "-less", did not render significant differences between randomized and non-randomized labels, indicating that the memory-based learning system was not able to discriminate these two affixes on the sole basis of their semantic vectors. This indicates that, although some of the semantic variance produced by derivational affixes can be captured, many subtler details are being overlooked.

5. Discussion

The analyses that we have performed on the vectors indicate that a high amount of lexical information has been captured by the combination of an SRN with VBSA. On the one hand, the results reported in section 4.2. indicate that the morpho-syntactic information that is coded in the hidden units of a SRN is maintained after the application of VSBA. Moreover, it is clear that the coding of the morpho-syntactic features can be extracted using a standard machine-learning technique such as Memory-Based Learning. This, by itself can be of great use in the bootstrapping of language resources. Given a fairly small set of words that have received morpho-syntactic tags, it is possible to train a machine learning system to identify these labels from their vectors, and then apply this to the vectors of words that are yet to receive morpho-syntactic tagging. Importantly, our technique relies only on word-external order and co-occurrence information, but does not make use of word-internal form information. As it it is evident that word-form information such as presence of inflectional affixes is crucial for morpho-syntactic tagging, our technique can be used to provide a confirmation of possible inflectional candidates. For instance, suppose that two words such as "rabi" and "rabies" are found in a corpora, one would be inclined to classify them as singular and plural version of the same word, when in fact they are both singular forms. The inflectional information in our vectors could be used to disconfirm this hypothesis. In this same aspect, the fact that inflectional variants of the same root tend to be very related in meaning could be used as additional evidence to reject this pair as being inflectional variants.

On the other hand, the nearest neighbors, the TOEFL scores, the results on detecting inflectionally and derivationally related words, and the results on the WordNet synonyms, provide solid evidence that the vectors have succeeded in capturing a great deal of semantic information. Although it is clear to us that our technique needs further fine-tuning, the results are already surprising given the constraints that have been imposed on the system. For instance, the performance on the TOEFL test (51% without the use of the Z scores) is certainly lower than many results that have been reported in the literature. Sahlgren (2001), using the Random Indexing approach to VBSA with random vectors reports 72% correct responses on the same test items. However, he was using a tagged corpus

where all inflectional variants had been unified under the same type. Without the use of stemming, the best performance he reports is of 68%. In the current approach we have used vectors of 150 elements, that is, less than 10% of the size of the vectors used by Sahlgren, and much smaller than the vectors needed to apply techniques such Hyperspace Analog to Language (Lund et al., 1995; Lund and Burgess, 1996) or Latent Semantic Analysis (Landauer and Dumais, 1997) which need to deal with huge co-occurrence matrices. Given the computational requirements of using such huge vectors, we consider that our method provides a good alternative. Our result of 51% on the TOEFL test is clearly above chance performance (25%) and not that far from the results obtained by average foreign applicants to U.S. universities (64.5%). Interestingly, Landauer and Dumais (1997) reported a 64.4% performance on these test items using LSA, but this was only after the application of a dimensional reduction technique (SVD) to their original document co-occurrence vectors. Before the application of SVD, they report a performance of 36% on the plain normalized vectors. Of course, a technique such as SVD could be subsequently applied to the vectors obtained by our method, probably leading to some improvement in our results. However, given that our vectors already have a moderate size, and especially, given that, in their current state, one does not need to re-compute them to add information contained in new corpora, we do not favor the use of such techniques.

Regarding the evaluation of the system against synonym pairs extracted from the WordNet database, although the vectors represent synonyms as being more related than average, it still seems that most of the similarity in these cases was due to morpho-syntactic properties (the average difference in distances between the synonym and baseline conditions was always smaller than 0.1). We believe this is due to several factors. WordNet synonym sets (*synsets*) contain an extremely rich amount of information, that may be too rich for the purposes of evaluating our current vectors. First, many WordNet synonyms correspond to plain spelling variants of the same word in British and American English, e.g., "analyze"-"analise". Our whole training corpus was composed of British English, so the representation of words in American spelling is probably not very accurate. Second, and more importantly, given that the synsets encoded in WordNet reflect in many cases rare or even metaphoric uses of words, we think that the evaluation based on the average type representations provided by our system are not the most appropriate to detect these relations. Possibly, evaluating these synonyms against the vectors corresponding to the particular tokens referring to those senses might be more appropriate. An indication of this is also given by the TOEFL scores, which reflect that the meaning differences can still be detected in many cases. This is important because the synonyms pairs chosen in the TOEFL test, generally reflect the more standard senses of the words involved.

Another important issue is the difference between meaning *relatedness* and meaning *similarity*. These are two different concepts that appear to be somewhat confounded. While our representations reflect in many cases similarity relations, e.g, synonymy, they also appear to capture many relatedness and general world knowledge relations, for instance, the three nearest neighbors of "student" are "university" "pub" and "study", none of which is similar in meaning to "student", but all of them bearing a strong relationship to it. Sahlgren (2001) argues that using a small window to compute the co-occurrences (3 elements to each side, as compared to the 10 elements used in (Burgess and Lund, 1998)), has the effect of concentrating on similarity relations instead of relatedness, which would need much larger contexts such as the full documents used in LSA. The motivation to use very small context windows was to provide an estimation of the syntactic context of words. However, since syntactic information is already made more explicit by our SRN this may not be necessary in our case, and using larger window sizes might actually improve our performance both in similarity and relatedness. A further improvement that should be added to our vectors should come from the inclusion of word internal information. In a pilot experiment we have used the VBSA technique using (automatically constructed) distributed representations of the formal properties of words instead of the random labels. Performance on the TOEFL test were in the same range that was reported here (49%). This suggest that a combination of the technique described here with the formal vectors could probably provide much more precise semantic representations, exploiting both word internal and internal sources of information. This is also in line with the improvement of results found by (Sahlgren, 2001) when using a stemming technique. The use of formal vectors provides an interesting alternative, as it would supply implicit stemming information to the system.

In this paper, we have presented a representation that encodes jointly morpho-syntactic and semantic aspects of words. We have also provided evidence on how morphology is an important cue to meaning, and vice-versa, meaning is also an important cue to morphology. This corroborates previous results from (Schone and Jurafsky, 2001). The idea of integrating formal, syntactic and semantic knowledge about words in one single representation is currently gaining strength within the psycholinguistic community (Gaskell and Marslen-Wilson, 2001; Plaut and Booth, 2000). Some authors are considering morphology as the "convergence of codes", that is, as a set of quasi-regular correspondences between form and meaning, that would probably be linked at a joint representation level (Seidenberg and Gonnerman, 2000). Clear evidence of this strong link has also been put forward by (Ramscar, 2001) showing that the choice of regular or non-regular past tense inflection of a nonce verb is strongly influenced by the context in which the nonce verb appears. If the word appears in a context which entails a meaning similar to that of an irregular verb that is also similar in form to the nonce word, e.g. "frink" - "drink", participants form its past tense in the same manner as the irregular form, e.g., "frank" from "drank". If it appears in a context alike to a similar regular verb, e.g, "wink", participants inflect in regularly, e.g. "frinked" from "winked". Crucially, the meaning of this form is totally determined by context. This in line with the results of (McDonald and Ramscar, 2001), which show how

the meaning of a nonce word is modulated by the context in which it appears. In this respect, our vectors constitute a first approach to such kind of representation: they include contextual and syntactic information. A further step will be the inclusion of word form information in this system, which is left for future research. Our lexical representations are formed by accumulation of predictions. On the one hand, several authors are currently investigating the strong role played by anticipation and prediction in human cognitive processing (e.g., Altmann, 2001). On the other hand, some current models of human lexical processing include the notion of accumulation, generally by recurrent loops in the semantic representations (e.g., Plaut and Booth, 2000).

Acknowledgments We are indebted to Harald Baayen and Rob Schreuder for helpful discussion of the ideas and techniques described in this paper.

The first author was supported by the Dutch Research Council (NWO) through a PIONIER grant awarded to R. Harald Baayen. The second author is funded through the DUMAS project, supported by the European Union IST Programme (contract IST-2000-29452).

Detection of Errors in PoS-Tagged Corpora by Bootstrapping Generalized Negative *n*-grams

Pavel Květoň and Karel Oliva

Abstract

This paper presents two simple yet in practice very efficient bootstrapping techniques serving for automatic detection of those positions in a part-of-speech tagged corpus where an error is to be suspected. The first approach is based on the idea of stepwise learning and application of "negative bigrams", i.e. on the search for pairs of adjacent tags which constitute an incorrect configuration in a text of a particular language (in English, e.g., the bigram *ARTICLE - FINITE VERB*). As the second technique, the paper describes the stepwise generalization of the "negative bigrams" into "negative *n*-grams" (for increasing $n \in N$) which indeed provides a powerful tool for error detection in a corpus. The evaluation of results of the approach when used for error detection in the NEGRA corpus of German and the general implications for the quality of results of statistical taggers are also discussed. Illustrative examples in the text are taken from German, and hence at least a basic command of this language would be helpful for their understanding - due to the complexity of the necessary accompanying explanation, the examples are neither glossed nor translated. However, the central ideas of the paper should be understandable also without any knowledge of German.

1 Errors in PoS-Tagged Corpora

The importance of correctness (error-freeness) of language resources in general and of tagged corpora in particular cannot probably be overestimated. However, the definition of what constitutes an error in a tagged corpus depends on the intended usage of this corpus.

If we consider a quite typical case of a Part-of-Speech (PoS) tagged corpus used for training statistical taggers, then an error is defined naturally as any deviation from the regularities which the system is expected to learn; in this particular case this means that the corpus should contain neither errors in assignment PoS-tags nor ungrammatical constructions in the corpus body[1], since if any of the two cases is present in the corpus, then the learning process necessarily:

- gets a confused view of probability distribution of configurations (e.g., trigrams) in a correct text

and/or, even worse (and, alas, much more likely)

- gets positive evidence also about configurations (e.g., trigrams) which should not occur as the output of tagging linguistically correct texts, while simultaneously getting less evidence about correct configurations.

If we consider PoS-tagged corpora destinated for testing NLP systems, then obviously they should not contain any errors in tagging (since this would be detrimental to the validity of results of the testing) but on the other hand they should contain a certain amount of ungrammatical constructions, in order to test the behaviour of the tested system on a realistic input.

Both these cases share the quiet presupposition that the tagset used is linguistically adequate, i.e. it is sufficient for unequivocal and consistent assignment of tags to the source text[2].

As for using annotated corpora for linguistic research, it seems that even inadequacies in the tagset are tolerable provided they are marked off properly - in fact, these spots in the corpus might well be quite an important source of linguistic investigation since, more often than not, they constitute direct pointers to occurrences of linguistically "interesting" (or at least "difficult") constructions in the text.

2 Representativity

In corpus linguistics, the term representativity is understood as the representativity of a corpus wrt. kind of text or some phenomenon.

In this section, we intend to scrutinize the issue of representativity of a part-of-speech (PoS) tagged corpus wrt. to bigrams[3]. In this case, the phenomena[4] whose presence and relative frequency are at stake are:

- bigrams, i.e. pairs [First,Second] of tags of words occurring in the corpus adjacently and in this order
- unigrams, i.e. the individual tags.

We shall define the *qualitative representativity* wrt. bigrams as the kind of representativity meeting the following two complementary parts:

[1] In this paper we on purpose do not distinguish between "genuine" ungrammaticality, i.e. one which was present already in the source text, and ungrammaticality which came into being as a result of faulty conversion of the source into the corpus-internal format, e.g., incorrect tokenization, OCR-errors, etc.

[2] This problem might be – in a very simplified form – illustrated on an example of a tagset introducing tags for NOUNS and VERBS only, and then trying to tag the sentence *John walks slowly* - whichever tag is assigned to the word *slowly*, it is obviously an incorrect one. Natural as this requirement might seem, it is in fact not met fully satisfactorily in any tagset we know of; for more, cf. (Květoň and Oliva in prep.).

[3] The case of a trigrams, used more usual in tagging practice, would be almost identical but require more lengthy explanations. For the conciseness of argument, we limit the discussion to bigrams in most parts of the text.

[4] In an indeed broadly understood sense of the word "phenomenon".

- the representativity wrt. *the presence of all valid bigrams* of the language in the corpus, which means that if any bigram [First,Second] is a bigram in a correct sentence of the language, then such a bigram occurs also in the corpus - this part might be called *positive representativity*
- the representativity wrt. *the absence of all invalid bigrams* of the language in the corpus, which means that if any bigram [First,Second] is a bigram which cannot occur in a correct (i.e. grammatical) sentence of the language, then such a bigram does not occur in the corpus - this part might be called *negative representativity*.

If a corpus is both positively and negatively representative, then indeed it can be said to be a qualitatively representative corpus[5]. In our particular example this means that a bigram occurs in a qualitatively representative (wrt. bigrams) corpus if and only if it is a possible bigram in the language (and from this it already follows that any unigram occurs in such a corpus if and only if it is a possible unigram[6]). From this formulation, it is also clear that the qualitative representativity depends on the notion of grammaticality, that is, on the "language competence" – on the ability of distinguishing between a grammatical and an ungrammatical sentence.

The *quantitative representativity* of a corpus wrt. bigrams can then be approximated as the requirement that the frequency of any bigram and any unigram occurring in the corpus be in the proportion "as in the language performance" to the frequency of occurrence of all other bigrams or unigrams, respectively[7]. However, even when its basic idea is quite intuitive and natural, it is not entirely clear whether quantitative representativity can be formalized rigorously. At stake is measuring the occurrence of a bigram (and of a unigram) within the "complete language performance", understood as set of utterances of a language. This set, however, is infinite if considered theoretically (i.e. as set of all possible utterances in the language) and finite but practically unattainable if considered as a set of utterances realized within a certain time span (also, due to immanent language change, it is questionable whether the concept of set of utterances over a time span is a true performance of a single language). Notwithstanding these problems, the frequencies are used in practice (e.g., for the purpose of training statistical taggers), and hence it is useful to state openly what they really mean: in our example, it is the relative frequencies of the bigrams (and unigrams) in a particular (learning or otherwise referential) corpus. For this reason, since we would not like to be bound to a particular corpus, we refrain from quantitative representativity in the following and we shall deal only with qualitative representativity.

3 PoS-Tagging Errors Detection

In this (core) section, we shall concentrate on methods and techniques of generating "almost error-free" corpora, or, more precisely, on the possibilities of (semi-)automatic detection (and hence correction) of errors in a PoS-tagged corpus. Due to this, i.e. to the aim of achieving an "error-free" corpus, we shall not distinguish between errors due to incorrect tagging, faulty conversion or ill-formed input, and we shall treat them on a par.

The approach as well as its impact on the correctness of the resulting corpus will be demonstrated on the version 2 of the NEGRA corpus of German (for the corpus itself see www.coli.uni-sb.de/sfb378/negra-corpus, for description cf. (Skut et al. 1997)). However, we believe the solutions developed and presented in this paper are not bound particularly to correcting this corpus or to German, but hold generally.

The error search we use has several phases which differ in the amount of context that has to be taken into consideration during the error detection process. Put plainly, the extent of context mirrors the linguistic complexity of the detection, or, in other words, at the moment when the objective is to search for "complex" errors, the "simple(r)" errors should be already eliminated. The first, preliminary phase, is thus the search for errors which are detectable in the minimal local context of one neighbouring word.

3.1 Bootstrapping Impossible Bigrams

Our starting point is the search for "impossible bigrams". These as a rule occur in a realistic large-scale PoS-tagged corpus, for the following reasons:

- in a hand tagged corpus, an "impossible bigram" results from (and unmistakeably signals) either an ill-formed text in the corpus body (including wrong conversion) or a human error in tagging
- in a corpus tagged by a statistical tagger, an "impossible bigram" may result also from an ill-formed source text, as above, and further either from incorrect tagging of the training data (i.e. the error was seen as a "correct configuration (bigram)" in the training data, and was hence learned by the tagger) or from the process of so-called "smoothing", i.e. of assignment of non-zero probabilities also to configurations (bigrams, in the case discussed) which were not seen in the learning phase[8].

For learning the process of detecting errors in PoS-tagging, let us make a provisional and in practice unrealistic assumption (which we shall correct immediately) that we have a qualitatively representative (wrt. bigrams) corpus of sentences of a certain language at our disposal.

Given such a (hypothetical) corpus, all the bigrams in the corpus are to be collected to a set **CB** (correct bigrams), and then the complement of **CB** to the set of all possible bigrams is to be computed; let this set be called **IB** (incorrect bigrams). The idea is now that if any element of

[5] The definitions of positive and negative representativity are obviously easily transferable to cases with other definitions of a phenomenon. Following this, the definition of qualitative representativity holds of course generally, not only in the particular case of a corpus representative wrt. bigrams.

[6] This assertion holds only on condition that each sentence of the language is of length two (measured in words) or longer. Similarly, a corpus qualitatively representative wrt. trigrams is qualitatively representative wrt. bigrams and wrt. unigrams only on condition that each sentence is of length three at least, etc.

[7] From this it easily follows that any quantitatively representative corpus is also a qualitatively representative corpus.

[8] This "smoothing" is necessary in any purely statistical tagger since - put very simply - otherwise configurations (bigrams) which were not seen during the learning phase cannot be processed if they occur in the text to be tagged.

IB occurs in a PoS-tagged corpus whose correctness is to be checked, then the two adjacent corpus positions where this happened must contain an error (which then can be corrected).

When implementing this approach to error detection, it is first of all necessary to realize that learning the "impossible bigrams" is extremely sensible to both aspects of the qualitative representativity of the learning corpus:

- *the lack of negative representativity:* The presence of an erroneous bigram in the set of **CB** causes that the respective error cannot be detected in the corpus whose correctness is to be checked (even a single occurrence of a bigram in the learning corpus means correctness of the bigram),
- *the lack of positive representativity:* The absence of a correct bigram from the **CB** set causes this bigram to occur in **IB**, and hence any of its occurrences in the checked corpus to be marked as a possible error (absence of a bigram in the learning corpus means incorrectness of the bigram).

However, the available corpora are[9] - at least as a rule - not (qualitatively) representative. Therefore, in practice this deficiency has to be compensated for by appropriate means. When applying the approach to NEGRA, we employed

- bootstrapping for achieving positive representativity as good as possible on a given "training" corpus
- manual pruning of the **CB** and **IB** sets for achieving negative representativity.

We started by very careful hand-cleaning errors in a very small sub-corpus of about 80 sentences (about 1.200 words). From this small corpus, we generated the **CB** set, and pruned it manually, using linguistic knowledge (as well as linguistic imagination) about German syntax. Based on the **CB** set achieved, we generated the corresponding **IB** set and pruned it manually again. The resulting **IB** set was then used for automatic detection of "suspect spots" in the sample of next 500 sentences from the corpus, and for hand-elimination of errors in this sample where appropriate (obviously, not all **IB** violations were genuine errors !). Thus we arrived at a cleaned sample of 580 sentences, which we used just in the same way for generating **CB** set, pruning it, generating **IB** set and pruning this set, arriving at an **IB** set which we used for detection of errors in the whole body of the corpus (about 20.500 sentences, 350.000 positions).

The procedure was then re-applied to the whole corpus. For this purpose, we divided the corpus into four parts of approximately 5.000 sentences each. Then, proceeding in four rounds, first the **IB** set was generated (without manual checking) out of 15.000 sentences and then the **IB** set was applied to the rest of the corpus (on the respective 5.000-sentence partition). The corrections based on the results improved the corpus to such an extent that we made the final round, this time dividing the corpus into 20 partitions with approximately 1.000 sentences each and then reapplying the whole process 20 times.

[9] and will hardly ever become, disregarding their size: e.g., in the body of the 100.000.000 positions of the Czech National Corpus, we easily dicovered a case of a missing trigram (and there are most probably many more missing - we just did not search for them)

3.2 Bootstrapping Impossible *n*-grams

The "impossible bigrams" are a powerful tool for checking the correctness of a corpus, however, a tool which works on a very local scale only, since it is able to detect solely errors which are detectable as deviations from the set of possible pairs of adjacently standing tags. Thus, obviously, quite a number of errors remain undetected by such a strategy. As an example of such an as yet "undetectable" error in German we might take the configuration where two words tagged as finite verbs are separated from each other by a string consisting of nouns, adjectives, articles and prepositions only. In particular, such a configuration is erroneous since the rules of German orthography require that some kind of clause separator (comma, dash, coordinating conjunction) occur inbetween two finite verbs[10].

In order to be able to detect also such kind of errors, the above "impossible bigrams" have to be extended substantially. Searching for the generalization needed, it is first of all necessary to get a linguistic view on the "impossible bigrams", in other words, to get a deeper insight into the impossibility for a certain pair of PoS-tags to occur immediately following each other in any linguistically correct and correctly tagged sentence. The point is that this indeed does not happen by chance, that any "impossible bigram" comes into being as a violation of a certain - predominantly syntactic[11] - rule(s) of the language. Viewed in more detail, these violations might be of the following nature:

- *violation of constituency:* The occurrence of an "impossible bigram" in the text signals that - if the tagging were correct - there is a basic constituency relation violated (resulting in the occurrence of the "impossible bigram"); as an example of such configuration, we might consider the bigram PREPOSITION - FINITE VERB (possible German example string: *...für-PREP reiche-VFIN...*). From this it follows that either there is indeed an error in the source text (in our example, probably a missing word, e.g., *Der Sprecher der UNO-Hilfsorganisation teilte mit, für Arme reiche diese Hilfe nicht.*) or there was a tagging error detected (in the example, e.g., an error as in the sentence *... für reiche Leute ist solche Hilfe nicht nötig...*). The source of the error is in both cases violation of the linguistic rule postulating that, in German, a preposition must always be followed by

[10] At stake are true regular finite forms, exempted are words occurring in fixed collocations which do not function as heads of clauses. As an example of such usage of a finite verb form, one might take the collocation *wie folgt*, e.g., in the sentence *Diese Übersicht sieht wie folgt aus: ...* Mind that in this sentence, the verb *folgt* has no subject, which is impossible with any active finite verb form of a German verb subcategorizing for a subject (and possible only marginally with passive forms, e.g., in *Gestern wurde getanzt*, or – obviously – with verbs which do not subcategorize for a subject, such as *frieren, grauen* in *Mich friert, Mir graut vor Statistik*).

[11] Examples of other such violations are rare and are related mainly to phonological rules. In English, relevant cases would be the word pairs *an table, a apple*, provided the tagset were so fine-grained to express such a distinction, better examples are to be found in other languages, e.g. the case of the Czech ambiguous word *se*, cf. (Oliva to appear).

a corresponding noun (NP) or at least by an adjectival remnant of this NP[12].

- *violation of feature cooccurrence rules* (such as agreement, subcategorization, etc.): The point here is that there exist configurations such that if two wordforms (words with certain morphological features) occur next to each other, they necessarily stand in such a configuration, and because of this also in a certain grammatical relation. This relation, in turn, poses further requirements on the (morphological) features of the two wordforms, and if these requirements are not met, the tags of the two wordforms result in an "impossible bigram". Let us take an example again, this time with tags expressing also morphological characteristics: if the words ... *Staaten schickt* ... are tagged as *Staaten*-NOUN-MASC-PL-NOM and *schickt*-MAINVERB-PRES-ACT-SG, then the respective tags NOUN-MASC-PL-NOM and MAINVERB-PRES-ACT-SG (in this order) create an "impossible bigram". The reason for this bigram being impossible is that if a noun in nominative case occurs in a German clause headed by a finite main verb different from *sein/werden* (which, however, are not tagged as main verbs in the STTS tagset used in NEGRA), then either this noun must be the verb's subject, which in turn requires that the noun and the verb agree in number, or that the noun is a part of coordinated subject, in which case the verb must be in plural. The configuration from the example meets neither of these conditions, and hence it generates an "impossible bigram".

The central observation lies then in the fact that the property of being an impossible configuration can often be retained also after the components of the "impossible bigram" get separated by material occurring inbetween them. Thus, for example, in both our examples the property of being an impossible configuration is conserved if an adverb is placed inbetween, creating thus an "impossible trigram". In particular, in the first example, the configuration PREP ADV VFIN cannot be a valid trigram, exactly for the same reasons as PREP VFIN was not a valid bigram: ADV is not a valid NP remnant. In the second case, the configuration NOUN-MASC-PL-NOM ADV MAINVERB-PRES-ACT-SG is not a valid trigram either, since obviously the presence (or absence) of an adverb in the sentence does not change the subject-verb relation in the sentence. In fact, due to recursivity of language, also two, three and in fact any number of adverbs would not make the configuration grammatical and hence would not disturb the error detection potential of the "extended impossible bigrams" from the examples.

These linguistic considerations have a straightforward practical application. Provided a qualitatively representative (in the above ideal sense) corpus is available, it is possible to construct the **IB** set. Then, for each bigram *[First,Second]* from this set, it is possible to collect all trigrams of the form *[First,Between,Second]* occurring in the corpus, and collect all the possible tags *Between* in the set *Possible_Inner_Tags*. Furthermore, given the impossible bigram *[First,Second]* and the respective set *Possible_Inner_Tags*, the learning corpus is to be searched for all tetragrams *[First,Middle_1,Middle_2, Second]*. In case one of the tags *Middle_1, Middle_2* occurs already in the set *Possible_Inner_Tags*, no action is to be taken, but in case the set *Possible_Inner_Tags* contains neither of *Middle_1, Middle_2*, both the tags *Middle_1* and *Middle_2* are to be added into the set *Possible_Inner_Tags*. The same action is then to be repeated for pentagrams, hexagrams, etc., until the maximal length of sentence in the learn corpus prevents any further prolongation of the *n*-grams and the process terminates.

If now the set *Impossible_Inner_Tags* is constructed as the complement of *Possible_Inner_Tags* relatively to the whole tagset, then any *n*-gram consisting of the tag *First*, of any number of tags from the set *Impossible_Inner_Tags* and finally from the tag *Second* is very likely to be an *n*-gram impossible in the language and hence if it occurs in the corpus whose correctness is to be checked, it is to be signalled as a "suspect spot". Obviously, this idea is again based on the assumption of qualitative representativity of the learning corpus, so that for training on a realistic corpus the correctness of the resulting "impossible *n*-grams" has to be hand-checked. This, however, is well-worth the effort, since the resulting "impossible *n*-grams" are an extremely efficient tool for error detection. The implementation of the idea is a straightforward extension of the above approach to "impossible bigrams". The respective algorithm in a semi-formal coating looks like as in Fig 1.

The above approach does not guarantee, however, that all "impossible *n*-grams" are considered. In particular, any "impossible trigram" *[First,Second,Third]* cannot be detected as such (i.e. as impossible) if the *[First,Second]*, *[Second,Third]* and *[First,Third]* are all possible bigrams (i.e. they all belong to the set **CB**). Such an "impossible trigram" in German is, e.g., *[nominative-noun, main_verb,nominative-noun]* - this trigram is impossible[13] since no German verb apart from *sein/werden* (which, as said above, are not tagged as main verbs in NEGRA) can occur in a context where a nominative noun stands both to its right and to its left, however, all the respective bigrams occur quite commonly (e.g., *Johann schläft, Jetzt schläft Johann, König Johann schläft*). Here, an obvious generalization of the approach from "impossible bigrams" to "impossible trigrams" (and "impossible tetragrams", etc.) is possible, however, we did not perform this in full due to the amount of possible trigrams as well as to the data sparseness problem which, taken together, would make the manual work on checking the results unfeasible in practice. We rather applied only about 20 "impossible trigrams" and 6 "impossible tetragrams" stemming from "linguistic invention" (such as the trigram discussed above).As above, this empirical (performance-based) result has to be checked manually (through a human language competence) for correctness, since the performance results might be distorted by tagging errors or by lack of representativity of the corpus.

[12] unlike English, (standard) German has no preposition stranding and similar phenomena - we disregard the colloquial examples like *Da weiss ich nix von*.

[13] Exempted are quotations and other metalinguistic contexts, such as *Der Fluss heisst Donau, Peter übersetzte Faust - eine Tragödie ins Englische als Fist - one tragedy,* which, however, are as a rule lexically specific and hence can be coped with as such.

```
forall invalid_bigram [First, Second]
{ n := 3;
  possible_i_t := Ø;
  while n =< maximal_sentence_length_in_corpus
                do { find all inner-sentential n-grams [First, V1, V2, .., Vn-2, Second];
                     for each n-gram found
                         do if {V1, V2, .., Vn-2} ∩ possible _i_t = Ø
                              then allowed_i_t := possible _i_t U {V1, V2, .., Vn-2};
                     n := n + 1;
                   };
       impossible_i_t([First, Second]) := tagset - possible _i_t;
}
```

Figure 1: Algorithm for Bootstrapping Negative *n*-grams

The above approach does not guarantee, however, that all "impossible *n*-grams" are considered. For example, any "impossible trigram" *[First,Second,Third]* cannot be detected as such (i.e. as impossible) if the *[First,Second]*, *[Second,Third]* and *[First,Third]* are all possible bigrams (i.e. they all belong to the set **CB**). Such an "impossible trigram" in German is, e.g., *[nominative-noun, main_verb,nominative-noun]* - this trigram is impossible[14] since no German verb apart from *sein/werden* (which, as said above, are not tagged as main verbs via the STTS tagset used in NEGRA) can occur in a context where a nominative noun stands both to its right and to its left, however, all the respective bigrams occur quite commonly (e.g., *Johann schläft, Jetzt schläft Johann, König Johann schläft*). Here, an obvious generalization of the approach from "impossible bigrams" to "impossible trigrams" (and "impossible tetragrams", etc.) is possible, however, we did not perform this in full due to the amount of possible trigrams as well as to the data sparseness problem which, taken together, would make the manual work on checking the results unfeasible in practice. We rather applied only about 20 "impossible trigrams" and 6 "impossible tetragrams" stemming from "linguistic invention" (such as the trigram discussed above).

4 Evaluation of the Results

By means of the error-detection techniques described above, we were able to correct 2.661 errors in the NEGRA corpus. These errors were of all sorts mentioned in Sect. 1, however the prevailing part was that of incorrect tagging (only less than 8% were genuine source errors, about 26% were errors in segmentation). The whole resulted in changes on 3.774 lines of the corpus; the rectification of errors in segmentation resulted in reducing the number of corpus positions by over 700, from 355.096 to 354.354

After finishing the corrections, we experimented with training and testing the TnT tagger (Brants, 2000) on the "old" and on the "corrected" version of NEGRA. We used the same testing as described by Brants, i.e. dividing each of the corpus into ten contiguous parts of equal size, each part having parallel starting and end position in each of the versions, and then running the system ten times, each time training on nine parts and testing on the tenth part, and finally computing the mean of the quality results. In doing so, we arrived at the following results:

- if both the training and the testing was performed on the "old" NEGRA, the tags assigned by the TnT tagger differed from the hand-assigned tags within the test sections on (together) 11.138 positions (out of the total of 355.096), which yields the error rate of 3,14%
- if both the training and the testing was performed on the "correct" NEGRA, the tags assigned by the TnT tagger differed from the hand-assigned tags of the test sections on (together) 10.889 positions (out of the total of 354.354), which yields the error rate of 3,07%
- in the most interesting final experiment, the training was performed on the "old" and the testing on the "correct" NEGRA; in the result, the tags assigned by TnT differed from the hand-assigned tags in the test sections on (together) 12.075 positions (out of the total of 354.354), yielding the error rate of 3,41%.

These results show that there was only a negligible (and, according to the χ^2 test, statistically insignificant) difference between the results in the cases when the tagger was both trained and tested on "old" corpus and both trained and tested on the "corrected" corpus. However, the difference in the error rate when the tagger was once trained on the "old" and once on the "corrected" version, and then in both cases tested on the "corrected" version[15], brought up a relative error improvement of 9,97%. This improvement documents the old and hardly surprising truth that - apart from the size - also the correctness of the training data is absolutely essential for the results of a statistical tagger.

Conclusions

The main contribution of this paper lies in the presentation of a method for detecting errors in part-of-speech tagged corpus which is both quite powerful (as to coverage of errors) and - due to bootstrapping - easy to apply, and hence it offers a relatively low-cost means for achieving high-quality PoS-tagged corpora. The main advantage is that the approach described is based on the combination of focussed search for errors of a particular, specific type with bootstrapping of the search, which makes it possible to detect errors even in a very large corpus where manual checking would not be feasible (at least in practice), since it requires passing through the

[14] Exempted are quotations and other metalinguistic contexts, such as *Der Fluss heisst Donau, Peter übersetzte Faust - eine Tragödie ins Englische als Fist - one tragedy,* which, however, are as a rule lexically specific and hence can be coped with as such.

[15] For obvious reasons, we did not even consider training on the "corrected" corpus and testing on the "old" one.

whole of the text and paying attention to all kinds of possible violations - while the approach described concentrates on violations of particular phenomena on particular spots. Hence, it allows for straightforward checking whether an error really occurs - and if so, for a direct correction.

As a side-effect, it should be also mentioned that the method allows not for detecting errors only, but also for detecting inconsistencies in hand-tagging (i.e. differences in application of a given tagging scheme by different human annotators and/or in different time), and even inconsistencies in the tagging guidelines. A particular issue is further the area of detecting and tagging idioms and collocations, in the particular case when these take a form which makes them deviate from the rules of standard syntax (i.e. they are detected as "suspect spots" by the method). For details on all these points, including the particular problems encountered in NEGRA, cf. (Květoň and Oliva in prep.).

Abstract

Information Extraction systems offer a way of automating the discovery of information from text documents. Research and commercial systems use considerable training data to learn dictionaries and patterns to use for extraction. Learning to extract useful information from text data using only minutes of user time means that we need to leverage unlabeled data to accompany the small amount of labeled data. Several algorithms have been proposed for bootstrapping from very few examples for several text learning tasks but no systematic effort has been made to apply all of them to information extraction tasks. In this paper we compare a bootstrapping algorithm developed for information extraction, meta-bootstrapping, with two others previously developed or evaluated for document classification; cotraining and coEM. We discuss properties of these algorithms that affect their efficacy for training information extraction systems and evaluate their performance when using scant training data for learning several information extraction tasks. We also discuss the assumptions underlying each algorithm such as that seeds supplied by a user will be present and correct in the data, that noun-phrases and their contexts contain redundant information about the distribution of classes, and that syntactic co-occurrence correlates with semantic similarity. We examine these assumptions by assessing their empirical validity across several data sets and information extraction tasks.

1. Introduction

Information Extraction systems offer a way of automating the discovery of information from text documents. Both research and commercial systems for information extraction need large amounts of labeled training data to learn dictionaries and extraction patterns. Collecting these labeled examples can be very expensive, thus emphasizing the need for algorithms that can provide accurate classifications with only a a few labeled examples. One way to reduce the amount of labeled data required is to develop algorithms that can learn effectively from a small number of labeled examples augmented with a large number of unlabeled examples.

Several algorithms have been proposed for bootstrapping from very few examples for several text learning tasks. Using Expectation Maximization to estimate maximum a posteriori parameters of a generative model for text classification (Nigam et al., 2000), using a generative model built from unlabeled data to perform discriminative classification (Jaakkola and Haussler, 1999), and using transductive inference for support vector machines to optimize performance on a specific test set (Joachims, 1999) are some examples that have shown that unlabeled data can significantly improve classification performance, especially with sparse labeled training data. For information extraction, Yangarber et al. used seed information extraction template patterns to find target sentences from unlabeled documents, then assumed strongly correlated patterns are also relevant, for learning new templates. They used an unlabeled corpus of 5,000 to 10,000 documents, and suggest extending the size of the corpus used, as many initial patterns are very infrequently occurring (Yangarber et al., 2000a; Yangarber et al., 2000b).

A related set of research uses labeled and unlabeled data in problem domains where the features naturally divide into two disjoint sets. Blum and Mitchell (Blum and Mitchell, 1998) presented an algorithm for classifying web pages that builds two classifiers: one over the words that appear on the page, and another over the words appearing in hyperlinks pointing to that page. Datasets whose features naturally partition into two sets, and algorithms that use this division, fall into the co-training setting (Blum and Mitchell, 1998). Meta-Bootstrapping (Riloff and Jones, 1999) is an approach to learning dictionaries for information extraction starting only from a handful of phrases which are examples of the target class. It makes use of the fact that noun-phrases and the partial-sentences they are embedded in can be used as two complementary sources of information about semantic classes. Similar methods have been used for named entity classification (Collins and Singer, 1999).

Although a lot of effort has been devoted to developing bootstrapping algorithms for text learning tasks, there has been very little work in systematically applying these algorithms for information extraction and evaluating them on a common set of documents. All of the previously mentioned techniques have been tested on different types of problems, with different sets of documents, under different experimental conditions, thus making it difficult to objectively evaluate the applicability and effectiveness of these algorithms. In this paper, we first describe a range of bootstrapping approaches that fall into the cotraining setting and lay out the underlying assumptions for each. We then experimentally compare the performance of each algorithm on a common set of information extraction tasks and docu-

ments and relate it to the degree to which the assumptions are satisfied in the data sets and semantic learning tasks.

2. The Information Extraction Task

The information extraction tasks we tackle in this paper involve extracting noun phrases that fall into the following three semantic classes: organizations, people and locations. It is important to note that although named entity recognizers are usually used to extract these classes, the distinction we make in this paper is to extract all noun phrases (including "construction company", "jail warden", and "far-flung ports") instead of restricting our task to only proper nouns (which is the case in standard named entity recognizers). Because our focus is extraction of general semantic classes, we have not used many of the features common in English-language named entity recognition, including ones based on sequences of charactes in upper case, and matches to dictionaries, though adding these could improve the accuracy for these classes. This is important to note since that makes it likely that our results will translate to other semantic classes which are not found in online lists or written in capital letters.

The techniques we compare here are similar to those that have been used for semantic lexicon induction (eg (Riloff and Jones, 1999)). However, we believe that the noun-phrases we extract should be taken "in context". Thus, terms we generally consider unambiguous, such as place-names or dictionary terms, can now have different meanings depending on the context that they occur in. For example, the word "Phoenix" usually refers to a location, as in the following sentence:

> *A scenic drive from Phoenix lies a place of legendary beauty.*

but can also refer to the "Phoenix Land Company", as in this sentence:

> *Phoenix seeks to divest non-strategic properties if alternate uses cannot de monstrate sustainable 20% returns on capital investment.*

We can group these types of occurences in three broad categories:

General Polysemy: many words have multiple meanings. For example, "company" can refer to a commercial entity or to companionship.

General Terms: many words have a broad meaning that can refer to entities of various types. For example, "customer" can refer to a person or a company.

Proper Name Ambiguity: proper names can be associated with entities of different types. For example, "John Hancock" can refer to a person or a company, sicne companies are often named after people.

In general, we belive that the context determines whether the meaning of the word can be further determined and that we can correctly classify the noun phrase into the semantic class by examining the immediate context, in addition to the words in the noun phrase. Therefore we approach this problem as an information extraction task, where the goal is to extract and label noun phrase instances that correspond to semantic categories of interest.

3. Data Set and Representation

As our data set, we used 4392 corporate web pages collected for the WebKB project (Craven et al., 1998) of which 4160 were used for training and 232 were set aside as a test set. We preprocessed the web pages by removing HTML tags and adding periods to the end of sentences when necessary.[1] We then parsed the web pages using a shallow parser.

We marked up the held out test data by labeling each noun phrase as one or more of (NP) instance as an organization, person, location, or none. We addressed each task as a binary classification task. Each *noun phrase context* consists of two items: (1) the noun phrase itself, and (2) and the context (an extraction pattern). We used the AutoSlog (Riloff, 1996) system to generate extraction patterns.

By using both the noun phrases and the contexts surrounding them, we provide two different types of features to our classifier. In many cases, the noun phrase itself will be unambiguous and clearly associated with a semantic category (e.g., "the corporation" will nearly always be an organization). In these cases, the noun phrase alone would be sufficient for correct classification. In other cases, the context itself is a dead give-away. For example, the context containing the pattern "subsidiary of <np>" nearly always extracts an organization. In those cases, the context alone is sufficient. However, we suspect that both the noun phrase and the context often play a role in determining the correct classification.

4. Bootstrapping Algorithms

In this section we give a brief overview of each of the algorithms we will be using for bootstrapping. We analyze how the properties and assumptions of each may affect accuracy.

4.1. Baseline Methods

Since our bootstrapping algorithms all use seed noun-phrases for an initial labeling of the training data, we should look at how much of their accuracy is based on the use of those seeds, and how much is derived from bootstrapping using those seeds. To this end, we implemented two baselines which use *only* the seeds, or noun-phrases containing the seeds, but use no bootstrapping.

4.1.1. Extraction Using Seeds Only

All the algorithms we describe use seeds as their source of information about the target class. A useful way of assessing what we gain by using a bootstrapping algorithm is to use the seeds as our sole model of information about the target class. The seeds we use for bootstrapping all algorithms are shown in Table 1.

[1] Web pages pose a problem for parsers because separate lines do not always end with a period (e.g., list items and headers). We used several heuristics to insert periods whenever an independent line or phrase was suspected.

The algorithm for seed extraction is: any noun-phrase in the test set exactly matching a word on the seed list is assigned a score of 1. All other noun-phrases are assigned the prior.

4.1.2. Head Labeling Extraction

All the bootstrapping algorithms we discuss use the seeds to perform *head-labeling* to initialize the training set. The algorithm for head labeling is: any noun-phrase in the training set whose head matches a word on the seed list is assigned a score of 1. This may not lead to completely accurate initialization, if any of the seeds are ambiguous. We will discuss this in more detail in Section 5.1.

In order to evaluate the contribution of the head-labeling to overall performance of the bootstrapping, we performed experiments using the head-labeling alone as information in order to extracted from the unseen test set.

The algorithm for *head labeling extraction* is: any noun-phrase in the test set whose head matches a word on the seed list is assigned a score of 1. All other noun-phrases are assigned the prior.

4.2. Bootstrapping Methods

The bootstrapping methods we describe fall under the cotraining setting where the features naturally partition into multiple disjoint sets, any of which individually is sufficient to learn the task. The separation into feature sets we use for the experiments in this paper is that of noun-phrases, and noun-phrase-contexts.

4.2.1. Cotraining

Cotraining (Blum and Mitchell, 1998) is a bootstrapping algorithm that was originally developed for combining labeled and unlabeled data for text classification. At a high level, it uses a feature split in the data and starting from seed examples, labels the unlabeled data and adds the most confidently labeled examples incrementally. When used in our information extraction setting, the algorithm details are as follows:

1. Initialize NPs from both positive and negative seeds
2. Use labeled NPs to score contexts
3. Select k most confident positive and negative contexts, assign them the positive and negative labels
4. Use labeled contexts to label NPs
5. Select k most confident positive and negative NPs, assign them the positive and negative labels
6. goto 2.

Note that cotraining assumes that we can accurately model the data by assigning noun-phrases and contexts to a class. When we add an example, it is either a member of the class (assigned to the positive class, with a probability of 1.0) or not (assigned to the negative class, with a probability of 0.0 of belonging to the target class). As we will see in section 5.2., many noun-phrases, and many more contexts, are inherently ambiguous. Cotraining may harm its performance through its hard (binary 0/1) class assignment.

4.2.2. CoEM

coEM was originally proposed for semi-supervised text classification by Nigam & Ghani (Nigam and Ghani, 2000) and is similar to the cotraining algorithm described above, but incorporates some features of EM. coEM uses the feature split present in the data, like co-training, but is instead of adding examples incrementally, it is iterative, like EM. It starts off using the same initialization as cotraining and creates two classifiers (one using the NPs and the other using the context) to score the unlabeled examples. Instead of assigning the scored examples positive or negative labels, coEM uses the scores associated with *all* the examples and adds *all* of them to the labeled set probabilistically (in the same way EM does for semi-supervised classification). This process iterates until the classifiers converge.

Muslea et al. (Muslea et al., 2000) extended the co-EM algorithm to incorporate active learning and showed that it has a robust behavior on a large spectrum of problems because of its ability to ask for the labels of the most ambiguous examples, which compensates for the weaknesses of the underlying semi-supervised algorithm.

In order to apply coEM to learning information extraction, we seed it with a small list of words. All noun-phrases with those words as heads are assigned to the positive class, to initialize the algorithm.

Note that coEM does not perform a hard clustering of the data, but assigns probabilities between 0 and 1 of each noun-phrase and context belonging to the target class. This may reflect well the inherent ambiguity of many terms.

4.2.3. Meta-bootstrapping

Meta-bootstrapping (Riloff and Jones, 1999) is a simple two-level bootstrapping algorithm using two features sets to label one another in alternation. It is customized for information extraction, using the feature sets *noun-phrases* and *noun-phrase-contexts* (or *caseframes*). There is no notion of negative examples or features, but only positive features and unlabeled features. The two feature sets are used asymmetrically. The noun-phrases are used as initial data and the set of positive features grows as the algorithm runs, while the noun-phrase-contexts are relearned with each outer iteration.

Heuristics are used to score the features from one set at each iteration, based on co-occurrence frequency with positive and unlabeled features, using both frequency of co-occurrence, and diversity of co-occurring features. The highest scoring features are added to the positive feature list.

Meta-bootstrapping treats the noun-phrases and their contexts asymmetrically. Once a context is labeled as positive, *all* of its co-occurring noun-phrases are assumed to be positive. However, a noun-phrase labeled as positive is part of a committee of noun-phrases voting on the next context to be selected. After a phase of bootstrapping, all contexts learned are discarded, and only the best noun-phrases are retained in the permanent dictionary. The bootstrapping is then recommenced using the expanded list of noun-phrases. Once a noun-phrase is added to the permanent dictionary, it is assumed to be representative of the positive class, with confidence of 1.0.

Class	Seeds
locations	australia, canada, china, england, france, germany, japan, mexico, switzerland, united states
organizations	inc., praxair, company, companies, dataram, halter marine group, xerox, arco, rayonier timberlands, puretec
people	customers, subscriber, people, users, shareholders, individuals, clients, leader, director, customer

Table 1: Seeds used for initialization of bootstrapping.

4.3. Active Initialization

As we saw in the discussion of head-labeling (Section 4.1.2.), using seed words for initializing training may lead to initialization that includes errors. We give measures of the rate of errors in head-labeling in Table 3. We will augment the intialization of bootstrapping by correcting those errors before bootstrapping begins, and seeing the effects on test set extraction accuracy. We call this *active initialization*, by analogy to active learning.

5. Assumptions in Bootstrapping Algorithms

The bootstrapping algorithms described in Section 4.2. have a number of assumptions in common; that initialization from seeds leads to labels which are accurate for the target class, that seeds will be present in the data, that similar syntactic distribution correlates with semantic similarity, and that noun-phrases and their contexts are redundant and unambiguous with respect to the semantic classes we are attempting to learn. We assess the validity of each of these assumptions by examining the data.

5.1. Initialization from Seeds Assumption

All the algorithms we describe use seed words as their source of information about the target class. An assumption made by all the algorithms we present is that seed words suggested by a user will be present in the data. We assess this by comparing seed density for three different tasks over two types of data, one collected specifically for the task at hand, one drawn according to a uniform random distribution over documents on the world wide web. The seeds we use for initializing bootstrapping all algorithms are shown in Table 1. We show the density of seed words in different corpora in Table 2. Note that the `people` and `organizations` classes are much more prevalent in the company data we are working with than in documents randomly obtained using Yahoo's random URL page.

Another assumption that arises from using seeds is that labeling using them accurately labels items in the target semantic class. All three algorithms initialize the unlabeled data by using the seeds to perform *head labeling*. Any noun-phrase with a seed word as its head is labeled as positive. For example, when *canada* is in the seed word list, both "eastern canada" and "marketnet inc. canada" are labeled as being positive examples. Table 3 shows the accuracy for `locations` and `people`. For `people`, some

Corpus	Class	Seed-density (/10,000)
fixed	locations	18
random		21
fixed	organizations	112
random		17
fixed	people	70
random		33

Table 2: Density of seed words per 10,000 noun-phrases in fixes corpus of company web pages, and corpus of randomly collected web pages.

Class	Accuracy
`locations`	98%
`people`	95%

Table 3: Accuracy of labeling examples automatically using seed-heads.

words were mostly unambiguous, with the exception of a few examples, "customers", which was unambigous except in prhases such as "industrial customers". The seed-word "people" also led to some training examples of questionable utility, for example "invest in people". If we learn the context "invest in", it may not help in learning to extract words for people, in the general case. Other seed-words from the `people` class proved to be very ambiguous; "leader" was most often to used to describe a company, as in the sentence "Anacomp is a world leader in digital document-management services".

We will discuss the results of correcting these errors before beginning bootstrapping in Section 6.3.

5.2. Feature Sets Redundancy Assumption

The bootstrapping algorithms we discuss all assume that there is sufficient information in each feature set (noun-phrases and contexts) to use either to label an example. However, when we look at the ambiguity of noun-phrases in the test set (Table 4) we see that 81 noun-phrases were ambiguous between two classes, and 4 were ambiguous between three classes. This means that these 85 noun-phrases (2% of the 4413 unique noun-phrases occurring in the test set) are not in fact sufficient to identify the class. This discrepancy may hurt cotraining and meta-bootstrapping more, since they assume that we can classify noun-phrases into a class with 100% accuracy.

When we examine the same information for contexts (Table 4) we see even more ambiguity. 36% of contexts are ambiguous between two or more classes.

We have another measure of the inherent ambiguity of the noun-phrases making up our target class when we measure the inter-rater(labeler) agreement on the test set. We randomly sampled 230 examples from the test collection, broken into two subsets of size 114 and 116 examples. We had four labelers label subsets with different amounts of information. The three conditions were:

- noun-phrase, local syntactic context, and full sentence (*all*)
- noun-phrase, local syntactic context (*np-context*)

Ambiguity	Class(es)	Number of NPs
1	none	3574
	loc	114
	org	451
	person	189
2	loc, none	6
	org, none	31
	person, none	25
	loc, org	6
	org, person	13
3	loc, org, none	1
	org, person, none	3

Table 4: Distribution of test NPs in classes

Ambiguity	Class(es)	Number of Pats
1	none	1068
	loc	25
	org	98
	person	59
2	loc, none	51
	org, none	271
	person, none	206
	loc, org	5
	org, person	50
3	loc, org, none	18
	org, person, none	83
4	loc, org, person, none	6

Table 5: Distribution of test patterns in classes

- noun-phrase only (*np*).

The labelers were asked to label each example with any or all of the labels `organization`, `person` and `location`. Before-hand, they each labeled 100 examples separate from those described above (in the *all* condition) and discussed ways of resolving ambiguous cases (agreeing, for example, to count "we" as both `person` and `organization` when it could be referring to the organization or the individuals in it. The distribution of conditions to labelers is shown in Figure 6.

We found that when the labelers had access to the noun-phrase, context, and the full sentence they occurred in, they agreed on the labeling 90.5% of the time. However, when one did not have the sentence (only the noun-phrase and context), agreement dropped to 88.5%. Our algorithms have only the noun-phrase and contexts to use for learning. Based on the agreement of our human labelers, we conjecture that the algorithms could do better with more information.

Labeler	Set 1 Condition	Set 2 Condition
1	NP-context	all
2	all	NP-context
3	NP	all
4	all	NP

Table 6: Conditions for inter-rate evaluation - All stands for NP, context and the entire sentence in which the NP-context pair appeared

5.3. Syntactic - Semantic Correlation Assumption

All the algorithms we address in this paper use the assumption that phrases with similar syntactic distributions have similar semantic meanings. It has been shown (Dagan et al., 1999) that syntactic cooccurrence leads to clusterings which are useful for natural language tasks. However, since we seek to extract items from a single semantic target class at a time, syntactic correlation may not be sufficient to represent our desired semantic similarity.

The mismatch between syntactic correlation and semantic similarity can be measured directly by measuring context ambiguity, as we did in Section 5.2.. Consider the context "visit <X>", which is ambiguous between all four of our classes `location`, `person`, `organization` and `none`. It occurs as a `location` in "visit our area", ambiguously between `person` and `organization` in "visit us", and as `none` in "visit our website".

Similarly, examining the ambiguous noun-phrases we see that occurring with a particular noun-phrase does not necessarily determine the semantics of a context. Three of the three-way ambiguous noun-phrases in our test set are: "group", "them" and "they". Adding "they" to the model when learning one class may cause an algorithm to add contexts which belong to a different class.

Meta-bootstrapping deals with this problem by specifically forbidding a list of 35 stop words (mainly prepositions) from being added to the dictionaries. In addition, the heuristic that a caseframe be selected by many different noun-phrases in the seed list helps prevent the addition of a single ambiguous noun-phrase to have too strong an influence on the bootstrapping. The probabilistic labeling used by coEM helps prevent problems from this ambiguity. Though we also implemented a stop-list for cotraining, its all-or-nothing labeling means that ambiguous words not on the stop list (such as "group") may have a strong influence on the bootstrapping.

6. Empirical Comparison of Bootstrapping Algorithms

After running bootstrapping with each algorithm we have two models: (1) a set of noun-phrases, with associated probabilities or scores, and (2) a set of contexts with probabilities or scores. We then use these models to extract examples of the target class from a held-out hand annotated test corpus. Since we are able to associate scores with each test example, we can sort the test results by score, and calculate precision-recall curves.

6.1. Extraction on the Test Corpus

There are several ways of using the models produced by bootstrapping to extract from the test corpus:

1. Use only the noun-phrases. This corresponds to using bootstrapping to acquire a lexicon of terms, along with probabilities or weights reflecting confidence assigned by the bootstrapping algorithm. This may have advantage over lists of terms (such as proper names) which

have no such probabilities associated with them. The probabilities allow us to sort extracted phrases and thus control whether we obtain few, highly probable members of the target class, or obtain good coverage, at the expense of accuracy. We will measure these trade-offs using precision and recall, discussed in Section 6.2..

2. Use only the contexts. In this case we discard the noun-phrases we learned during bootstrapping, and use only the contexts as extraction patterns for extracting on the test set. We extract a noun-phrase when it occurs with one of the contexts in our model, using the score assigned by that context. This may have the advantage of allowing greater generalization. Unseen words and phrases can be extracted from the test corpus, and overspecialization based on the training corpus can be avoided.

3. Use both models. To score a noun-phrase context pair in the test set, assume independence, and multiply the model noun-phrase and context scores to get a probability for the example. Noun-phrases and contexts not seen in the training corpus are given a score based on the prior probability. This has the advantage of combining all the information we acquired during training. This method is most effective for methods which assign probability-like scores (coEM and cotraining). For meta-bootstrapping, there is no natural way of combining the scores.

We experimented with these extraction methods for all three algorithms, and found that method 2, extracting using only the contexts, was by far the best for meta-bootstrapping, so all our results for meta-bootstrapping use this extraction method. CoEM and cotraining performed best with method 3, combining information from both noun-phrase and context models, so all results reported for coEM and cotraining use this extraction method.

6.2. Evaluation

We use the models to score all noun-phrase instances in the test corpus, using context-scoring for meta-bootstrapping, and noun-phrase-context scoring for coEM and cotraining, as described in Section 6.1.. Since we could select a variety of thresholds if we used our models for classifiation, depending on the target application, we use a large number of thresholds, calculating precision and recall for each. Precision is given by

$$Precision = \frac{tp_t}{tp_t + fp_t}$$

where tp_t is the number of correct examples above the threshold, and fp_t is the number of incorrect examples above the threshold. Recall is given by

$$Recall = \frac{tp_t}{tp_t + fn_t}$$

where tp_t is the number of correct examples above the threshold and fn_t is the number of correct examples below the threshold.

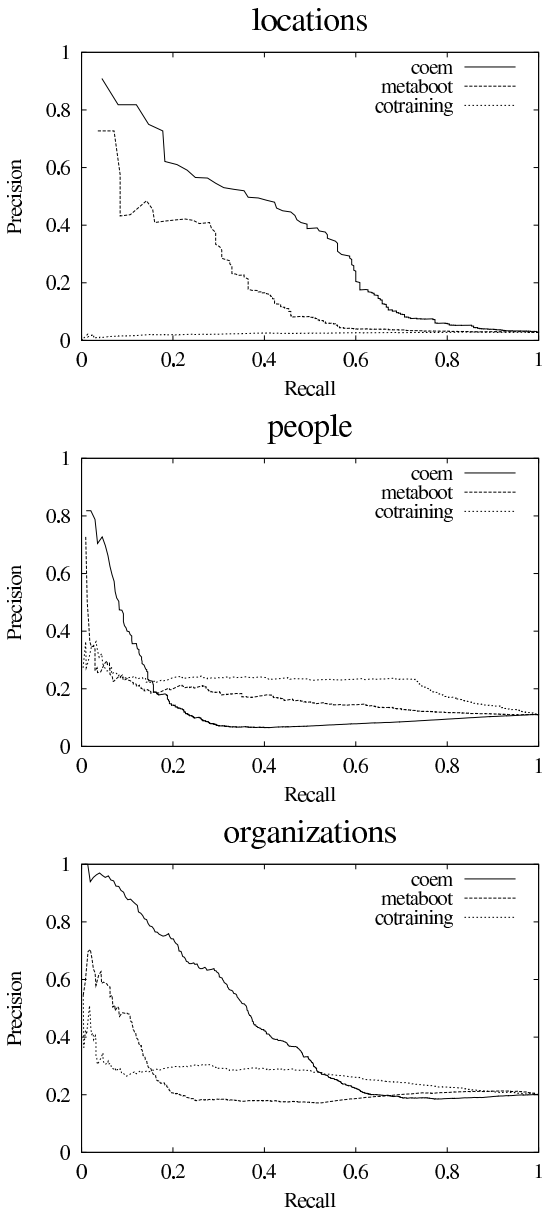

Figure 1: Comparison of bootstrapping using coEM, meta-bootstrapping and cotraining, for the classes `locations`, `people` and `organizations`.

6.3. Experimental Results

Figure 1 compares using models obtained by bootstrapping with coEM, meta-bootstrapping and cotraining, for extracting on a held out test set. CoEM performs better than meta-bootstrapping, while cotraining does very poorly.

Figure 2 shows that bootstrapping using unlabeled documents gives us significant gains over using just the seeds, or noun-phrases with the seeds as heads, for extracting from the test corpus. This difference is least marked for the class `people`, which had the most ambiguous seed words.

Figure 3 shows that only a small gain is obtained by hand-labeling all 669 examples matching the `location` seeds before commencing bootstrapping, and all 2521 examples matching the `people` class before commencing bootstrapping.

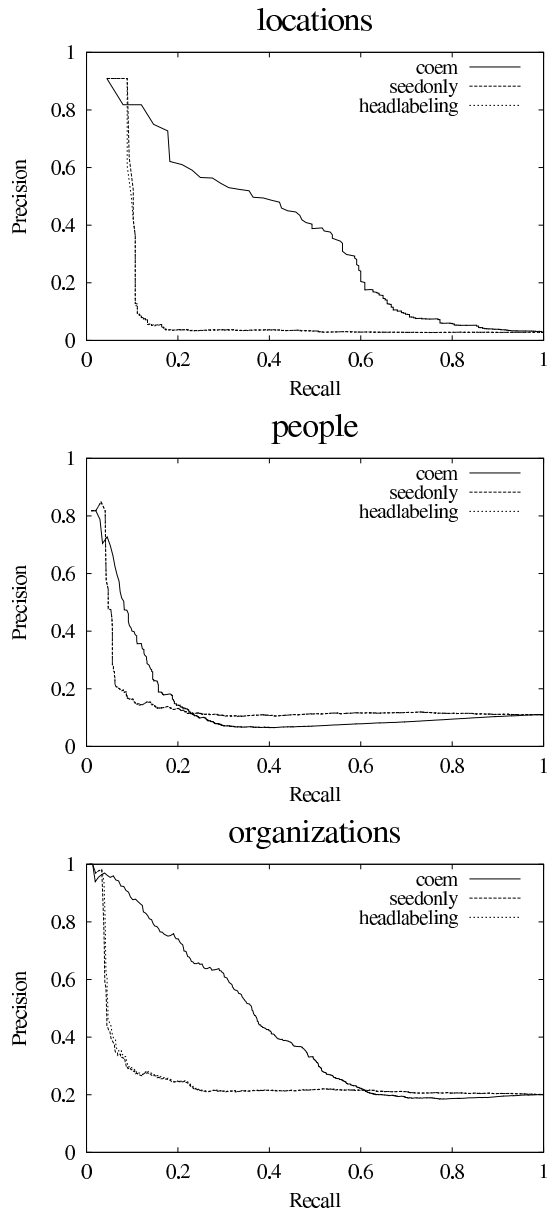

Figure 2: Comparison of the effects of using seeds alone, noun-phrases with seeds as heads (head-labeling) and models learned by bootstrapping with coEM to extract on the unseen test set. Seeds and head-labeling lead to good precision, but poor recall. Bootstrapping using coEM improves recall without loss of precision.

7. Discussion

The advantage coEM has over meta-bootstrapping and cotraining may reflect the good match between its probabilistic treatment of the data, and the inherent ambiguity of the classes. This permits an ambiguous example to be labeled with a probability that reflects its true ambiguity, rather than committing it to a class, then being overly influenced by its presence in that class. Since meta-bootstrapping repeatedly discards the contexts, ambiguity in the contexts does not hurt the algorithm as much as it hurts cotraining.

We can see from the comparison of gains from bootstrapping over using the seeds or head-labeling, that classes for which we have ambiguous seeds words, such as our

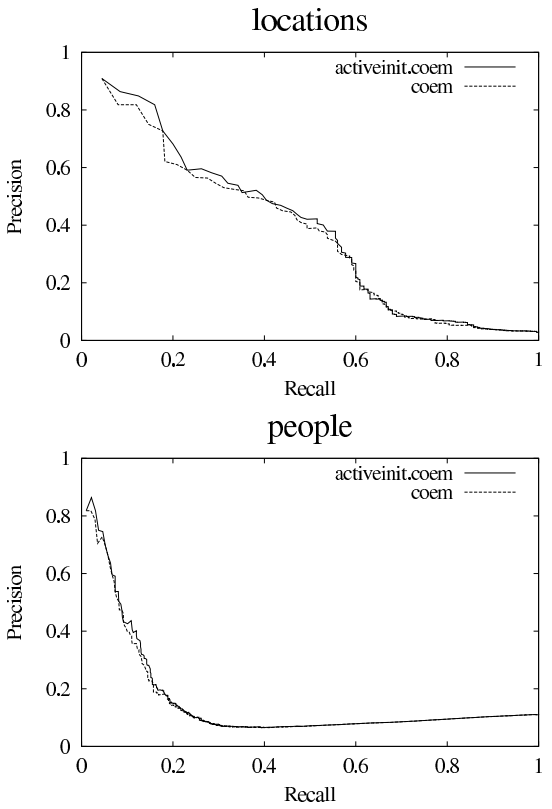

Figure 3: Comparison of the effects of hand-labeling all examples matching the seed-words before commencing bootstrapping (active initialization), against bootstrapping assuming all are correct (coem). A small gain is obtained by labeling all data input.

`people` class benefit less from bootstrapping than those with relatively unambiguous seed words. However, we still benefit from bootstrapping. This may be because the noise introduced by the ambiguous seed-words is somewhat mitigated by the presence of the less ambiguous seed words.

For `locations` and `people` we saw that correcting by hand the examples labeled using the seed words did not have a significant impact on the results. This means that for relatively unambiguous seed words, at least, hand-labeling them in context does not give us an advantage over using automatic head-labeling.

For the seed-words and datasets we used, seed density in the training corpus does not appear to be a major issue.

8. Conclusions and Future Work

We presented a range of bootstrapping algorithms for information extraction and provide experimenal results comparing cotraining, coEM and meta-bootstrapping over a common set of documents and semantic learning tasks. We also analyzed the underlying assumptions for each of the algorithms and found that performance is affected by the degree to which the assumptions are violated in the data set and the task at hand.

We also analyzed several ways of initializing the bootstrapping algorithms and found that the accuracy does not appear to hinge greatly on initialization that is 100% accurate. A greater density of seeds in the training set for a class (`organizations` and `people` had greater seed density

than `locations`) does not appear to lead to greater extraction accuracy on the held out test set. Algorithms which cater to the ambiguity inherent in the feature set are more reliable for bootstrapping, whether they do that by using the feature sets asymmetrically (like meta-bootstrapping), or by allowing probabilistic labeling of examples (like coEM).

Although we have limited the scope of this paper to algorithms that utilize a feature split present in the data (co-training setting), we believe that this comparison of algorithms should be extended to settings where such a split of the features dies not exist, for examples algorithms like expectation maximization (EM) over the entire combined feature set. It would also be helpful to extend the analysis to a greater variety of semantic classes and larger sets of documents.

Using Decision Trees to Predict Human Nouns in Spanish Parsed Text

Abstract

This paper discusses the use of decision tree models in the acquisition of human nouns for a Spanish monolingual dictionary. This method uses decision tree models to learn the contexts in which a pre-classified set of human nouns occur. We then use the predictions of the model to acquire new human nouns at run time during sentence parsing. The acquisition process was done in 5 stages. First, we annotated automatically all nouns in a selected corpus from Spanish Encarta as "human" and "non-human". Then, we parsed all sentences in the corpus, and extracted linguistic features from the parsed sentences in which each annotated noun occurs. Afterwards we built decision tree models using the data and the features extracted. The task was to classify and assign probabilities to the contexts in which human nouns occur. Finally, we dynamically acquired new human nouns for the Spanish dictionary during sentence parsing; we used the predictions made by the model in this acquisition task.

1. Introduction

Manual annotation schemes to acquire lexical knowledge are costly and time-consuming. To circumvent this problem, different methods to bootstrap already annotated data have been proposed in the literature. One of the bootstrapping methods proposed is using already existing taggers to annotate more data. Some of the work reported focuses on the use of already existing taggers to create mappings between the older tagger and the new tag set (Atwell et al., 1994; Teufel, 1994, among others). Other work proposes combining existing taggers to improve accuracy rates (Van Halteren et al., 1998; Brill and Wu, 1998; Van Halteren et al., 2000; Zavrel and Daelemans, 2000).

Another bootstrapping method that has been proposed is using the statistical distributions of already lexically-classified words to classify new words (Stevenson et al., 1999; Stevenson and Merlo, 1997; Schulte im Walde, 1998). Stevenson and Merlo (2000) discuss a method to automatically classify verbs into semantic classes by looking at the statistical distributions of a few annotated verbs within a big corpus.

Along the lines of the second method mentioned above, this paper discusses a bootstrapping technique to acquire human nouns for a Spanish monolingual dictionary. This method uses decision tree models to learn the contexts in parsed text in which a pre-classified set of human nouns occur. The predictions of the model are then used in the acquisition of new human nouns at run time during sentence parsing.

2. Human Nouns in our Spanish NLP System

The Spanish monolingual dictionary that is part of our Natural Language Processing (NLP) system contains 140,664 entries, of which 72,445 are nouns. Out of these 72,445 nouns, 9,068 are tagged as human nouns in the dictionary. These human nouns were annotated partially by hand and also automatically by using information in their dictionary definitions.

Our system has several strategies to deal with human nouns occurring in text and that are not part of the Spanish dictionary. The first strategy is using derivational morphology rules. If a noun is not in the Spanish dictionary, the system tries to derive it morphologically from a noun that is present in the dictionary. Furthermore, if the noun from which this unfound noun is derived is human, we copy the human information from the base noun. In figure 1 we provide an example of a noun record created derivationally. The noun *camarerito* 'little waiter' is derived from *camarero* 'waiter'. As the base noun is tagged Humn (which stands for "human") in the dictionary, the human tag is copied to the derived noun as well.

```

Bases
{Lemma     "camarero"
Bits       N_ito
Cat        Noun}
```

Figure 1. Example of a human noun record created by derivational morphology

We also have a strategy to identify human names that are not in the dictionary when they occur in a collocation. In figure 2, we provide an example of a human name identified by our system, *Boris Karloff*. Although neither *Boris* nor *Karloff* is in the Spanish dictionary, the system is able to recognize them as the first name and last name of a person. Nevertheless, if either *Boris* or *Karloff* appears alone, they are not identified as human names.

```
{Segtype   NOUN
 Nodetype  NOUN
 Nodename  NOUN1
 Ft-Lt     1-2
 String    "Boris Karloff"
 CopyOf    NOUN2

           LASTNAME1 "Karloff"
 FactPred  person
 FactClass PERSON }
```

Figure 2. Record of a human name identified by our system

Despite these strategies, our system sometimes fails to identify some human nouns that are encountered in text. Knowing whether a noun is human is essential for our Spanish parser as this information is used to identify sentential subjects. Sentential position alone is not sufficient for successful subject identification because Spanish subjects may appear in multiple positions.

Decisions on subject identification are taken as our parser builds up the syntactic tree. Whether a noun is human or not is crucial for subject identification in many instances. One of these cases is when a sentence contains two noun phrases (NPs) that both appear to the right of the verb. If one of the NPs is recognized as human, and the other is not, our parser takes the human NP to be the subject of the sentence.

```
Ayer declaró la ley marcial el presidente de la república.
DECL1     AVP1      ADV1*     "Ayer"
          VERB1*    "declaró"  (Subject NP1  Object NP2)
          NP2       DETP1     ADJ1*     "la"
                    NOUN1*    "ley"  (Predadj AJP1)
                    AJP1      ADJ2*     "marcial"
          NP1       DETP2     ADJ3*     "el"
                    NOUN2*    "presidente"
                    PP1       PP2       PREP1*    "de"
                              DETP3     ADJ4*     "la"
                              NOUN3*    "república"
          CHAR1     "."
```

Translation: Yesterday, the president of the Republic declared martial law.

Figure 3. Example of a Spanish sentence with two NPs to the right of the verb.

In figure 3 we provide an example of a Spanish sentence where human information on an NP is used for subject identification. In this sentence there are two NPs appearing to right of the verb *declaró* 'you-formal declared', NP1, *el presidente de la república* 'the president of the Republic', and NP2, *la ley marcial* 'martial law'. In order to determine that NP1 is the subject of the sentence, the parser uses the fact that the head of the NP *presidente* is marked human in the Spanish dictionary.

3. Motivation and Experiment Design

Motivated by the importance of human nouns for our NLP system, we designed a bootstrapping method to add new human nouns to the Spanish dictionary. This method uses decision tree models to learn the contexts in parsed text in which a pre-classified set of human nouns occur. The predictions made by the model are then used in the dynamic acquisition of new human nouns during sentence parsing.

There were 5 stages in the experiment design:

- Automatic annotation of all nouns in a selected corpus into "human" and "non-human".
- Parsing of sentences in the selected corpus.
- Linguistic feature extraction from the parsed sentences in which each annotated noun occurs. The goal was determining which features were relevant or not with respect to human nouns.
- Building decision tree models using the features extracted. The task was to classify and assign probabilities to the contexts in which human nouns occur.
- Dynamically adding new human nouns to the Spanish dictionary based on the predictions made by the model.

In section 4 we will describe the first 4 stages of our experiment, which have to do with the different steps in building the decision tree models. In section 5 we will discuss the dynamic acquisition of new human nouns using the model predictions.

4. Using Decision Trees to Predict Human Nouns

4.1. Data and Feature Extraction

We used the Spanish version of Encarta as the data resource for our experiment because this encyclopedia is a good source of human nouns. We gathered 126,935 sentences, and extracted all their nouns. There were a total of 641,673 nouns, which we then annotated automatically. Those nouns that were recognized as human by our system were tagged as "human", and the rest were tagged as "not-human". Unfound words were excluded from the annotation task for obvious reasons.

We were quite confident that these automatic tags had a high degree of accuracy. Our confidence was based on the fact that the Spanish system has mechanisms to identify human nouns that are not in the dictionary. Furthermore, over the years we have done manual revisions of the 10,000 most common nouns in the Spanish dictionary; in these revisions we made sure that all the human nouns in the high-frequency set were tagged correctly.

Despite our degree of confidence in the accuracy of the automatic tags, we did some manual revision to have an estimation of our error rate. We reviewed 3,000 tagged nouns by hand; they were extracted at random from different parts of the corpus. We did not find any errors in the subset of tags reviewed; this gave us confidence that the error rate was small.[1]

[1] We would like to thank an anonymous reviewer for his/her comments on making sure that our tags were correct. His/her

The next step in the experiment was parsing all the sentences associated with the tagged nouns. We discarded sentences that did not obtain a complete parse. Afterwards, we automatically extracted 232 linguistic features from the parsed tree of the sentence associated with each tagged noun. Our approach was extracting the full set of features available in the parse, instead of performing manual feature selection. Nevertheless, one of the features extracted, "the ending of the noun", was selected manually. We included this morphological feature because of its highly suspected relevance.

The pool of extracted features fell into the following categories:

- All verbal features present in the main verb of the sentence.
- Selected features of the parent and the grandparent of the noun, such as gender, number, and (in) definiteness, among others.
- All the features present in the pre-modifiers and post-modifiers of the parent.
- The lemma of the preposition governing the parent, if present.
- The syntactic label of the parent and the grandparent.
- The ending of the noun.

In figure 4 we provide a sample of some features extracted for the noun *películas* 'movies'. The noun and its sentence are listed first. Under *Values* some values for the features extracted are listed. The first value is always the value of the tag, which is "NoHuman" in this case.

Sentence: [películas]: Durante los últimos veinticinco años de su vida, Gabin hizo unas veinticuatro películas, entre ellas destaca El clan de los sicilianos (1969) de Henri Verneuil, obra maestra del cine negro francés.

Translation: During the last twenty-five years of his life, Gabin made twenty-four movies, among them 'The Sicilian Clan' (1969), directed by Henri Verneuil, master piece of the French *film noir*.

Values:
A~is_human_noun = "NoHuman"
A~has_possible_human_ending = "NoPossHumEnding"
1~Sing~Parent = "0"
1~Plur~Parent = "1"
1~Art~Parent = "1"
1~Def~Parent = "0"
1~PPobj~Parent = "0"
1~Nodetype~Parent = "NP"

Figure 4. Values of some of the features extracted for the noun *películas* 'movies'

4.2. Building and Examining the Models

Once the feature extraction was completed, we used the data and the values extracted to build decision tree models. The goal was to classify the features by their relevance in predicting human nouns. Decision trees are a popular tool used in machine-learning for classification tasks. They provide a classification of selected features and rank their relative importance in predicting a target feature. The tools that we used to build our decision trees are the WinMine toolkit (Chickering *et al.*, 1997, n.d.), developed at Microsoft Research. Decision trees built by WinMine predict a probability distribution over all possible target values.

These tools take as input a text file with the characteristics shown in figure 4. The data is split into training and testing at a 70/30 rate. For both training and testing, we only extracted features from sentences that had a complete parse. The tools produce several decision tree models at different levels of accuracy. All the models are in xml format.

In order to inspect the models, we use a model viewer that allows the user to view the shape of the decision tree. This tool also shows the relative importance of all the relevant features selected by the model. All features that are found relevant in the human model are connected with arrows to the target feature that we are trying to predict, which appears in the center of the viewer. The features that are not found relevant by the model are shown disconnected at the bottom of the screen.

In figure 5 we provide a snapshot of the four best predictors in the model for human nouns. The viewer has a slider (to the left of the figure) that highlights the strongest predictors as the slider goes up. The following characteristics of the main verb are the top predictors in the model shown in figure 5:

- The verb takes a nominal predicate object (e.g.: *Lo considero mi amigo* 'I consider him my friend').
- The verb is transitive.
- The verb is transitive and followed by preposition + infinitive (e.g.: *Te animo a venir* 'I encourage you to come').
- The verb takes an adjectival predicate object (e.g.: *No te creo tonto* 'I don't believe you stupid').

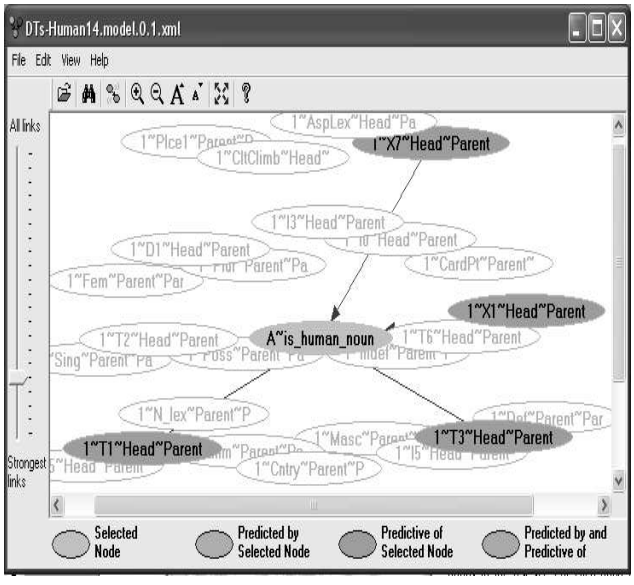

Figure 5. Snapshot of the four top predictors in the model for human nouns

concern was that we would tag as "non-human" true human nouns that were just missing the tag in our dictionary. The manual revision of a 3000 noun sample confirmed to us that the error rate was small.

4.3. Model Predictions

Out of the 232 features that were extracted for each noun, 111 were found to have predictive value in the model for human nouns. The selected features fell into the following categories:

- Ending of the noun. Certain endings such as *–or* '-er', and *–ista* '-ist' were found to be strong indicators that the noun is human.
- Governing preposition of the parent. Certain prepositions such as *a* 'to' and *por* 'by' were found likely to govern a human noun, while others such as *en* 'in' tend not to govern human nouns.
- The noun was upper case. Upper case was found to be a strong predictor in certain contexts, for example, nominal apposition.
- Syntactic label of the parent and grandparent.
- Whether the parent is in apposition to another noun.
- Syntactic features of the sentence main verb.
- Whether the parent of the noun has pre-modifiers.
- Some features of the pre-modifiers and post-modifiers of the parent (e.g.: whether the parent has a definite post-modifier, and the pre-modifier is a possessive pronoun).
- Whether the parent is definite.
- Whether the parent has a post-modifier that is a relative clause.

Some of the predictions made by the model were pretty straightforward, such as the relevance of the noun ending or capitalization. Other predictions were not as straightforward, such as the relevance of the parent being post-modified by a relative clause.

One of the main advantages of the decision tree model for human nouns was its complexity. The model had 1,194 branching nodes, which means that 1,194 linguistic decisions were made when predicting whether a noun is likely to be human or not. Manually coding each one of these decisions would be extremely time-consuming.

As for evaluation numbers, the best model had an overall accuracy of 84.29% over a 69.83% baseline. The baseline corresponds to the accuracy if the most frequent value (non-human) had been assigned to all nouns in the test set. In table 1 we provide the evaluation numbers for this model. These calculations are based on the 1922502 nouns in the test set. For each noun in the test set, the value predicted by the model was compared to the value observed.

	Human	Non-Human	Total
Total	58066	134436	192502
Predicted	54238	138264	
Correctly Predicted	46030	116228	162258
Precision	84.86%	84.06%	
Recall	79.27%	86.45%	
F-measure	81.97%	85.23%	
Baseline			69.83%
Overall Accuracy			84.29%

Table 1. Evaluation numbers for the human model

5. Using the Decision Tree Model to Acquire New Human Nouns

The last step in our experiment was using the predictions made by the model in the acquisition of human nouns that were not yet in the Spanish dictionary. The plan was to add new human noun records dynamically during sentence analysis using the decision tree predictions.

Our NLP system has in place rules to do lexical learning at run time during sentence parsing. Lexical-learning rules are used dynamically to create domain-specific corpus-based lexicons. These domain-specific dictionaries are used as supplements to the general dictionary (see Pentheroudakis (technical report), and Wu et al.,2002).

In preparation for lexical learning, we gathered 57,397 sentences from Spanish Encarta; we made sure that these sentences contained unfound words.[2] Afterwards, the decision tree model for human nouns was invoked from the lexical-learning rules while parsing the sentences.

After parsing the sentences, a new learned lexicon was created; this lexicon contained 16,902 human nouns. After quickly inspecting a handful of dictionary entries, we realized that a good amount of the learned nouns were human names. This realization seemed consistent with the fact that Encarta is an encyclopedia, and that our Spanish dictionary does not contain many proper names. Some examples of the names that were learned were *Filippo, Yourcenar* and *Hemingway*, among others. Among the "non-proper name" human nouns that were learned were *zapatistas* 'zapatists', *antirreeleccionista* 'anti-reelectionist', and *clarinero* 'clarinist', among others.

To evaluate the accuracy of the learned dictionary, we randomly gathered 600 nouns from the pool of sentences used for the creation of the dictionary. We then manually reviewed all the words in the 600 set. We checked whether each noun was truly human or not, and whether it was part of the learned dictionary. 41 nouns from the 600 set were discarded because they were either typos or did not have a noun part of speech; we ended up with a total of 559 nouns.[3] In table 2, we provide the results of the manual evaluation.

	Human	Non-Human	Total
Total	269	290	559
Predicted	230	329	
Correctly Predicted	205	265	470
Precision	89.13%	80.54%	
Recall	76.20%	91.37%	
Baseline			51.88%
F-measure	82.16%	85.61%	
Overall Accuracy			84.07%

Table 2. Summary of manual evaluation of 559 nouns from Encarta

[2] The first time that we invoked the model during parsing, we did not make sure that unfound words were in the data. As a result, few new human nouns were learned.

[3] Our NLP system assigns by default a noun part of speech to unfound words. It is possible that some of the unfound nouns that were in the test set were not nouns.

6. Conclusions

In this paper we have presented a method to augment the number of human nouns in the Spanish dictionary of our NLP system. This method uses decision tree models to learn the contexts in which a pre-classified set of human nouns occur. The experiment was done in 5 stages. First, we annotated automatically all nouns in a selected corpus from Spanish Encarta into "human" and "non-human". We then parsed all sentences in the corpus, and extracted several linguistic features from each parsed sentence. We then built decision tree models using the features extracted. The task was to classify and assign probabilities to the contexts in which human nouns occur. Finally we added dynamically new human nouns to the Spanish dictionary based on the predictions made by the model.

Evaluation of our experiment showed that we were able to learn a significant amount of human nouns at good accuracy levels. This method reduces human effort in dictionary maintenance. We see another two advantages to using decision tree models for human noun acquisition. The first one is that the model makes complex decisions that would be very costly and time-consuming to be hand-coded. And, second, the model made more complete predictions than our native speaker intuitions.

Abstract

Discourse Markers (DMs) are among the most popular clues for capturing discourse structure for NLP applications. However, they suffer from inconsistency and uneven coverage. In this paper we present X-TRACTOR, a language-independant system for automatically extracting DMs from plain text. Seeking low processing cost and wide applicability, we have tried to remain independent of any hand-crafted resources, including annotated corpora or NLP tools. Results of an application to Spanish point that this system succeeds in finding new DMs in corpus and ranking them according to their likelihood as DMs. Moreover, due to its modular architecture, X-TRACTOR evidences the specific contribution of each out of a number of parameters to characterise DMs. Therefore, this tool can be used not only for obtaining DM lexicons for heterogeneous purposes, but also for empirically delimiting the concept of DM.

1. Motivation

The problem of capturing discourse structure for complex NLP tasks has often been addressed by exploiting surface clues that can yield a partial structure of discourse (Marcu, 1997; Dale and Knott, 1995; Kim et al., 2000). Cue phrases such as *because*, *although* or *in that case*, usually called Discourse Markers (DMs), are among the most popular of these clues because they are both highly informative of discourse structure and have a very low processing cost.

However, they present two main shortcomings: inconsistency in their characterisation and uneven coverage. The lack of consensus about the concept of DM, both theoretically and for NLP applications, is the main cause for these two shortcomings. In this paper, we will show how a knowledge-poor approach to lexical acquisition is useful for addressing both these problems and providing partial solutions to them.

1.1. Delimitation of the concept of DM

A general consensus has not been achieved about the concept of DM. The set of DMs in a language is not delimited, nor by intension neither by extension. But however controversial DM characterisation may be, there is a core of well-defined, prototypical DMs upon which a high consensus can be found in the literature. By studying this lexicon and the behaviour of the lexical units it stores in naturally occurring text, DM characterising features can be discovered. These features can be applied to corpus to obtain lexical items that are similar to the original ones. Applying bootstraping techniques, these newly identified lexical items can be incorporated to the lexicon and this enhanced lexicon can be used for discovering new characterising features. This process can be repeated until the obtained lexical items are not considered valid any more.

It may be argued that enlarging this starting set implies making it more controversial, by adding items whose status as DMs is questionable. However, being empirically grounded, this enlargement is relatively unbiased, and it yields an enhancement of the concept of DM that may be useful for NLP applications.

Taking it to the extreme, unendlessly enhancing the concept of DM implies that anything loosely signalling discourse structure would be considered as a DM. Although this might sound absolutely undesirable, it could be argued that a number of lexical items can be assigned a varying degree of marking strength or *markerhood*[1]. It would be then up to the human expert to determine the load of *markerhood* required for a lexical item to be considered a DM in a determined theoretical framework or application. Lexical acquisition can evidence the load of discursive information in every DM by evaluating it according to the DM characterising features used for extraction.

1.2. Scalability and Portability of DM Resources

Work concerning DMs has been mainly theoretical, and applications to NLP have been mainly oriented to restricted NLGeneration applications. So, DM resources of wide coverage have still to be built. The usual approach to building DM resources is fully manual. For example, DM lexicons are built by gathering and describing DMs from corpus or literature on the subject, a very costly and time-consuming process. Moreover, due to variability among humans, DM lexicons tend to suffer from inconsistency in their extension and intension. To inherent human variability, one must add the general lack of consensus about the appropriate characterisation of DMs for NLP. All this prevents reusability of these costly resources.

[1]By analogy with *termhood*(Kageura and Umino, 1996), which is the term used in terminology extraction to indicate the likelihood that a term candidate is an actual term, we have called *markerhood* the likelihood that a DM candidate is an actual DM.

As a result of the fact that DM resources are built manually, they present uneven coverage of the actual DMs in corpus. More concretely, when working on previously unseen text, it is quite probable that it contains DMs that are not in a manually built DM lexicon. This is a general shortcoming of all knowledge that has to be obtained from corpus, but it becomes more critical with DMs, since they are very sparse in comparison to other kinds of corpus-derived knowledge, such as terminology. As follows, due to the limitations of humans, a lexicon built by mere manual corpus observation will cover a very small number of all possible DMs.

The rest of the paper is organised as follows. In Section 2., we present the architecture of the proposed extraction system, X-TRACTOR, with examples of an application of this system to acquiring a DM lexicon for discourse-based automated text summarisation in Spanish. In Section 2 we present the results obtained for this application, to finish with conclusions and future directions.

2. Proposed Architecture

One of the main aims of this system is to be useful for a variety of tasks or languages. Therefore, we have tried to remain independent of any hand-crafted resources, including annotated texts or NLP tools. Following the line of (Engehard and Pantera, 1994), syntactical information is worked by way of patterns of function words, which are finite and therefore listable. This makes the cost of the system quite low both in terms of processing and human resources.

Focusing on adaptability, the architecture of X-TRACTOR is highly modular. As can be seen in Figure 1, it is based in a language-independent kernel implemented in perl and a number of modules that provide linguistic knowledge.

The input to the system is a starting DM lexicon and a corpus with no linguistic annotation. DM candidates are extracted from corpus by applying linguistic knowledge to it. Two kinds of knowledge can be distinguished: general knowledge from the language and that obtained from a starting DM lexicon.

The DM extraction kernel works in two phases: first, a list of all might-be-DMs in the corpus is obtained, with some characterising features associated to it. A second step consists in ranking DM candidates by their likelihood to be actual markers, or *markerhood*. This ranked list is validated by a human expert, and actual DMs are introduced in the DM lexicon. This enhanced lexicon can be then re-used as input for the system.

In what follows we describe the different parts of X-TRACTOR in detail.

2.1. Linguistic Knowledge

Two kinds of linguistic knowledge are distinguished: general and lexicon-specific. General knowledge is stored in two modules. One of them accounts for the distribution of DMs in naturally occurring text in the form of rules. It is rather language-independant, since it exploits general discursive properties such as the occurrence in discursively salient contexts, like beginning of paragraph or sentence. The second module is a list of stopwords or function words of the language in use.

Lexicon-specific knowledge is obtained from the starting DM lexicon. It also consists of two modules: one containing classes of words that constitute DMs and another with the rules for legally combining these classes of words. We are currently working in an automatic process to induce these rules from the given classes of words and the DMs in the lexicon.

In the application of this system to Spanish, we started with a Spanish DM lexicon consisting of 577 DMs [2]. Since this lexicon is oriented to discourse-based text summarisation, each DM is associated to information useful for the task (see Table 1), such as *rhetoric type*. We adapted the system so that some of this information could also be automatically extracted for the human expert to validate. Results were excellent for the feature of *syntactic type*, and very good for *rhetorical content* and *segment boundary*.

We transformed this lexicon to the kind of knowledge required by X-TRACTOR, and obtained 6 classes of words (adverbs, prepositions, coordinating conjunctions, subordinating conjunctions, pronouns and content words), totalling 603 lexical items, and 102 rules for combining them. For implementation, the words are listed and they are treated by pattern-matching, and the rules are expressed in the form of *if - then - else* conditions on this pattern-matching (see Table 2).

2.2. DM candidate extraction

DM candidates are extracted by applying the above mentioned linguistic knowledge to plain text. Since DMs suffer from data sparseness, it is necessary to work with a huge corpus to obtain a relatively good characterisation of DMs. In the application to Spanish, strings were extracted by at least one of the following conditions:

- Salient location in textual structure: beginning of paragraph, beginning of the sentence, marked by punctuation.
- Words that are typical parts of DMs, such as those having a strong rhetorical content. thetorical content types are similr to those handled in RST (Mann and Thompson, 1988).
- Word patterns, combinations of function words, sometimes also combined with DM-words.

2.3. Assessment of DM-candidate markerood

Once all the possible might-be-DMs are obtained from corpus, they are ponderated as to their *markerhood*, and a ranked list is built.

Different kinds of information are taken into account to assess *markerhood*:

- **Frequency** of occurrence of the DM candidate in corpus, normalised by its length in words and exclusive of stopwords. Normalisation is achieved by the function $normalised\ frequency = length \cdot \log(frequency)$.

[2] We worked with 784 expanded forms corresponding to 577 basic cue phrases

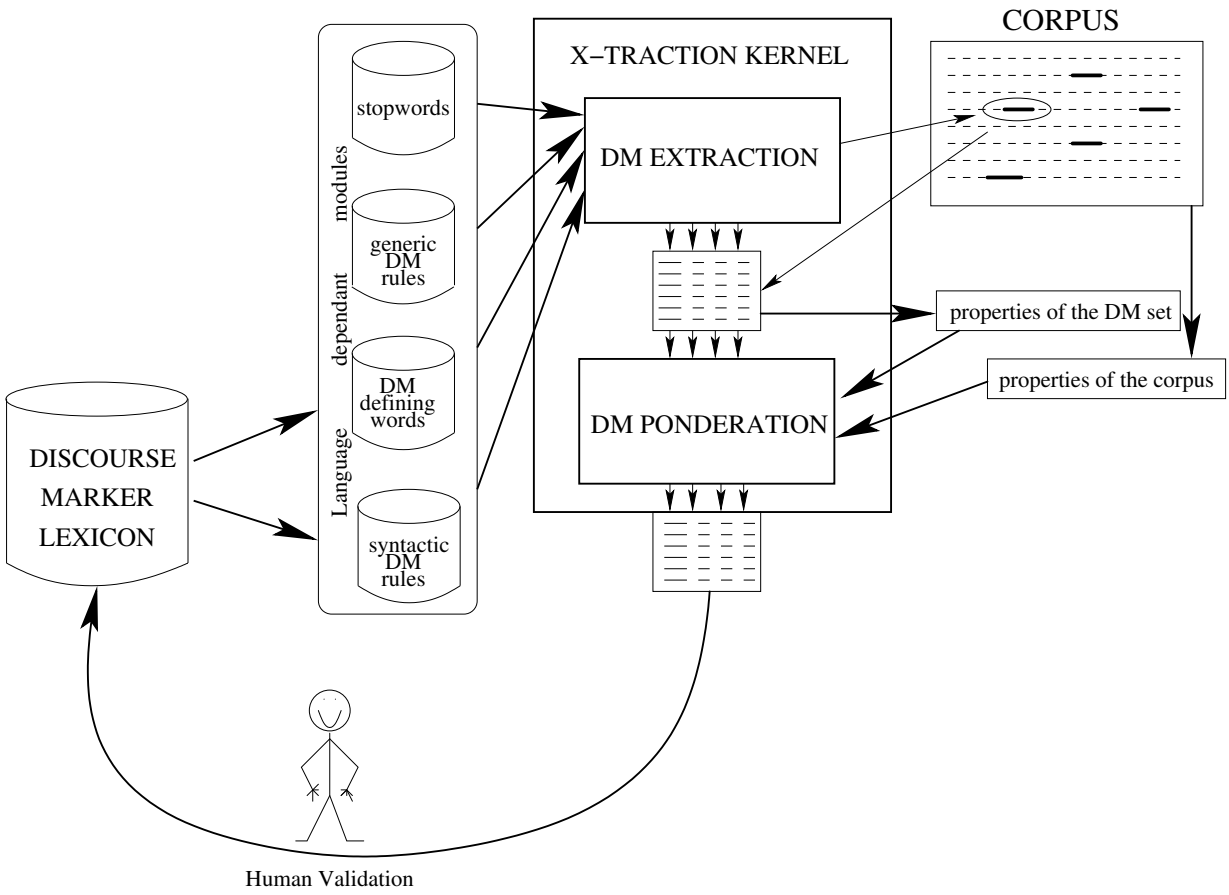

Figure 1: Architecture of X-Tractor

DM	boundary	syntactic type	rhetorical type	direction	con tent
además	not appl.	adverbial	satellizer	inclusion	reinforcement
a pesar de	strong	preposition	satellizer	right	concession
así que	weak	subordinating	chainer	right	consequence
dado que	weak	subordinating	satellizer	right	enablement

Table 1: Sample of the cue phrase lexicon

- Frequency of occurrence in **discursively salient context**. Discursively salient contexts are preferred occurrence locations for DMs. This parameter has been combined with DM classes motivated by clustering in (Alonso et al., 2002).
- **Mutual Information** of the words forming the DM candidate. Word strings with higher mutual information are supposed to be more plausible lexical units.
- **Internal Structure** of the DM, that is to say, whether it follows one of the rules of combination of DM-words. For this application, X-TRACTOR was aimed at obtaining DMs other than those already in the starting lexicon, therefore, longer well-structured DM candidates were priorised, that is to say, the longer the rule that a DM candidate satisfies, the higher the value of this parameter.
- **Rhetorical Content** of the DM candidate is increased by the number of words with strong rhetorical content it contains. These words are listed in one of the modules of external knowledge, and each has a rhetorical content associated to them. This rhetorical content can be pre-assigned to the DM candidate for the human expert to validate.
- **Lexical Weight** accounts for the the presence of non frequent words in the DM candidate. Unfrequent words make a DM with high *markerhood* more likely as a segment boundary marker.
- **Linking Function** of the DM candidate accounts for its power to link spans of text, mostly by reference.
- **Length** of the DM candidate is relevant for obtaining new DMs if we take into consideration the fact that DMs tend to aggregate.

These parameters are combined by weighted voting for *markerhood* assessment, so that the importance of each of them for the final *markerhood* assessment can be adapted

```
for each word in string
        if word is a preposition, then
          if word-1 is an adverb, then
            if word-2 is a coordinating conjunction, then
              if word+1 is a rhetorical-content word, then
                if word+2 is a preposition, then
                  assign the DM candidate structural weight 5
                elsif word+2 is a subordinating conjunction, then
                  assign the DM candidate structural weight 5
                else assign the DM candidate structural weight 4
              elsif word+1 is a pronoun, then
                assign the DM candidate structural weight 4
            else assign the DM candidate structural weight 3
```

Figure 2: Example of rules for combination of DM-constituing words

to different targets. By assigning a different weight to each one of these parameters, the system can be used for extracting DMs useful for heterogeneous tasks, for example, automated summarisation, anaphora resolution, information extraction, etc.

In the application to Spanish, we were looking for DMs that signal discourse structure useful for automated text summarisation, that is to say, mostly indicators of relevance and coherence relations.

3. Results and Discussion

We ran X-TRACTOR on a sample totalling 350,000 words of Spanish newspaper corpus, and obtained a ranked list of DMs together with information about their syntactical type, rhetorical content and an indication of their potential as segment boundary markers. Only 372 out of the 577 DMs in the DM lexicon could be found in this sample, which indicates that a bigger corpus would provide a better picture of DMs in the language, as will be developed below.

3.1. Evaluation of Results

Evaluation of lexical acquisition systems is a problem still to be solved. Typically, the metrics used are standard IR metrics, namely, *precision* and *recall* of the terms retrieved by an extraction tool evaluated against a document or collection of documents where terms have been identified by human experts (Vivaldi, 2001). Precision accounts for the number of term candidates extracted by the system which have been identified as terms in the corpus, while recall states how many terms in the corpus have been correctly extracted.

This kind of evaluation presents two main problems: first, the bottleneck of hand-tagged data, because a large-scale evaluation implies a costly effort and a long time for manually tagging the evaluation corpus. Secondly, since terms are not well-defined, there is a significant variability between judges, which makes it difficult to evaluate against a sound golden standard.

For the evaluation of DM extraction, these two problems become almost unsolvable. In the first place, DM density in corpus is far lower than term density, which implies that judges should read a huge amount of corpus to identify a number of DMs significant for evaluation. In practical terms, this is almost unaffordable. Moreover, X-TRACTOR's performance is optimised for dealing with huge amounts of corpus. On the other hand, the lack of a reference concept for DM makes inter-judge variability for DM identification even higher than for term identification.

Given these difficulties, we have carried out an alternative evaluation of the presented application of the system. To give a hint of the recall of the obtained DM candidate list, we have found how many of the DMs in the DM lexicon were extracted by X-TRACTOR, and how many of the DM candidates extracted were DMs in the lexicon[3]. To evaluate the goodness of *markerhood* assessment, we have found the ratio of DMs in the lexicon that could be found among the first 100 and 1000 highest ranked DM candidates given by X-TRACTOR. To evaluate the enhancement of the initial set of DMs that was achieved, the 100 highest ranked DMs were manually revised, and we obtained the ratio of actual DMs or strings containing DMs that were not in the DM lexicon. Noise has been calculated as the ratio of non-DMs that can be found among the 100 highest ranked DM candidates.

3.2. Parameter Tuning

To roughly determine which were the parameters more useful for finding the kind of DMs targeted in the presented application, we evaluated the goodness of each single parameter by obtaining the ratio of DMs in the lexicon that could be found within the 100 and 1000 DM candidates ranked highest by that parameter.

In Figure 3 it can be seen that the parameters with best behaviours in isolation are *content*, *structure*, *lexical weight* and *occurrence in pausal context*, although none of them performs above a dummy baseline fed with the same corpus sample. This baseline extracted 1- to 4-word strings after punctuation signs, and ranked them according to their frequency, so that the most frequent were ranked highest. Frequencies of strings were normalised by length, so that $normalised\ frequency = length \cdot \log(frequency)$. Moreover, the frequency of strings containing stopwords was reduced.

[3]We previously checked how many of the DMs in the lexicon could actually be found in corpus, and found that only 386 of them occurred in the 350,000 word sample; this is the upper bound of in-lexicon DM extraction.

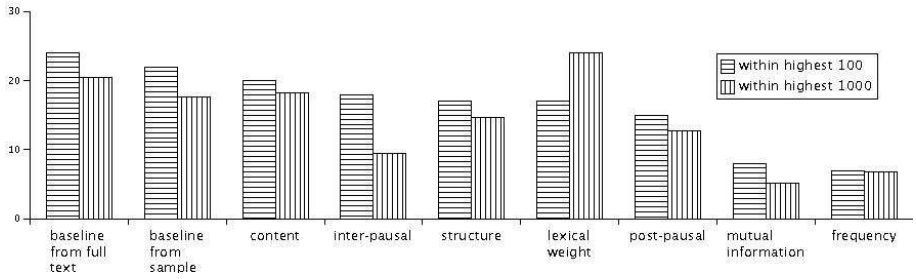

Figure 3: Ratio of DM andidates that contain a DM in the lexicon among the 100 and 1000 highest ranked by each individual parameter

	baseline	X-TRACTOR
Coverage of the DM lexicon	88%	87.5%
ratio of DMs in the lexicon		
within 100 highest ranked	31%	41%
within 1000 highest ranked	21%	21.6%
Noise		
within the 100 highest ranked	57%	32%
Enhancement Ratio		
within the 100 highest ranked	9%	15%

Table 2: Results obtained by X-TRACTOR and the baseline

However, the same dummy baseline performed better when fed with the whole of the newspaper corpus, consisting of 3,5 million words. This, and the bad performance of the parameters that are more dependant on corpus size, like *frequency* and *mutual information*, clearly indicates that the performance of X-TRACTOR, at least for this particular task, will tend to improve when dealing with huge amounts of corpus. This is probably due to the data sparseness that affects DMs.

This evaluation provided a rough intuition of the goodness of each of the parameters, but it failed to capture interactions beteween them. To assess that, we evaluated combinations of parameters by comparing them with the lexicon. We finally came to the conclusion that, for this task, the most useful parameter combination consisted in assigning a very high weight to structural and discourse-contextual information, and a relatively important weight to content and lengh, while no weight at all was assigned to frequency or mutual information. This combination of parameters also provides an empirical approach to the delimitation of the concept of DM, by eliciting the most influential among a set of DM-characterising features.

However, the evaluation of parameters failed to capture the number of DMs non present in the lexicon retrieved by each parameter or combination of parameters. To do that, the highest ranked DM candidates of each of the lists obtained for each parameter or parameter combination should have been revised manually. That's why only the best combinations of parameters were evaluated as to the enhancement of the lexicon they provided.

3.3. Results with combined parameters

In Table 2 the results of the evaluation of X-TRACTOR and the mentioned baseline are presented. From the sample of 350,000 words, the baseline obtained a list of 60,155 DM candidates, while X-TRACTOR proposed 269,824. Obviously, not all of these were actual DMs, but both systems present an 88% coverage of the DMs in the lexicon that are present in this corpus sample, which were 372.

Concerning goodness of DM assessment, it can be seen that 43% of the 100 DM candidates ranked highest by the baseline were or contained actual DMs, while X-TRACTOR achieved a 68%. Out of these, the baseline succeeded in identifying a 9% of DMs that were not in the lexicon, while X-TRACTOR identified a 15%. Moreover, X-TRACTOR identified an 8% of temporal expressions. The fact that they are identified by the same features characterising DMs indicates that they are very likely to be treated in the same way, in spite of heterogeneous discursive content.

In general terms, it can be said that, for this task, X-TRACTOR outperformed the baseline, suceeded in enlarging an initial DM lexicon and obtained quality results and low noise. It seems clear, however, that the dummy baseline is useful for locating DMs in text, although it provides a limited number of them.

4. Conclusions and Future Directions

By this application of X-TRACTOR to a DM extraction task for Spanish, we have shown that bootstrap-based lexical acquisition is a valid method for enhancing a lexicon of DMs, thus improving the limited coverage of the starting resource. The resulting lexicon exploits the properties of the input corpus, so it is highly portable to restricted domains. This high portability can be understood as an equivalent of domain independence.

The use of this empirical methodology circumvents the bias of human judges, and elicits the contribution of a number of parameters to the identification of DMs. Therefore, it can be considered as a data-driven delimitation of the concept of DM. However, the impact of the enhancement obtained by bootstraping the lexicon should be assessed in terms of prototypicality, that is to say, it should be studied how enlarging a starting set of clearly protoypical DMs

may lead to finding less and less prototypical DMs. For an approach to DM prototypicality, see (Alonso et al., 2002).

Future improvements of this tool include applying techinques for interpolation of variables, so that the tuning of the parameters for *markerhood* assessment can be carried out automatically. Also the process of rule induction from the lexicon to the rule module can be automatised, given classes of DM-constituting-words and classes of DMs. Moreover, it has to be evaluated in bigger corpora.

Another line of work consists in exploiting other kinds of knowledge for DM extraction and ponderation. For example, annotated corpora could be used as input, tagged with morphological, syntactical, semantic or even discursive information. The resulting DM candidate list could be pruned by removing proper nouns from it, for example, with the aid of a proper noun data base or *gazetteer* (Arévalo et al., 2002).

To test the portability of the system, it should be applied to other tasks and languages. An experiment to build a DM lexicon for Catalan is currently under progress. To do that, we will try to alternative strategies: one, translating the linguistic knowledge modules to Catalan and directly applying X-TRACTOR to a Catalan corpus, and another, obtaining an initial lexicon by applying the dummy baseline presented here and carrying out the whole bootstrap process.

5. Acknowledgements

This research has been conducted thanks to a grant associated to the X-TRACT project, PB98-1226 of the Spanish Research Department. It has also been partially funded by projects HERMES (TIC2000-0335-C03-02) and PETRA (TIC2000-1735-C02-02).

Creating and Using Semantics for Information Retrieval and Filtering

State of the Art and Future Research

Several experiments have been carried out in the last 15 years investigating the use of various resources and techniques (e.g., thesauri, synonyms, word sense disambiguation, etc.) to help refine or enhance queries. However, the conclusions drawn on the basis of these experiments vary widely. Results of some studies have led to the conclusion that semantic information serves no purpose and even degrades results, while others have concluded that the use of semantic information drawn from external resources significantly increases the performance of retrieval software. At this point, several question arise:

- Why do these conclusions vary so widely?
- Is the divergence a result of differences in methodology?
- Is the divergence a result of a difference in resources? What are the most suitable resources?
- Do results using manually constructed resources differ in significant ways from results using automatically extracted information?
- From corpus building to terminology structuring, to which methodological requirements resources acquisition has to comply with in order to be relevant to a given application?
- What is the contribution of specialized resources?
- Are present frameworks for evaluation (e.g., TREC) appropriate
- for evaluation of results?.

These questions are fundamental not only to research in document retrieval, but also for information searching, question answering, filtering, etc. Their importance is even more acute for multilingual applications, where, for instance, the question of whether to disambiguate before translating is fundamental.

Moreover, the increasing diversity of monolingual as well as multilingual documents on the Web invite to focus attention on lexical variability in connection with textual genre and with questioning the resources reusability stance.

The goal of this workshop is to bring together researchers in the domain of document retrieval, and in particular, researchers on both sides of the question of the utility of enhancing queries with semantic information gleaned from languages resources and processes.

The workshop will provide a forum for presentation of the different points of view, followed by a roundtable in which the participants will assess the state of the art, consider the results of past and on-going work and the possible reasons for the considerable differences in their conclusions. Ultimately, they will attempt to identify future directions for research.

Finding Similar Documents in Document Collections

Thorsten Brants and Reinhard Stolle

Palo Alto Research Center (PARC)
3333 Coyote Hill Rd, Palo Alto, CA 94304, USA
{brants,stolle}@parc.com

Abstract

Finding similar documents in natural language document collections is a difficult task that requires general and domain-specific world knowledge, deep analysis of the documents, and inference. However, a large portion of the pairs of similar documents can be identified by simpler, purely word-based methods. We show the use of Probabilistic Latent Semantic Analysis for finding similar documents. We evaluate our system on a collection of photocopier repair tips. Among the 100 top-ranked pairs, 88 are true positives. A manual analysis of the 12 false positives suggests the use of more semantic information in the retrieval model.

1. Introduction

Collections of natural language documents that are focused on a particular subject domain are commonly used by communities of practice in order to capture and share knowledge. Examples of such "focused document collections" are FAQs, bug-report repositories, and lessons-learned systems. As such systems become larger and larger, their authors, users and maintainers increasingly need tools to perform their tasks, such as browsing, searching, manipulating, analyzing and managing the collection. In particular, the document collections become unwieldy and ultimately unusable if obsolete and redundant content is not continually identified and removed.

We are working with such a knowledge-sharing system, focused on the repair of photocopiers. It now contains about 40,000 technician-authored free text documents, in the form of tips on issues not covered in the official manuals. Such systems usually support a number of tasks that help maintain the utility and quality of the document collection. Simple tools, such as keyword search, for example, can be extremely useful. Eventually, however, we would like to provide a suite of tools that support a variety of tasks, ranging from simple keyword search to more elaborate tasks such as the identification of "duplicates." Fig. 1 shows a pair of similar tips from our corpus. These two tips are about the same problem, and they give a similar analysis as to why the problem occurs. However, they suggest different solutions: Tip 118 is the "official" solution, whereas Tip 57 suggests a short-term "work-around" fix to the problem. This example illustrates that "similarity" is a complicated notion that cannot always be measured along a one-dimensional scale. Whether two or more documents should be considered "redundant" critically depends on the task at hand. In the example of Fig. 1, the work-around tip may seem redundant and obsolete to a technician who has the official new safety cable available. In the absence of this official part, however, the work-around tip may be a crucial piece of information.

Our goal is to develop techniques that analyze the conceptual contents of natural language documents at a granularity that is fine enough to capture distinctions like the one between Tips 57 and 118, described in the previous paragraph. In order to do that, we are designing formal representations of document contents that will allow us to assess not only whether two documents are about the same subject but also whether two documents actually say the same thing. We are currently focusing on the tasks of computer-assisted redundancy resolution. We hope that our techniques will eventually extend to support even more ambitious tasks such as the identification and resolution of inconsistent knowledge, knowledge fusion, question answering, and trend analysis.

We believe that, in general, the automated or computer-assisted management of collections of natural language documents requires a fine-grained analysis and representation of the documents' contents. This fine granularity in turn mandates deep linguistic processing of the text and inference capabilities using extensive linguistic and world knowledge. Following this approach, our larger research group has implemented a prototype, which we will briefly describe in the next section. This research prototype system is far from complete. Meanwhile, we are investigating to what extent currently operational techniques are useful to support at least some of the tasks that arise from the maintenance of focused document collections. We have investigated the utility of Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999b) for the task of finding similar documents. Section 3. describes our PLSA model and Section 4. reports on our experimental results in the context of our corpus of repair tips. In that section, we also attempt to characterize the types of similarities that are easily detected and contrast them to the types that are easily missed by the PLSA technique. Finally, we speculate how symbolic knowledge representation and inference techniques that rely on a deep linguistic analysis of the documents may be coupled with statistical techniques in order to improve the results.

2. Knowledge-Based Approach

Our goal is to build a system that supports a wide range of knowledge management tasks for focused document collections. We believe that powerful tools for tasks like redundancy resolution, topic browsing, question answering, knowledge fusion, and so on, need to analyze and represent the documents' conceptual contents at a fine level of granularity.

Concentrating on the task of redundancy resolution, our

	Tip 57		Tip 118
Problem:	Left cover damage	Problem:	The current safety cable used in the 5100 Document Handler fails prematurely, causing the Left Document Handler Cover to break.
Cause:	The left cover safety cable is breaking, allowing the left cover to pivot too far, breaking the cover.	Cause:	The plastic jacket made the cable too stiff. This causes stress to be concentrated on the cable ends, where it eventually snaps.
Solution:	Remove the plastic sleeve from around the cable. Cutting the plastic off of the cable makes the cable more flexible, which prevents cable breakage. Cable breakage is a major source of damage to the left cover.	Solution:	When the old safety cable fails, replace it with the new one, which has the plastic jacket shortened.

Figure 1: Example of Eureka tips

project group has so far built a prototype whose goal is to identify conceptually similar documents, regardless of how they are written. This task requires extensive knowledge about language and of the world. Since most of this knowledge engineering effort is performed by hand at the moment, our system's coverage is currently limited to fifteen pairs of similar tips. We are in the process of scaling the system up by one to two orders of magnitude. Eventually, we hope to also support more general tasks, namely identify the parts of two documents that overlap; and identify parts of the documents that stand in some relation to each other, such as expanding on a particular topic or being in mutual contradiction. Such a system will enable the maintenance of vast document collections by identifying potential redundancies or inconsistencies for human attention.

State-of-the-art question answering and information extraction techniques (e.g., (Bear et al., 1997)) are sometimes able to identify entities and the relations between them at a fine level of granularity. However, the functionality and coverage of these techniques is typically restricted to a limited set of types of entities and relations that have been formalized upfront using static templates. Like a small number of other research projects (e.g., the TACITUS project (Hobbs et al., 1993)), our approach is based on the belief that the key to solving this problem is a principled technique for producing formal representations of the conceptual contents of the natural language documents. In our approach, a deep analysis based on Lexical Functional Grammar theory (Kaplan and Bresnan, 1982) combined with Glue Semantics (Dalrymple, 1999) produces a compact representation of the syntactic and semantic structures for each sentence. From this language-driven representation of the text, we map to a knowledge-driven representation of the contents that abstracts away from the particular natural language expression. This mapping includes several—not necessarily sequential—steps. In one step, we rely on a domain-specific ontology to identify canonicalized entities and events that are talked about in the text. In our case, these entities and events include things like parts, e.g., photoreceptor belt, and relevant activities such as cleaning, for example. Another step performs thematic role assignments and assembles fragments of conceptual structures from the normalized entities and events (e.g., cleaning a photoreceptor belt). Furthermore, certain relations are normalized; for example, "stiff" and "flexible" (in Fig. 1) both refer to the rigidity of an object, one being the inverse of the other. Yet another step composes structure fragments into higher-level structures that reflect causal or temporal relations, such as action sequences or repair plans. All steps involve ambiguity resolution as a central problem, which requires inference based on extensive linguistic and world knowledge. For a more detailed description of this approach and its scalability, see (Crouch et al., 2002).

Finally, we assess the similarity of two documents using a variant of the Structure Mapping Engine (SME) (Forbus et al., 1989). SME anchors its matching process in identical elements that occur in the same structural positions in the base and target representations, and from this builds a correspondence. The larger the structure that can be recursively constructed in this manner, while preserving a systematicity constraint of one-to-one correspondence between base and target elements and the identicality of anchors, the greater the similarity score.

We expect that the fine-grained conceptual representations discussed in this section will eventually enable our system to detect whether two documents are not only about the same subject but also saying the same thing. Many interesting cases of similarity can, however, be detected with lighter-weight techniques. This is the topic of the next section.

3. The Word-Based Statistical Model

While in the general case deep processing, knowledge about the world, and inference are necessary to identify similar documents, there may be a large number of similar pair that can be discovered by a shallow approach. We now view the task of finding similar pairs of documents as an information retrieval problem where documents are matched based on the words that occur in the documents, i.e., we use a vector space model of the documents. Comparison is done using Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999b).

3.1. Document Preprocessing

Each document is first preprocessed by:

1. Separating the document fields. Each tip usually comes with additional administrative information like author, submission date, location, status, contact information, etc. We extract the information that is contained in the `CHAINS`, `PROBLEM`, `CAUSE`, and `SO-`

LUTION fields[1].

2. Tokenizing the document. Words and numbers are separated at white space, punctuation is stripped, abbreviations are recognized.

3. Lemmatizing each token, i.e., each word is uniquely mapped to a base form. We use the LinguistX lemmatizer[2] to perform this task.

Steps 1 to 3 identify the terms in the vocabulary. We select the subset of those terms that occur in at least two documents. Given this vocabulary, each document d is represented by its term-frequency vector $f(d,w)$, where w are the terms of the document.

3.2. Probabilistic Latent Semantic Indexing

Probabilistic Latent Semantic Analysis (PLSA) is a statistical latent class model or aspect model (Hofmann, 1999a; Hofmann, 1999b). It can be seen as a statistical view of Latent Semantic Analysis (LSA) (Deerwester et al., 1990). The model is fitted to a training corpus by the Expectation Maximization (EM) algorithm (Dempster et al., 1977). It assigns probability distributions over classes to words and documents and thereby allows them to belong to more than one class, and not to only one class as is true of most other classification methods. PLSA represents the joint probability of a document d and a word w based on a latent class variable z:[3]

$$P(d,w) = P(d)\sum_z P(w|z)P(z|d) \tag{1}$$

The model makes an independence assumption between word w and document d if the latent class z is given, i.e., $P(w|z,d) = P(w|z)$. PLSA has the following view of how a document is generated: first a document $d \in \mathcal{D}$ (i.e., its dummy label) is chosen with probability $P(d)$. For each word in document d, a latent topic $z \in \mathcal{Z}$ is chosen with probability $P(z|d)$, which in turn is used to choose the word $w \in \mathcal{W}$ with probability $P(w|z)$.

A model is fitted to a document collection $\mathcal{D}$ by maximizing the log-likelihood function $\mathcal{L}$:

$$\mathcal{L} = \sum_{d\in\mathcal{D}}\sum_{w\in d} f(d,w) log P(d,w) \tag{2}$$

The E-step in the EM-algorithm is

$$P(z|d,w) = \frac{P(z)P(d|z)P(w|z)}{\sum_{z'} P(z')P(d|z')P(w|z')} \tag{3}$$

and the M-step consists of

$$P(w|z) = \frac{\sum_d f(d,w)P(z|d,w)}{\sum_{d,w'} f(d,w')P(z|d,w')} \tag{4}$$

$$P(d|z) = \frac{\sum_w f(d,w)P(z|d,w)}{\sum_{d',w} f(d',w)P(z|d',w)} \tag{5}$$

$$P(z) = \frac{\sum_{d,w} f(d,w)P(z|d,w)}{\sum_{d,w} f(d,w)} \tag{6}$$

The parameters are either randomly initialized or according to some prior knowledge.

After having calculated the reduced dimensional representations of documents in the collection, we map the vectors back to the original term space to yield vectors $P(w|d)$ by

$$P(w|d) = \sum_z P(w|z)P(z|d) \tag{7}$$

$P(w|d)$ can be seen as a smoothed version of the empirical distribution $r(w|d) = f(d,w)/f(d)$ of words in the document. The advantage of the smoothed version is that it captures semantic similarities through the lower-dimensional representation.

Note that this process is intended for the pairwise comparison of all documents in the training collection. It can be extended to new documents q (query or test documents) by using the folding-in process. Folding-in uses Expectation-Maximization as in the training process; the E-step is identical, the M-step keeps all the $P(w|z)$ constant and recalculates $P_{fi}(z|q)$. Usually, a very small number of iterations is sufficient for folding-in. We get a smoothed representation of a folded-in document by

$$P_{fi}(w|q) = \sum_z P(w|z)P_{fi}(z|q) \tag{8}$$

This corresponds to the PLSI-U model described in (Hofmann, 1999b).

3.3. Document Comparison

A standard way of comparing vector space representations of documents d_1 and d_2 is to calculate the cosine similarity score of tf-idf weighted document vectors (Salton, 1988):

$$\mathrm{sim}_{\cos}(d_1,d_2) = \frac{\sum_w \hat{f}(d_1,w)\hat{f}(d_2,w)}{\sqrt{\sum_w \hat{f}(d_1,w)^2}\sqrt{\sum_w \hat{f}(d_2,w)^2}} \tag{9}$$

$\hat{f}(d,w)$ is the weighted frequency of word w in document d:

$$\hat{f}(d,w) = f(d,w)\log\frac{N}{df(w)} \tag{10}$$

where N is the total number of documents, and $df(w)$ is the number of documents containing word w.

We additionally perform the comparison on the PLSA representation of $P(w|d)$. Pairwise comparisons are done by

$$\mathrm{sim}^{\mathrm{PLSA}}_{\cos}(d_1,d_2) = \frac{\sum_w P(w|d_1)P(w|d_2)}{\sqrt{\sum_w P(w|d_1)^2}\sqrt{\sum_w P(w|d_2)^2}} \tag{11}$$

[1]The CHAINS field contains a numerical identifier of the product line.

[2]For information about the LinguistX tools, see www.inxight.com/products/linguistx/

[3]Unless otherwise noted, we use the following notational conventions: training documents $d, d' \in \mathcal{D}$, test documents $q, q' \in \mathcal{Q}$, words $w, w' \in \mathcal{W}$, and classes $z, z' \in \mathcal{Z}$.

Table 1: Precision of the statistical model for the n top-ranked pairs. A pair of tips is considered a "true positive" if their conceptual contents are categorized to be the same, similar, or in the subset relationship.

n	precision
10	100%
20	100%
30	100%
40	96%
50	92%
60	92%
70	90%
80	87%
90	88%
100	88%

Both similarities are combined with a weight λ to yield the final similarity score (see (Hofmann, 1999b)).

$$\mathrm{sim}(d_1, d_2) = \lambda \mathrm{sim}_{\cos}(d_1, d_2) + (1 - \lambda)\mathrm{sim}_{\cos}^{\mathrm{PLSA}}(d_1, d_2) \quad (12)$$

The output of the algorithm is a list of pairs ranked according to their similarity.

4. Experiments

We applied the algorithm described in Section 3. to a subset of the Eureka database consisting of 1,321 tips. PLSA representations of $P(w|d)$ were created for each tip, and pairs of tips were ranked according to their similarity. Following (Hofmann, 1999b), we created models with $Z = 32, 48, 64, 80, 128$ latent classes, calculated the average $P(w|d)$. The similarity score was combined with the standard tf-idf cosine similarity with a weight of $\lambda = \frac{1}{6}$.

4.1. Precision and Recall

We manually inspected the 100 top-ranked pairs of tips and classified their similarity by hand according to the types of similarity described in Section 4.2.. The results are shown in Table 1. Of the 10 top-ranked pairs, all 10 were actual duplicates,[4] of the 40 top-ranked pairs, 96% were true positives, and so on. The manual inspection of the 100 top-ranked pairs (of the potential 871,860 pairs) revealed 88 true positives.

Independent manual sampling of the subset of 1,321 tips, which is a very tedious and time-consuming task, revealed 17 similar pairs (14 pairs and 1 triple). 3 of these pairs were among the top 100 emitted by the word-based statistical model. This is a recall of 18% on the manually identified similar pairs. However, it is unclear how this number relates to the overall recall because the distribution of the other similar pairs is currently unclear.

[4] A pair of tips is considered "duplicates" if their conceptual contents are categorized to be the same. A pair of tips is considered a "true positive" if their conceptual contents are categorized to be the same, similar, or in the subset relationship. See Section 4.2..

Table 2: Number of pairs with structural and conceptual match in the 100 top-ranked pairs of documents. We are interested in finding the conceptually same/similar/subset pairs. False positives are shown in *italics*.

		conceptual				
		same	sim	subset	diff	sum
surface	same	24	0	10	*2*	36
	sim	17	24	13	*8*	62
	diff	0	0	0	*2*	2
	sum	41	24	23	*12*	100

4.2. Types of Similarity

The word-based statistical model of Section 3. seems to be good at identifying pairs whose texts are similar *at a surface level*. In order to see how well the model does at identifying pairs whose contents are *conceptually similar*, we manually performed a qualitative evaluation and classified each of the 100 top-ranked pairs according to the following criteria:

Surface similarity of texts: *same, similar, different*. Surface similarity describes the similarity of the set of words and syntactic constructions used in the documents. *Same* means that the documents are (almost) identical. *Similar* means that some words may be different or replaced by synonyms (e.g., "fault" vs. "failure" vs. "problem", "motor" vs. "drive", "line" vs. "wire", etc.), constructions are different, order of sentences may be different. *Different* means that the texts are different.

Conceptual similarity of contents: *same, similar, subset, different*. Conceptual similarity refers to the semantic/conceptual contents of the document, independent of how it is expressed as surface text. *Same* means that the documents have (almost) the same contents (e.g., "cutting the plastic off of the cable makes the cable more flexible" vs. "the plastic jacket made the cable too stiff"). *Similar* means that there is a significant overlap of conceptual contents between the two documents; for example, the tips describe the same problem but suggest different solutions (see Fig. 1), or, the tips describe an analogous problem exhibited at different mechanical parts (see Fig. 2).

Subset describes cases where the conceptual contents of one document form a proper subset of the conceptual contents of the other document—for example, if one document elaborates on the other. *Different* describes conceptually different documents.

Table 2 shows how many of the pairs fall into the different categories. Since the PSLA model is word-based, almost none of the pairs have different surface similarity. In the 100 top-ranked pairs, the majority of false positives occur when the surface texts are similar but the conceptual contents are different (8 out of 12).

The algorithm identifies surface similarity very well, only 2 out of 100 pairs are different at the surface text level.

Tip 690		Tip 714	
Problem:	08-110, Tray 3 misfeed	Problem:	08-100, Tray 1 misfeed
Cause:	J201 Pin 1 loose. Drive coupling set screw loose, Blower hose came off, Fang plate out of adjustment, Stack height out of adjustment, Defective DRCC1.	Cause:	Set screw on feed clutch loose. Stack height sensor out of bracket. Feeder drive coupling loose. Blower hose off.
Solution:	Reseat J201 Pin 1. Tighten drive coupling, Reconnect blower hose , Adjust fang plate, Adjust stack height. Replace DRCC1.	Solution:	Adjust clutch. Repair stack height sensor. Tighten feeder driv e coupling. Repair blower hose.

Figure 2: True positive: this pair at rank 68 has similar surface text and is similar at the conceptual level.

Tip 1280		Tip 1281	
Problem:	Xerox Binder 120. The "READY FOR AUTO FEED" message does not change when set clamp assy is pulled in	Problem:	Xerox Binder 120. The Binder 120 does not display "Ready for auto feed" message.
Cause:	Set Clamp extended sensor (Q23) is "H" all the time	Cause:	Set Clamp extended sensor (Q23) is "Lo" all the time
Solution:	check the set clamp sensor wires for an open circuit, if ok, Replace the set clamp extended sensor (Q23)	Solution:	Check the set clamp extended sensor wires for Short circuit to frame, Set clamp out flag is in the sensor correctly, if ok, replace the sensor.

Figure 3: False positive: this pair at rank 37 has almost the same surface text but is different at the conceptual level.

These two pairs involve very long documents (average of 1030 tokens per document compared to 132 tokens per document overall average). The documents have an overlap in vocabulary, but the sentences and sequences of sentences are very different.

Correlation with conceptual similarity can also be found, but it is smaller. 10 out of 100 pairs were categorized as the same or similar at the surface but are conceptually different; from the viewpoint of a user in the context of a conceptual task, these pairs should not be identified as similar tips. We believe that a deeper analysis of the document contents as outlined in Section 2. will help distinguish between conceptually different documents and, therefore, reduce the number of such false positives.

One of the two pairs that are almost the same at the surface level but have different conceptual contents is shown in Fig. 3.

They use the same or very similar words, but make opposite statements at the conceptual level. Tip 1280 describes a sensor signal that is erroneously "high" because of an open circuit. Tip 1281 describes a sensor signal that is erroneously "low" because of a short circuit. This difference cannot be found by the word-based statistical model. The topics of these two documents are very similar; however, a correct analysis of the contents requires the recognition of the difference between "does not display" and "does not change", the difference between "Lo" and "H", and the difference between "open circuit" and "short circut" despite the fact that these phrases often occur in similar contexts.

Fig. 4 shows a pair with similar surface texts but different conceptual contents. Tip 227 explains how to repair or prevent a particular failure that is caused by a ring's wearing out. Tip 173 says that an improved repair kit can be ordered; it also provides a work-around for the case in which that improved kit is not available.

The two examples in Figures 3 and 4 show that in many cases it is necessary to process the text more deeply than at the word level in order to be able to recognize fine-grained distinctions in the documents' contents. On the other hand, a large number of true positives are actually discovered by the word-based model (88 out of the 100 top-ranked pairs). The word-based statistical model even finds cases in which the conceptual contents are similar, but where this fact is not immediately obvious from the surface-level texts. Fig. 2 shows an example of this case. The two tips describe almost the same fault situation, except that one of them occurs in connection with Tray 1 while the other one occurs in connection with Tray 3. Even for a human—at least for an untrained human—, this pair is difficult to detect.

The examples suggests that symbolic and statistical techniques may be good at different tasks that complement each other nicely. Statistical techniques seem to be good at identifiying that the two tips are about the same topic. Knowledge-based techniques—specifically, a domain ontology—may help distinguish "Fuser Couplings" from the "Fuser Couplings and Shaft Repair Kit" (cf. Fig. 4), which in turn may trigger further distinctions between the two tips based on domain-specific knowledge. Similarly, the example in Fig. 3 suggests that a statistical analysis coupled with a limited normalization of relations that occur frequently in the domain may be a promising direction to pursue.

Fig. 5 shows the rank of a pair vs. its similarity. Our data set contains 1,321 documents, i.e., there are 871,860 pairs. Word-based similarity does not decrease linearly. There is a large drop at the beginning, then the curve is relatively flat, and it suddenly drops again at the very end. All of the manually found similar pairs (the 17 pairs described in Section 4.1.) are marked with a ∘ in the graph; they are among the first 7% (the lowest rank is 57,014). We do currently not

	Tip 173		Tip 227
Problem:	Improved Fuser Couplings 600K31031 Tag P-184. Broken calls when servicing failed Fuser Drive Couplings.	Problem:	Fuser Couplings and Shaft Repair Kit, 605K3950, Tag P-129. The retaining ring that holds the Fuser Assembly Drive Coupling in place wears out and falls off the shaft.
Cause:	The parts needed to repair a Fuser Drive failure are presently contained in two separate Kits. If the service representative does not have both Kits in inventory the service call is interrupted.	Cause:	The Fuser Assembly Drive Coupling rubs against the retaining ring as it turns.
Solution:	1. To repair Fuser Drive failures, order the new Fuser Couplings an d Shaft Repair Kit 600K31031, TAG P-184. This kit contains all the parts in Fuser Couplings and Shaft Repair Kit 605K3950 except that the improved Drive Coupling, issued separately in Kit 600K31030, has been substituted. 2. If you have 600K31030 as well as 605K3950 in inventory, these Kits can be salvaged to provide the same parts as the new Kit. Open 605K3950 and discard only the Fuser Drive Coupling, then use the Coupling contained in Kit number 600K31030 in its place.	Solution:	On the next service call check to see if P-129 is installed. If Tag P-129 is not installed, order and install the Fuser Couplings and Shaft Repair Kit, 605K3950.

Figure 4: False positive: this pair at rank 86 has similar surface text and is about similar parts, but is different at the conceptual level.

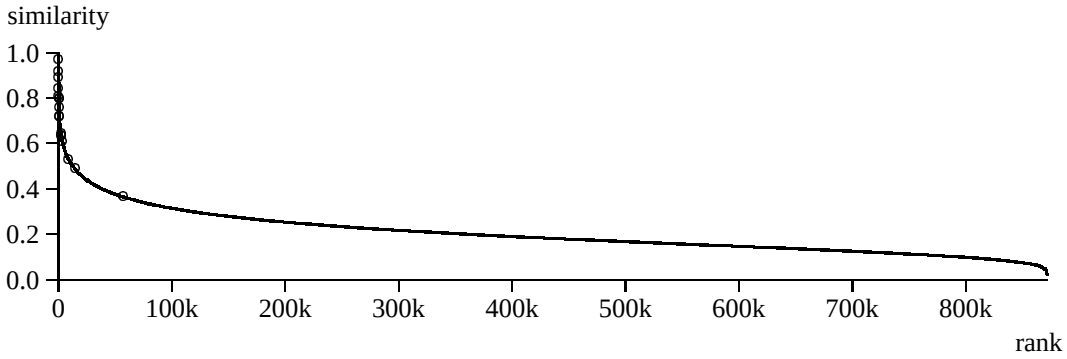

Figure 5: Rank vs. PLSA similarity. Manually found pairs are marked with ∘.

know whether there are any similar pairs below this rank, but it is probably safe to assume that almost all of the similar pairs are within the initial portion of the graph. Even if the presented statistical method does not rank all similar pairs at the very top, it seems to efficiently place them in a small initial segment at the top.

One focus of our current research effort is to understand the capabilities and limitations of the current PLSA model in order to design an improved system by, for example, (1) supplying the PLSA model with better-suited information for any given particular task, or (2) using the current version of the PLSA model as a prefilter for the knowledge-based approach.

5. Conclusions

We address the problem of matching the conceptual contents of documents. The domain of the documents in our experiments is the repair of photocopiers. In general, the problem requires world knowledge and deep processing of the documents. But in a large number of cases, similar documents can be found by shallow processing and a word-based statistical model. A quantitative evaluation shows that 88 of the 100 statistically top-ranked documents are true positives. An analysis of the erroneous cases indicates where the statistical model could benefit from deeper processing. Two important types of information that are currently absent from our statistical model are negation and relations between entities. We expect that providing the model with more semantic information along these lines will improve our system's performance and allow it to make finer distinctions among the documents' contents.

Abstract

Photos annotated with textual keywords can be thought of as resembling documents, and querying for photos by keywords is akin to the information retrieval done by search engines. A common approach to making IR more robust involves query expansion using a thesaurus or other lexical resource. The chief limitation is that keyword expansions tend to operate on a word level, and expanded keywords are generally lexically motivated rather than conceptually motivated. In our photo domain, we propose a mechanism for robust retrieval by expanding the *concepts* depicted in the photos, thus going beyond lexical-based expansion. Because photos often depict places, situations and events in everyday life, concepts depicted in photos such as place, event, and activity can be expanded based on our "common sense" notions of how concepts relate to each other in the real world. For example, given the concept "surfer" and our common sense knowledge that surfers can be found at the beach, we might provide the additional concepts: "beach", "waves", "ocean", and "surfboard". This paper presents a mechanism for robust photo retrieval by expanding annotations using a world semantic resource. The resource is automatically constructed from a large-scale freely available corpus of commonsense knowledge. We discuss the challenges of building a semantic resource from a noisy corpus and applying the resource appropriately to the task.

1. Introduction

The task described in this paper is the robust retrieval of annotated photos by a keyword query. By "annotated photos," we mean a photo accompanied by some metadata about the photo, such as keywords and phrases describing people, things, places, and activities depicted in the photo. By "robust retrieval," we mean that photos should be retrievable not just by the explicit keywords in the annotation, but also by other implicit keywords conceptually related to the event depicted in the photo.

In the retrieval sense, annotated photos behave similarly to documents because both contain text, which can be exploited by conventional IR techniques. In fact, the common query enrichment techniques such as thesaurus-based keyword expansion developed for document retrieval may be applied to the photo retrieval domain without modification.

However, keyword expansion using thesauri is limited in its usefulness because keywords expanded by their synonyms can still only retrieve documents directly related to the original keyword. Furthermore, naïve synonym expansion may actually contribute more noise to the query and negate what little benefit keyword expansion may add to the query, namely, if keywords cannot have their word sense disambiguated, then synonyms for all the word senses of a particular word may be used in the expansion, and this has the potential to retrieve many irrelevant documents.

1.1. Relevant Work

Attempting to overcome the limited usefulness of keyword expansion by synonyms, various researchers have tried to use slightly more sophisticated resources for query expansion. These include dictionary-like resources such as lexical semantic relations (Voorhees, 1994), and keyword co-occurrence statistics (Peat and Willet, 1991; Lin, 1998), as well as resources generated dynamically through relevance feedback, like global document analysis (Xu and Croft, 1996), and collaborative concept-based expansion (Klink, 2001).

Although some of these approaches are promising, they share some of the same problems as naïve synonym expansion. Dictionary-like resources such as WordNet (Fellbaum, 1998) and co-occurrence frequencies, although more sophisticated that just synonyms, still operate mostly on the word-level and suggest expansions that are lexically motivated rather than conceptually motivated. In the case of WordNet, lexical items are related through a very limited set of nymic relations. Relevance feedback, though somewhat more successful than dictionary approaches, requires additional iterations of user action and we cannot consider it fully automated retrieval, which makes it an inappropriate candidate for our task.

1.2. Photos vs. Documents

With regard to our domain of photo retrieval, we make a key observation about the difference between photos and documents, and we exploit this difference to make photo retrieval more robust. We make the observation that photos taken by an ordinary person has more structure and is more predictable than the average document on the web, even though that structure may not be immediately evident. The contents of a typical document such as a web page are hard to predict, because there are too many types and genres of web pages and the content does not predictably follow a stereotyped structure. However, with typical photos, such as one found in your photo album, there is more predictable structure. That is, the intended subject of photos often includes people and things in common social situations. Many of these situations depicted, such as weddings, vacations, sporting events, sightseeing, etc. are common to human experience, and therefore have a high level of predictability.

Take for example, a picture annotated with the keyword *"bride"*. Even without looking at the photo, a person may be able to successfully guess who else is in the photo, and what situation is being depicted. Common

sense would lead a person to reason that brides are usually found at weddings, that people found around her may be the groom, the father of the bride, bridesmaids, that weddings may take place in a chapel or church, that there may be a wedding cake, walking down the aisle, and a wedding reception. Of course, common sense cannot be used to predict the structure of specialty photos such as artistic or highly specialized photos; this paper only considers photos in the realm of consumer photography.

1.2.1. A Caveat

Before we proceed, it is important to point out that any semantic resource that attempts to encapsulate common knowledge about the everyday world is going to be somewhat culturally specific. The previous example of brides, churches and weddings illustrates an important point: knowledge that is *obvious* and *common* to one group of people (in this case, middle-class USA) may not be so obvious or common to other groups. With that in mind, we go on to define the properties of this semantic resource.

1.3. World Semantics

Knowledge about the spatial, temporal, and social relations of the everyday world is part of commonsense knowledge. We also call this *world semantics*, referring to the meaning of everyday concepts and how these concepts relate to each other in the world.

The mechanism we propose for robust photo retrieval uses a world semantic resource in order to expand concepts in existing photo annotations with concepts that are, *inter alia*, spatially, temporally, and socially related. More specifically, we automatically constructed our resource from a corpus of English sentences about commonsense by first extracting predicate argument structures, and then compiling those structures into a Concept Node Graph, where the nodes are commonsense concepts, and the weighted edges represent commonsense relations. The graph is structured much like MindNet (Richardson et al., 1998). Performing concept expansion using the graph is modeled as spreading activation (Salton and Buckley, 1988). The relevance of a concept is measured as the semantic proximity between nodes on the graph, and is affected by the strength of the links between nodes.

This paper is structured as follows: First, we discuss the source and nature of the corpus of commonsense knowledge used by our mechanism. Second, a discussion follows regarding how our world semantic resource was automatically constructed from the corpus. Third, we show the spreading activation strategy for robust photo retrieval, and give heuristics for coping with the noise and ambiguity of the knowledge. The paper concludes with a discussion of the larger system to which this mechanism belongs, potential application of this type of resource in other domains, and plans for future work.

2. OMCS: A Corpus of Common Sense

The source of the world semantic knowledge used by our mechanism is the Open Mind Common Sense Knowledge Base (OMCS) (Singh, 2002) - an endeavor at the MIT Media Laboratory that aims to allow a web-community of teachers to collaboratively build a database of "common sense" knowledge.

It is hard to define what actually constitutes common sense, but in general, one can think of it as knowledge about the everyday world that most people within some population consider to be "obvious." As stated earlier, common sense is somewhat culturally specific. Although many thousands of people from around the world collaboratively contribute to Open Mind Common Sense, the majority of the knowledge in the corpus reflects the cultural bias of middle-class USA. In the future, it may make sense to tag knowledge by their cultural specification.

OMCS contains over 400,000 semi-structured English sentences about commonsense, organized into an ontology of commonsense relations such as the following:

- A is a B
- You are likely to find A in/at B
- A is used for B

By semi-structured English, we mean that many of the sentences loosely follow one of 20 or so sentence patterns in the ontology. However, the words and phrases represented by A and B (see above) are not restricted. Some examples of sentences in the knowledge base are:

- Something you find in (a restaurant) is (a waiter)
- The last thing you do when (getting ready for bed) is (turning off the lights)
- While (acting in a play) you might (forget your lines)

The parentheses above denote the part of the sentence pattern that is unrestricted. While English sentence patterns has the advantage of making knowledge easy to gather from ordinary people, there are also problems associated with this. The major limitations of OMCS are four-fold. First, there is ambiguity resulting from the lack of disambiguated word senses, and from the inherent nature of natural languages. Second, many of the sentences are unusable because they may be too complex to fully parse with current parser technology. Third, because there is currently no truth maintenance mechanism or filtering strategy for the knowledge gathered (and such a mechanism is completely nontrivial to build), some of the knowledge may be anomalous, i.e. not common sense, or may plainly contradict other knowledge in the corpus. Fourth, in the acquisition process, there is no mechanism to ensure a broad coverage over many different topics and concepts, so some concepts may be more developed than others.

The Open Mind Commonsense Knowledge Base is often compared with its more famous counterpart, the CYC Knowledge Base (Lenat, 1998). CYC contains over 1,000,000 hand-entered rules that constitute "common sense". Unlike OMCS, CYC represents knowledge using formal logic, and ambiguity is minimized. In fact, it does not share any of the limitations mentioned for OMCS. Of course, the tradeoff is that whereas a community of non-experts contributes to OMCS, CYC needs to be somewhat carefully engineered. Unfortunately, the CYC corpus is not publicly available at this time, whereas OMCS *is* freely available and downloadable via the website (www.openmind.org/commonsense).

Even though OMCS is a more noisy and ambiguous corpus, we find that it is still suitable to our task. By

normalizing the concepts, we can filter out some possibly unusable knowledge (Section 3.2). The impact of ambiguity and noise can be minimized using heuristics (Section 4.1). Even with these precautionary efforts, some anomalous or bad knowledge will still exist, and can lead to seemingly semantically irrelevant concept expansions. In this case, we rely on the fail-soft nature of the application that uses this semantic resource to handle noise gracefully.

3. Constructing a World Semantic Resource

In this section, we describe how a usable subset of the knowledge in OMCS is extracted and structured specifically for the photo retrieval task. First, we apply sentence pattern rules to the raw OMCS corpus and extract crude predicate argument structures, where predicates represent commonsense relations and arguments represent commonsense concepts. Second, concepts are normalized using natural language techniques, and unusable sentences are discarded. Third, the predicate argument structures are read into a Concept Node Graph, where nodes represent concepts, and edges represent predicate relationships. Edges are weighted to indicate the strength of the semantic connectedness between two concept nodes.

3.1. Extracting Predicate Argument Structures

The first step in extracting predicate argument structures is to apply a fixed number of mapping rules to the sentences in OMCS. Each mapping rule captures a different commonsense relation. Commonsense relations, insofar as what interests us for constructing our world semantic resource for photos, fall under the following general categories of knowledge:

1. Classification: A dog is a pet
2. Spatial: San Francisco is part of California
3. Scene: Things often found together are: restaurant, food, waiters, tables, seats
4. Purpose: A vacation is for relaxation; Pets are for companionship
5. Causality: After the wedding ceremony comes the wedding reception.
6. Emotion: A pet makes you feel happy; Rollercoasters make you feel excited and scared.

In our extraction system, mapping rules can be found under all of these categories. To explain mapping rules, we give an example of knowledge from the aforementioned Scene category:

```
somewhere THING1 can be is PLACE1
somewherecanbe
THING1, PLACE1
0.5, 0.1
```

Mapping rules can be thought of as the grammar in a shallow sentence pattern matching parser. The first line in each mapping rule is a sentence pattern. THING1 and PLACE1 are variables that approximately bind to a word or phrase, which is later mapped to a set of canonical commonsense concepts. Line 2 specifies the name of this predicate relation. Line 3 specifies the arguments to the predicate, and corresponds to the variable names in line 1. The pair of numbers on the last line represents the confidence weights given to forward relation (left to right), and backward relation (right to left), respectively, for this predicate relation. This also corresponds to the weights associated with the directed edges between the nodes, THING1 and PLACE1 in the graph representation.

It is important to distinguish the value of the forward relation on a particular rule, as compared to a backward relation. For example, let us consider the commonsense fact, *"somewhere a bride can be is at a wedding."* Given the annotation *"bride,"* it may be very useful to return *"wedding."* However, given the annotation *"wedding,"* it seems to be less useful to return *"bride," "groom," "wedding cake," "priest,"* and all the other things found in a wedding. For our problem domain, we will generally penalize the direction in a relation that returns hyponymic concepts as opposed to hypernymic ones. The weights for the forward and backward directions were manually assigned based on a cursory examination of instances of that relation in the OMCS corpus.

Approximately 20 mapping rules are applied to all the sentences (400,000+) in the OMCS corpus. From this, a crude set of predicate argument relations are extracted. At this time, the text blob bound to each of the arguments needs to be normalized into concepts.

3.2. Normalizing Concepts

Because any arbitrary text blob can bind to a variable in a mapping rule, these blobs need to be normalized into concepts before they can be useful. There are three categories of concepts that can accommodate the vast majority of the parseable commonsense knowledge in OMCS: Noun Phrases (things, places, people), Attributes (adjectives), and Activity Phrases (e.g.: *"walk the dog," "buy groceries."*), which are verb actions that take either no argument, a direct object, or indirect object.

To normalize a text blob into a Noun Phrase, Attribute or Activity Phrase, we tag the text blob with part of speech information, and use these tags filter the blob through a miniature grammar. If the blob does not fit the grammar, it is massaged until it does or it is rejected altogether. Sentences, which contain text blobs that cannot be normalized, are discarded at this point. The final step involves normalizing the verb tenses and the number of the nouns. Only after this is done can our predicate argument structure be added to our repository.

The aforementioned noun phrase, and activity phrase grammar is shown below in a simplified view. Attributes are simply singular adjectives.

```
NOUN PHRASE:
(PREP) (DET|POSS-PRON) NOUN
(PREP) (DET|POSS-PRON) NOUN NOUN
(PREP) NOUN POSS-MARKER (ADJ) NOUN
(PREP) (DET|POSS-PRON) NOUN NOUN NOUN
(PREP) (DET|POSS-PRON) (ADJ) NOUN PREP NOUN

ACTIVITY PHRASE:
(PREP) (ADV) VERB (ADV)
(PREP) (ADV) VERB (ADV) (DET|POSS-PRON) (ADJ) NOUN
(PREP) (ADV) VERB (ADV) (DET|POSS-PRON) (ADJ) NOUN NOUN
(PREP) (ADV) VERB (ADV) PREP (DET|POSS-PRON) (ADJ) NOUN
```

The grammar is used as a filter. If the input to a grammar rule matches any optional tokens, which are in parentheses, then this is still considered a match, but the output will filter out any optional fields. For example, the phrase, *"in your playground"* will match the first rule and the phrase will stripped to just *"playground."*

3.3. Concept Node Graph

To model concept expansion as a spreading activation task, we convert the predicate argument structures gathered previously into a Concept Node Graph by mapping arguments to concept nodes, and predicate relations to edges connecting nodes. Forward and backward edge weights come from the mapping rule associated with each predicate relation. A segment of the graph is shown in Figure 1.

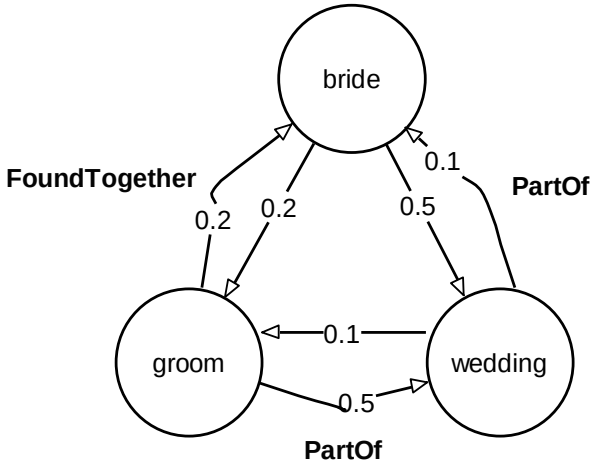

Figure 1. A portion of the Concept Node Graph. Nodes are concepts, and edges correspond to predicate relations.

The following statistics were compiled on the automatically constructed resource:

- 400,000+ sentences in OMCS corpus
- 50,000 predicate argument structures extracted
- 20 predicates in mapping rules
- 30,000 concept nodes
- 160,000 edges
- average branching factor of 5

4. Concept Expansion Using Spreading Activation

In this section, we explain how concept expansion is modeled as spreading activation. We propose two heuristics for re-weighting the graph to improve relevance. Examples of the spreading activation are then given.

In spreading activation, the origin node is the concept we wish to expand (i.e. the annotation) and it is the first node to be activated. Next, nodes one hop away from the origin node are activated, then two levels away, and so on. A node will only be activated if its activation score (AS) meets the activation threshold, which is a tolerance level between 0 (irrelevant) and 1.0 (most relevant). The origin node has a score of 1.0. Given two nodes A and B, where A has 1 edge pointing to B, the activation score of B is given in equation (1).

$$AS(B) = AS(A) * weight(edge(A,B)) \quad \textbf{(1)}$$

When no more nodes are activated, we have found all the concepts that expand the input concept up to our set threshold.

4.1. Heuristics to Improve Relevance

One problem that can arise with spreading activation is that nodes that are activated two or more hops away from the origin node may quickly lose relevance, causing the search to lose focus. One reason for this is noise. Because concept nodes do not make distinctions between different word senses (an aforementioned problem with OMCS), it is possible that a node represents many different word senses. Therefore, activating more than one hop away risks exposure to noise. Although associating weights with the edges provides some measure of relevance, these weights form a homogenous class for all edges of a common predicate (recall that the weights came from mapping rules).

We identify two opportunities to re-weight the graph to improve relevance: reinforcement and popularity. Both of these heuristics are known techniques associated with spreading activation networks (Salton and Buckley, 1988). We motivate their use here with observations about our particular corpus, OMCS.

4.1.1. Reinforcement

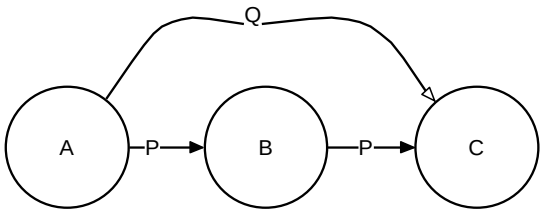

Figure 2. An example of reinforcement

As illustrated in Figure 2, we make the observation that if node C is connected to node A through both paths P and Q, then C would be more relevant to A than had either path P or Q been removed. We call this *reinforcement* and define it as two or more corroborating pieces of evidence, represented by paths, that two nodes are semantically related. The stronger the reinforcement, the higher the potential relevance.

Looking at this in another way, if three or more nodes are mutually connected, they form a cluster. Examples of clusters in our corpus are higher-level concepts like weddings, sporting events, parties, etc., that each have many inter-related concepts associated with them. Within each such cluster, any two nodes have enhanced relevance because the other nodes provide additional paths for reinforcement. Applying this, we re-weight the graph by detecting clusters and increasing the weight on edges within the cluster.

4.1.2. Popularity

The second observation we make is that if an origin node A has a path through node B, and node B has 100

children, then each of node B's children are less likely to be relevant to node A than if node B had had 10 children.

We refer to nodes with a large branching factor as being popular. It happens that popular nodes in our graph tend to either correspond to very common concepts in commonsense, or tend to have many different word senses, or word contexts. This causes its children to have in general, a lower expectation of relevance.

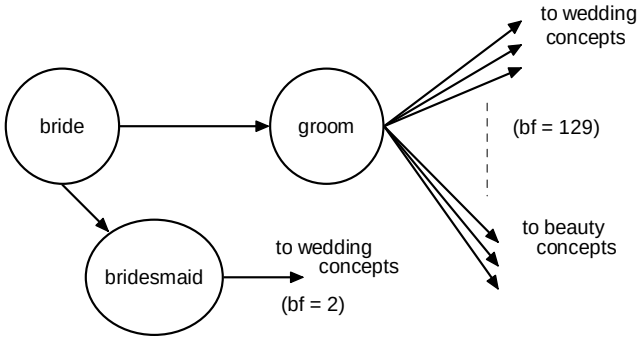

Figure 3. Illustrating the negative effects of popularity

As illustrated in Figure 3, the concept *bride* may lead to *bridesmaid* and *groom*. Whereas *bridesmaid* is a more specific concept, not appearing in many contexts, *groom* is a less specific concept. In fact, different senses and contexts of the word can mean "the groom at a wedding," or "grooming a horse" or "he is well-groomed." This causes *groom* to have a much larger branching factor.

It seems that even though our knowledge is common sense, there is more value associated with more specific concepts than general ones. To apply this principle, we visit each node and discount the weights on each of its edges based on the metric in equation (2). (α and β are constants):

$$newWeight = oldWeight * discount$$
$$discount = \frac{1}{\log(\alpha * branchingFactor + \beta)} \quad (2)$$

4.2. Examples

Below are actual runs of the concept expansion program using an activation threshold of 0.1. They were selected to illustrate what can be commonly expected from the expansions, including limitations posed by the knowledge.

```
>>> expand("bride")
('love', '0.632'), ('wedding', '0.5011')
('groom', '0.19'), ('marry', '0.1732')
('church', '0.1602'), ('marriage', '0.1602')
('flower girl', '0.131') ('happy', '0.131')
('flower', '0.131') ('lake', '0.131')
('cake decoration', '0.131') ('grass', '0.131')
('priest', '0.131') ('tender moment', '0.131')
('veil', '0.131') ('wife', '0.131')
('wedding dress', '0.131') ('sky', '0.131')
('hair', '0.1286') ('wedding bouquet', '0.1286')
('snow covered mountain', '0.1286')

>>> expand('london')
('england', '0.9618') ('ontario', '0.6108')
('europe', '0.4799') ('california', '0.3622')
('united kingdom', '0.2644') ('forest', '0.2644')
('earth', '0.1244')

>>> expand("symphony")
('concert', '0.5') ('music', '0.4')
('theatre', '0.2469')
('conductor', '0.2244')
('concert hall', '0.2244')
('xylophone', '0.1') ('harp', '0.1')
('viola', '0.1') ('cello', '0.1')
('wind instrument', '0.1') ('bassoon', '0.1')
('violin', '0.1')

>>> expand("listen to music")
('relax', '0.4816') ('be entertained', '0.4816')
('have fun', '0.4') ('relaxation', '0.4')
('happy', '0.4') ('hang', '0.4')
('hear music', '0.4') ('dorm room', '0.4')
('understand', '0.4') ('mother', '0.2')
('happy', '0.136')
('get away', '0.136') ('listen', '0.136')
('change psyche', '0.136') ('show', '0.1354')
('dance club', '0.1295') ('frisbee', '0.1295')
('scenery', '0.124') ('garden', '0.124')
('spa', '0.124') ('bean bag chair', '0.124')
```

The expansion of *"bride"* shows the diversity of relations found in the semantic resource. *"Love"* is some emotion that is implicitly linked to brides, weddings, and marriage. Expansions like *"priest", "flower girl,"* and *"groom"* are connected through social relations. *"Wife"* seems to be temporally connected. To *"marry"* indicates the function of a wedding.

However, there are also expansions whose connections are not as obvious, such as *"hair,"* and *"lake."* There are also other expansions that may be anomalies in the OMCS corpus, such as *"tender moment"* and *"snow covered mountain."* These examples point to the need for some type of statistical filtering of the knowledge in the corpus, which is not currently done.

In the last expansion example, the concept of "listen to music" is arguably more abstract than the wedding concept, and so the expansions may seem somewhat arbitrary. This illustrates one of the limitations of any common sense acquisition effort: deciding upon which topics or concepts to cover, how well they are covered, and to what granularity they are covered.

5. Conclusion

In this paper, we presented a mechanism for robust photo retrieval: using a world semantic resource to expand a photo's annotations. The resource was automatically constructed from the publicly available Open Mind Common Sense corpus. Sentence patterns were applied to the corpus, and simple predicate argument structures were extracted. After normalizing arguments into syntactically neat concepts, a weighted concept node graph was constructed. Concept expansion is modeled as spreading activation over the graph. To improve relevance in spreading activation, the graph was re-weighted using heuristics for reinforcement and popularity.

This work has not yet been formally evaluated. Any evaluation will likely take place in the context of the larger system that this mechanism is used in, called (A)nnotation and (R)etrieval (I)ntegration (A)gent (Lieberman et al., 2001) ARIA is an assistive software agent which automatically learns annotations for photos by observing how users place photos in emails and web pages. It also monitors the user as s/he types an email and finds opportunities to suggest relevant photos. The idea of using world semantics to make the retrieval process more robust comes from the observation that concepts depicted in photos are often spatially, temporally, and socially related in a commonsensical way. While the knowledge extracted from OMCS does not give very complete coverage of many different concepts, we believe that what concept expansions *are* done have added to the robustness of the retrieval process. Sometimes the concept expansions are irrelevant, but because ARIA engages in opportunistic retrieval that does not obstruct the user's task of writing the email, the user does not suffer as a result. We sometimes refer to ARIA as being "fail-soft" because good photo suggestions can help the task, but the user can ignore bad photo suggestions.

Robust photo retrieval is not the only IR task in which semantic resources extracted from OMCS have been successfully applied. (Liu et al., 2002) used OMCS to perform inference to generate effective search queries by analyzing the user's search goals. (Liu and Singh, 2002) uses the subset of causal knowledge in OMCS to generate crude story scripts.

In general, the granularity of the knowledge in OMCS can benefit any program that deals with higher-level social concepts of the everyday world. However, because of limitations associated with this corpus such as noise, ambiguity, and coverage, OMCS is likely to be only useful at a very shallow level, such as providing an associative mechanism between everyday concepts or performing first-order inference.

Future work is planned to improve the performance of the mechanism presented in this paper. One major limitation that we have encountered is noise, stemming from ambiguous word senses and contexts. To overcome this, we hope to apply known word sense disambiguation techniques to the concepts and the query, using word sense co-occurrence statistics, WordNet, or LDOCE. A similar approach could be taken to disambiguate meaning contexts, but it is less clear how to proceed.

Another point of future work is the migration from the sentence pattern parser to a broad coverage parser so that we can extract more kinds of commonsense relations from the corpus, and make more sentences "usable."

6. Acknowledgements

We thank our colleagues Push Singh, and Kim Waters at the MIT Media Lab, Tim Chklovski at the MIT AI Lab, and Erik Mueller at IBM, who are also working on the problem of commonsense, for their contributions to our collective understanding of the issues. We would especially like to thank Push for directing OMCS and for his advocacy of commonsense.

Abstract

This paper reports several experiments of document retrieval with TREC-6 using semantic knowledge. In a first set of experiments, synonyms and hyponyms given by WordNet are used in order to enrich queries. A small improvement is shown. The second set uses a word sense disambiguation system in order to cope with polysemy. There is almost no modification of performances but this is an important result considering Sanderson's results. Our system performs at 72% of accuracy when Sanderson concludes a system performing at less than 90% degrades results. When using both query enrichment and WSD, the improvements are a little better, especially for the first document retrieved. Lastly, a small set of experiments using specialized thesauri is presented, showing important improvements.

Keywords

Document Retrieval, Word Sense Disambiguation, Synonymy, Polysemy, WordNet, HMM

1 Introduction

From the beginning of automatic Document Retrieval (DR), researchers have tried to use thesaurus. But results were often disappointing: Salton (1968) used the Harris Synonym Thesaurus and noted a fall of performances. both Harman (1988) and Voorhees (1993, 1994) using WordNet, came to the same conclusion, even if Harman noted that when the user is involved in the process, results are improved.

In this paper, we report several experiments using TREC-6 (Harman, 1997) for evaluation, WordNet (Miller *et al.*, 1990) as a semantic lexicon and a Word Sense Disambiguation (WSD) system trained on SemCor (Miller *et al.*, 1993). The results of these experiments contradict some widespread ideas and some conclusions of other experiments.

The DR system used is described in section 2. In section 3 several experiments using query enrichment with synonyms or hyponyms from WordNet are analyzed. In section 4, the impact of WSD in DR is shown. Section 5 reports experiments using both information and section 6 reports the use of specialized thesauri.

2 The Document Retrieval system used

The DR system used for these experiments is *IndeXal* (Loupy *et al.*, 1998a). The similarity measure is the one proposed by Harman (1986) with a slight modification:

$$(1) \quad score(d) = \frac{\sum_{x \in d \cap q} TF_d(x) \cdot IDF(x)}{\sum_{x \in q} TF_d(x) \cdot IDF(x)}$$

where $score(d)$ is the score of document d according to the query, and:

$$(2) \quad IDF(x) = -\log\left(\frac{n(x)}{N}\right)$$

$$(3) \quad TF_d(x) = K + (1-K) \cdot \frac{\log(O_d(x))}{\log(L_d)}$$

with: $n(x)$ the number of documents containing x, N the total number of documents, $O_d(x)$ the number of occurrences of x in d, L_d the length of document d, and K a coefficient (here is the modification). This coefficient is used to determine the relative importance of *IDF* and *TF*. Best scores are obtained with $K = 0.3$. In this paper, the results are evaluated on TREC-6 (Voorhees & Harman, 1997). Only *Titles* were used (that is 1 to 4 words queries). The results of table 1 will serve as reference for comparison with the other results. *stem* represents the results obtained with a classic stemming procedure[1] and *lem* the ones obtained with a POS tagging system called

[1] We used Porter's stemmer (Porter, 1980)

ECSta (Spriet & El-Bèze, 1997) and a lemmatization. The performances for French are good (96.5% of efficiency). We trained the tagger on the SemCor which is a very small corpus. The final performances are only 88.8% of correct assignation. This seems very weak, but considering only the tagging of content words (nouns, verbs, adjectives and adverbs), the error rate is only 3.9%. This seems sufficient for the following experiments.

	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
lem	1984	21.1	39.6	36.0	30.7	16.8	25.6

Table 1: Basic results

Here, we chose to evaluate the different strategies using only the following statistics given in TREC:

- the number of relevant document retrieved (*Rel-Ret*)
- the average precision (*Av-Prec*)
- the precision at 5, 10, 20 and 100 documents retrieved
- the R-precision (*R-Prec*) that is the precision when there are as many documents returned by the system than relevant ones.

Though stemming seems to be the most efficient strategy, we can see that the precision of the first retrieved documents increases with lemmatization. We think that the precision of the first retrieved documents is the most important for evaluation because they are the documents a user will read and they can be used in an automatic relevance feedback procedure. So, lemmatization does not seem to be a bad strategy. But it would be interesting to improve performances concerning the other statistics, particularly for the precision when 20 documents are retrieved.
In the following experiments, enrichment and disambiguation procedures are used after lemmatization.

3 Using WordNet to Enrich Queries

Smeaton *et al.* (1995) showed relevant documents do not necessarily contain words of the query. One way to improve DR systems performances is to enrich the queries with synonyms or hyponyms.

3.1 Why are synonyms important?

Figure 1 shows the sets of documents containing "*woman*" or "*parliament*" or both terms or none of them and their intersection with the set of relevant documents for query *321* ("*woman in parliament*"). We can see that 10% of relevant documents do not contain the terms "*woman*" and "*parliament*".
It is legitimate to expect that the query enrichment should help the DR systems to retrieve these 10%. Using query enrichment with synonyms and hyponyms, Smeaton *et al.* (1995) retrieved 5% of relevant documents of TREC-3 (Harman, 1994) that do not contain any word of the queries. The following sections show experiments on TREC-6 using query enrichment with synonyms and hyponyms from WordNet 1.5 (Miller *et al.*, 1993).

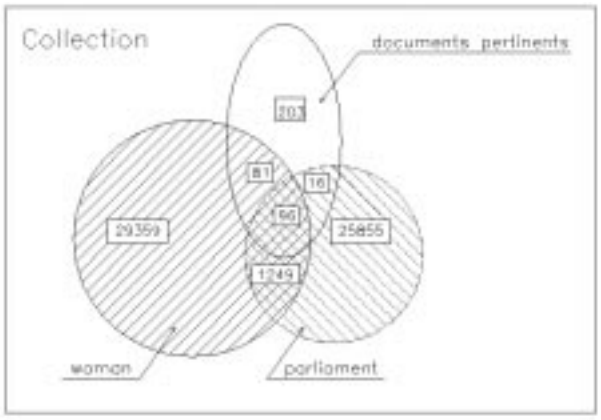

Figure 1: Distribution of documents for request 321

3.2 Presentation of the method

3.2.1 Similarity with enrichment

Enrichment is made at the word level. If a word x of the query has 2 synonyms (y and z), x is replaced by $X = (x, \alpha \cdot y, \alpha \cdot z)$ where $\alpha \in [0,1]$ indicates the importance given to the synonyms compared with the original word. So, we create a pseudo-word X with

(4) $$n(X) = \sum_d C(x,d)$$

with $C(x,d)=1$ if the document d contains x and $C(x,d)=\alpha$ if d does not contain x but contains y or z.
and

(5) $$O_d(X) = O_d(x) + \alpha \cdot O_d(y) + \alpha \cdot O_d(z)$$

It is very important to note that synonyms is taken into account for the calculation of *IDF* and *TF*. Usually, in query enrichment systems, words are added to the query as if they were independent. So each added word has its own *IDF* and *TF*.

3.3 Using Synonyms

In order to enrich queries, we used WordNet 1.5 synsets. 91 591 synsets are given in WordNet 1.5.

3.3.1 A single sense

In this first experiment, only monosemic words are expanded and the expansion concerns only monosemic synonyms. Therefore, polysemy has no influence on the results. The following table gives the results obtained according to the weight α ($\alpha = 0$ corresponds to the lem-basic results and $\alpha = 1$ means that synonyms are as important as original words).
Firstly, we can observe that modifications of the results are very small. But this is a very important observation. It is usually said that the use of synonyms decrease precision and here we can see that it is not the case.
Actually, only 22 queries are concerned by this enrichment. Compared with lemmatization, the performances are increased for 10 of them and decreased for the others (if we consider the average precision). If we

take $\alpha = 0.5$, the average precision is slightly increased (0.3) compared with *Av-prec* but this is not significant. The important fact is that all the decreases in average precision are lower that 1% (absolute values) when the query *317* ("*Unsolicited Faxes*") shows a 7.1 gain if it is enriched by "*unsought*" and "*facsimile*". The other increases are smaller than 4%.

α	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
lem	1984	21.1	39.6	36.0	30.7	16.8	25.6
0.1	1985	21.2	39.6	36.2	30.5	16.8	25.7
0.3	1988	21.3	39.6	36.2	30.5	16.8	25.8
0.5	1988	21.3	40.4	36.6	30.6	16.8	25.8
0.7	1986	21.4	40.4	36.8	30.6	16.8	25.8
0.9	1984	21.3	40.0	36.6	30.9	16.8	25.5
1	1981	21.0	39.2	36.2	30.9	16.8	25.5

Table 2: Enrichment of monosemic words with monosemic synonyms

Concerning query *302*, it is important to note that the gain (+2.8%) is not strictly due to synonymy enrichment. The query is: "*poliomyelitis post polio*". The terms *polio* and *poliomyelitis* are synonyms in WordNet. So, after enrichment, the query is: "(*poliomyelitis* OR *polio*) *post* (*polio* OR *poliomyelitis*)". There is no addition of words, but the calculation of scores is modified. This suggests the system should benefit of a modification of the similarity measure presented in section 2 (formulae 1, 2 and 3).

3.3.2 Several senses

In this section, we want to take into account the number of senses of original words and synonyms in order to see if it is interesting to enrich polysemic words. Table 3 gives the results of an enrichment according to the maximum of senses (*n*) an enriched word and its synonyms have.

n	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
lem	1984	21.1	39.6	36.0	30.7	16.8	25.6
1	1988	21.3	40.4	36.6	30.6	16.8	25.8
2	1996	21.4	40.8	36.6	30.7	17.0	26.0
3	1991	21.3	41.2	36.2	30.5	16.9	25.9
4	1967	21.3	40.8	36.0	30.1	16.8	25.7
5	1961	21.4	40.8	36.4	30.3	16.7	26.0

8	1960	21.2	40.4	35.2	30.5	16.5	25.7
9	1959	21.1	40.0	34.6	30.2	16.3	25.6
∞	1959	21.1	40.0	34.4	30.2	16.3	25.6

Table 3: Enrichment of polysemic words with polysemic synonyms

Here again, there are almost no differences between the basic lemmatization results and the one obtained after enrichment. Nevertheless, it is important to note that there is no decrease of performances when the words which have 3 or less senses are enriched with words which have 3 or less senses. This result will be used in the section 4.

3.4 Using Hyponyms

Another way to enrich queries is to use hyponyms instead of synonyms. The following table gives the results of such an enrichment according to the maximum number of senses (*n*) a word must have to be enriched by its hyponyms (if they also have less than *n* senses).

n	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
lem	1984	21.1	39.6	36.0	30.7	16.8	25.6
1	1999	21.4	39.6	36.2	30.9	16.8	25.7
2	2015	21.3	40.4	36.4	30.9	17.1	25.8
3	2026	21.4	41.6	36.2	31.5	17.0	25.9
4	2004	21.3	41.2	36.2	31.2	16.8	25.7
5	2003	21.3	41.2	36.4	31.7	16.8	25.9
syn	1991	21.3	41.2	36.2	30.5	16.9	25.9

Table 4: Enrichment of polysemic words with polysemic hyponyms

The differences are more important here. 32 queries are modified by this enrichment. For 20 queries, performances are increased (up to 9.2 % in absolute value) and for 12 of them performances decrease (down to –6.5 %). In fact, performances are better when using hyponyms instead of synonyms.
It is important to note that the performances for the first 20 documents are approximately the same using hyponyms or stemming.

4 WSD and DR

Polysemy is a very important problem in DR. In this section, we start by a reminder of some important previous experiments. Then, we shall present our own experiments.

4.1 Important previous works[2]

The most cited work concerning the use of WSD for DR is (Sanderson, 1994). Sanderson's conclusion is that a WSD system performing with less than 90% of accuracy decreases results of DR. This is really a problem because the two Senseval evaluations (Kilgarriff & Palmer, 2000) show that the performances of such systems is less than 80%.
This work has been criticized by Schütze and Pedersen (1995) because the use of pseudo-words (Yarowsky, 1993) by Sanderson does not fit the real behavior of polysemic words. They even showed an improvement of performances using WSD on TREC evaluation. But their system is based on automatic construction of a thesaurus.
Gonzalo *et al.* (1998b) used the SemCor (Miller *et al.*, 1993) in order to build an evaluation framework where the importance of WSD and synonymy can be easily evaluated. They report a great improvement of performances. This is encouraging but not really a proof. The evaluation corpus is very special: queries were built manually as abstracts of the SemCor documents and they

[2] A more precise description of previous works can be found in Sanderson (2000).

consider there is only one relevant document for a "query".
They also evaluated the influence of disambiguation errors, confirming the results of Sanderson: 10% of wrong disambiguation leads to a decrease in DR results. But, using both WSD and synonymy enrichment, the tolerance of errors is very much higher: with a WSD system performing at 70%, performances are increased and even with 40% of good identification, performances are stable. These results are a bit strange but quiet encouraging for further experiments.
In a further paper, Gonzalo *et al.* (1999) reproduced the Sanderson's experiments using pseudo-words and found a threshold of 75% instead of the 90% expected. This result is more in agreement with the ones of this paper.
The next sections present the use of a complete WSD system in a TREC experiment. We show that, even if performances are not increased, a quite basic system performing between 71.5% and 74.6% of accuracy does not degrade results.

4.2 Presentation of the Method

In section 3.2.2, we saw that enriching original words with synonyms even when they have three senses could be interesting. In this section, we use a WSD system in order to choose the most probable one, two or three senses for words according to their contexts.
The WSD system (Loupy *et al.*, 1998b) is based on HMM. A Baum-Welch algorithm (Baum *et al.*, 1970) is used in order to keep several senses. This is important for document retrieval in view of the following facts:

- the WSD system can do mistakes (see performances below)
- even if the sense of a word is obvious, the other senses are often kept in mind
- since WordNet senses are very fine grained (41 senses for the verb "*run*"), keeping several senses can be useful in order to represent a coarser sense which do not exist.
- it is sometimes impossible to disambiguate a polysemic word (Kilgarriff, 1994) even for a human being.

The HMM model were trained on the SemCor and its performances were evaluated using 95% for training and 5% for tests. The following table gives the scores when 1, 2 or 3 senses are kept, considering all words (*all*) or only ambiguous ones (*amb*). Moreover, two results are given for each case. The first one corresponds to an evaluation when part-of-speech is known (real evaluation of WSD) and the second one when this POS is not known (real world). The model is a bigram one. With unisem, the performances are slightly inferior (of about 0.4).

		1 sense		2 senses		3 senses	
		all	*amb*	*all*	*amb*	*all*	*amb*
POS	**known**	74.6%	62.5%	87.7%	78.0%	92.9%	83.2%
	unk.	71.5%	59.7%	84.5%	74.9%	89.8%	79.6%

Table 5: Performances of the WSD system

So, the performances are really lower than the one given by Sanderson when he said that a WSD system must perform at 90% or more.

4.3 A simple use of disambiguation

If we keep 3 senses during disambiguation, there are many ways to use it. Figure 2 shows the combinations between a disambiguated query and a disambiguated document.

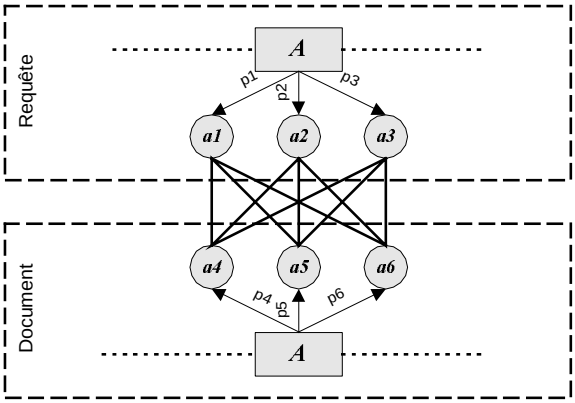

Figure 2 : Combinations between query and document when using disambiguation

Several combinations were tested. Table 6 gives the results. The first line (*all*) gives the results when no disambiguation is made. The other lines (*m-n*) represent a disambiguation where *m* senses are kept in the query and *n* senses are kept in the documents.

m-n	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
lem	1984	21.1	39.6	36.0	30.7	16.8	25.6
1-1	1976	20.9	41.2	36.0	30.3	16.8	25.1
1-2	1978	21.1	41.2	35.6	30.6	16.7	25.4
1-3	1979	21.1	40.4	35.8	30.6	16.8	25.5
2-1	1979	21.1	40.8	36.2	30.5	16.8	25.4
2-2	1974	21.2	41.2	36.2	31.2	16.8	25.6
2-3	1969	21.2	40.8	36.2	31.2	16.7	25.6
3-1	1983	21.1	40.4	36.0	30.7	16.8	25.6
3-2	1969	21.2	40.8	36.6	31.4	16.8	25.6
3-3	1971	21.2	40.8	36.4	31.4	16.7	25.6

Table 6: Results of a simple use of WSD in a DR system

Performances are almost the same with WSD (whatever the strategy is) and without. But, here again, there is a very tiny improvement for the first documents retrieved.
If we consider only Average Precision for the *1-1* strategy, results are improved for 24 queries and decreased for only 10 queries. But, while no query is improved by more than 1%, the query *339* ("*Alzheimer's drug treatment*") decreases by 9.5%. The fall of precision of the other queries is less than 1.3%.
So, even if we consider that the problem of the query *339* is an "accident", improvements are very poor. But, we can also conclude that a WSD system performing at 72% does not decrease results of a DR system contrary to what Sanderson claims.

Another interesting point is that there is almost no modification of recall.

4.4 Using sense probability from WSD system

Previous experiments were made without taking into account the probabilistic information (probability of each of the three senses) given by the WSD system. It should be interesting to use them. The similarity measure is the same as the one given in section 2 but the way the number of occurrences is counted is modified:

(6) $$n(x)=S_q(x)\cdot\sum_d Max\left(S_d(x,i)\right)$$

where $S_d(x,i)$ is the probability given by the WSD system to the word-sense x at the position i and $S_Q(x)$ the probability of the word-sense x in the query.

(7) $$O_d(x)=S_Q(x)\cdot\sum_i S_d(x,i)$$

Table 7 gives the results of such a heuristic.

	m-n	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
	stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
	all	1984	21.1	39.6	36.0	30.7	16.8	25.6
sense	**1-1**	1976	20.9	41.2	36.0	30.3	16.8	25.1
	2-2	1974	21.2	41.2	36.2	31.2	16.8	25.6
	3-3	1971	21.2	40.8	36.4	31.4	16.7	25.6

	2-2	1921	20.3	39.6	34.8	29.9	16.2	24.0
	3-3	1929	20.3	39.6	35.0	29.8	16.2	24.0
doc	**1-1**	1859	18.6	37.2	31.6	27.5	15.1	22.3
	2-2	1881	18.7	36.0	31.8	28.5	15.2	23.2
	3-3	1884	18.8	37.2	32.4	28.5	15.1	23.3
req+doc	**1-1**	1774	17.8	36.4	31.4	26.4	14.4	21.1
	2-2	1777	17.9	36.4	31.8	26.5	14.5	21.2
	3-3	1780	17.9	36.4	31.6	26.6	14.5	21.2

Table 7: Results of using WSD in a DR system taking probabilities into account

The lines *sens* give the results reported in section 4.3 (probabilities are not involved in scores). The lines *req* report the use of WSD probabilities for queries only, *doc* for documents only and *req+doc* for both queries and documents.

We can see that the results have decreased. This is very surprising. Another heuristic may help us to overcome this problem.

5 Using Both WSD and Query Enrichment

In the previous sections, we use query enrichment and WSD in separate experiments. In this section, we shall combine both strategies. The following tables show the performances obtained when one, two or three senses are kept after WSD.

m-n	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
lem	1984	21.1	39.6	36.0	30.7	16.8	25.6
syn 1-1	1999	21.4	39.6	36.2	30.9	16.8	25.7
wsd 1-1	1976	20.9	41.2	36.0	30.3	16.8	25.1
syn+wsd	1971	21.1	42.4	36.2	30.2	16.8	25.6

Table 8: combining enrichment and WSD with one sense

m-n	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
lem	1984	21.1	39.6	36.0	30.7	16.8	25.6
syn 2-2	2015	21.3	40.4	36.4	30.9	17.1	25.8
wsd 2-2	1974	21.2	41.2	36.2	31.2	16.8	25.6
syn+wsd	1968	21.4	42.4	36.8	31.4	16.8	26.0

Table 9: combining enrichment and WSD with two senses

m-n	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
lem	1984	21.1	39.6	36.0	30.7	16.8	25.6
syn 3-3	2026	21.4	41.6	36.2	31.5	17.0	25.9
wsd 3-3	1971	21.2	40.8	36.4	31.4	16.7	25.6
syn+wsd	1968	21.3	42.0	36.8	31.4	16.8	25.7

Table 10: combining enrichment and WSD with three senses

The results show little improvements when keeping 2 or 3 senses and enriching with WordNet synonyms. Of course, the question is: is the gain interesting compared to the cost?

6 Combining synonyms and stemming

As the use of synonyms does not show any improvement, another possibility is to use both information. The following table gives the results of this strategy.

n	Rel-Ret	Av-Prec	5	10	20	100	R-Prec
stem	2068	22.3	38.2	34.8	31.9	17.2	26.1
lem	1984	21.1	39.6	36.0	30.7	16.8	25.6
syn 3-3	2026	21.4	41.6	36.2	31.5	17.0	25.9
lem-stem	2124	23.1	39.2	36.0	31.7	17.9	26.9
lem-stem-syn	2140	22.7	40.8	36.0	32.8	17.3	26.1

Table 11: Results of using both stemming and synonymy enrichment

In this table, we can see that the use of both lemmatization and stemming is more interesting than using one of these strategy alone. The strategy using all these information (*lem-stem-syn*) gives better results than *stem* and *lem* for all statistics. It seems to be an interesting strategy although the precision for 5 documents is lower than the use of synonyms.

Other experiments should be done to evaluate the performances of hyponyms used with stems and synonyms.

7 Using expert knowledge

It is clear for all that the use of expert knowledge should improve performances of DR systems (Anand *et al.*, 1995). For this experiment, a specialized lexicon has been built for each of the ten first queries of TREC-6. The time necessary for this construction is more or less 5 minutes per thesaurus. The built lexicons are, therefore, very small. It is clear that, we never looked at relevant documents to search for relevant terms. Words linked to the words of a query were added to this query. The following list gives the words used for each of the ten queries:

301: international organized (crime drug prostitution cocaine ectasy extasy heroin trafficking traffic terrorism terrosrist criminal mafia maffia triad tong cartel)

302: (poliomyelitis polio brunhilde lansing léon paralysis) post (polio poliomyelitis brunhilde lansing léon paralysis)

303: hubble (telescope space_telescope infrared_telescope optical_mirror space black_hole invisible_space big_bang) (achievement accomplishment)

304: endangered (specie coinage mintage) (mammal panda whale)

305: most (dangerous unsafe grave graver gravest grievous) (vehicle car bus highway road)

306: (african africa angola angolan luanda namibia namibian windhoek bostwana gaborome swaziland mbabame lesotho maseroni south_africa cape_town zimbabwe zimbabwean harare zambia zambian luzaka tanzania tanzanian dar_es_salamm burundi burundian bujumbura uganda ugandan kamdala rwanda rwandan kinshasa congo congolese brazzaville gabon gabonese libreville cameroon cameroonian yaoundé nigeria nigerian abuja chad chadian djamena ndjamena sudani sudanese khartoum ethiopia ethiopian addis_abeba eritrea eritrean asimara somalia somalian mogadishu egypt egyptian cairo libya libyan tripoli tunisia tunisian tunis algeria algerian algiers morocco moroccan rabat mauritania mauritanian nouskshott senegal senegalese dakar mali bamako sierra_leone freetown madagascar madagascana madagascan antananarivo) civilian (death kill war killed killing)

307: (new newer newest) hydroelectric (project undertaking task task projection)

308: (implant implantation) (dentistry dentist tooth)

309: rap music ((crime drug prostitution cocaine ectasy extasy heroin trafficking traffic terrorism terrosrist criminal mafia maffia triad tong cartel)

310: (radio phone) wave brain cancer

We can see, for example, *dentistry* is associated with *dentist* and *tooth* and *vehicle* with *car*, *bus*, *highway* and *road*.

Table 11 gives the results obtained.

4 values are studied: number of relevant documents retrieved (*Rel-Ret*), precision for 20 document retrieved (*20*), average precision and R-precision. They are compared in 3 experiments: the basic one (*bas* - see section 2), query enrichment by WordNet synonyms (*syn* - see section 3.3.2) and query enrichment using expert knowledge (*use* - synonyms, hyponyms, see also links). The last figure represent the gain using specialized thesaurus (*use-bas*).

We can see that, in almost all cases, a specialized thesaurus increases performances. For query *306*, the gain is only due to a very simple geographic thesaurus.

Table 11: Using expert knowledge for TREC queries

8 Conclusion

The experiments reported in this paper were only made on TREC-6. In order to confirm the results, they should be applied on other evaluation frameworks. Moreover, it would be interesting to use different heuristics, specially in section 4.4. But these results already lead to several conclusions:

- Using synonymy enrichment not necessarily decreases precision.
- Using WSD not necessarily decreases recall.
- A WSD system performing at 72% of accuracy does not necessarily degrades results, contrary to Sanderson's conclusions.
- The contribution of synonymy enrichment and WSD can be very poor compared to the amount of work necessary to build the necessary resources and tools.
- The combination of resources gives the best results.
- The use of specialized resources can be very useful in order to improve performances.

Of course, it seems that the "cost" is too important regarding the small improvement. In fact, the problem may come from the knowledge source, that is WordNet. It has been often criticized for DR applications for the following reasons:

- Semantic links are only possible in the same part of speech (for instance, there is no link between "*to cook*" and "*cooking*") (Gonzalo *et al.*, 1998a).
- There is no link between words of the same domain. Fellbaum *et al.* (1996) point out that the words *tennis*, *racket*, *ball* and *tennis player* have no relation.

- Senses are too fine grained (Palmer, 1998).

Another problem is that some senses are ignored. Shütze and Pedersen (1995) noticed the sense *horse race* is ignored for the word *derby* which is only tagged as a *hat*. According to them, this is an argument to use specialized automatically built resources instead of a general manually built one. An alternative solution should be find at the intersection of the two worlds: using lexical resources to have a basic knowledge and learn some relations from corpus while indexing.
One very important fact is that it is almost every time beneficial to involve users in the whole process. The next step of information retrieval will be to interact with the user. And one of the most interesting way to do that is to use lexical resources (automatically built or not) and systems performing WSD in order to help the user and to save him time. Particularly, it should be interesting to manually disambiguate queries.

The Semantic Wildcard

Rada F. MIHALCEA

Abstract

The IRSLO (Information Retrieval using Semantic and Lexical Operators) project aims at integrating semantic and lexical information into the retrieval process, in order to overcome some of the impediments currently encountered with today's information retrieval systems. This paper introduces the semantic wildcard, one of the most powerful operators implemented in IRSLO, which allows for searches along general-specific lines. The semantic wildcard, denoted with #, acts in a manner similar with the lexical wildcard, but at semantic levels, enabling the retrieval of subsumed concepts. For instance, a search for *animal#* will match any concept that is of type *animal*, including *dog*, *goat* and so forth, thereby going beyond the explicit knowledge stated in texts. This operator, together with a lexical locality operator that enables the retrieval of paragraphs rather than entire documents, have been both implemented in the IRSLO system and tested on requests of information run against an index of 130,000 documents. Significant improvement was observed over classic keyword-based retrieval systems in terms of precision, recall and success rate.

1. Introduction

As the amount of information continues to increase, there must be new ways to retrieve and deliver information. Information is of no use if it cannot be located and the key to information location is a retrieval system. Traditionally, information retrieval systems use keywords for indexing and retrieving documents. These systems end up retrieving a lot of irrelevant information along with some useful information that the query/question was intended to elicit. Moreover, implicit knowledge makes often the bridge between a question and a document, and classic retrieval systems do not have the capability of going beyond explicit knowledge embedded in texts, thereby missing the answers to such queries.

To overcome some of the impediments currently encountered with today's information retrieval systems, we have started the IRSLO (Information Retrieval using Semantic and Lexical Operators) project that aims at integrating semantic and lexical information into the retrieval process, to the end of obtaining improved precision and recall. This paper introduces the *semantic wildcard*, one of the most powerful operators implemented in IRSLO.

Users' information needs are most of the times expressed along general-specific lines, and this paper provides analytical support towards this fact. *What sport*, *What animal*, *What body part*, are all examples of question types that require implicit knowledge about what constitutes a *sport*, *animal*, or *body-part*. The *semantic wildcard*, denoted with #, is designed to retrieve subsumed concepts. For instance, a search for *animal#* will match any concept that is of type *animal*, thereby going beyond the explicit knowledge stated in texts.

The *semantic wildcard*, together with a lexical locality operator previously introduced that enables the retrieval of paragraphs rather than entire documents (Mihalcea, 1999), were implemented in the IRSLO system and tested on requests of information run against an index of 130,000 documents. Significant improvement was observed over classic retrieval systems, in terms of precision, recall and success rate.

The paper is organized as follows. First, we present an analysis of questions asked by real time users, bringing evidence towards the fact that information need is most of the times expressed along general-specific lines. Next, we show how a novel encoding scheme - referred to as *DD-encoding* - can be applied to WordNet, in order to exploit the general-specific relations encoded in this semantic net. We then present the architecture of IRSLO, with emphasis on the *semantic wildcard* operator and the *paragraph operator*, together with experiments, results and walk through examples.

2. Defining Information Need

In order to define users' information need and assess the role that may be played by semantics in an information retrieval environment, we have performed a qualitative and quantitative analysis of information requests expressed by users in the form of natural language questions. Two sets of data are used during the experiments: (1) the Excite question log, for a total of 68,631 questions asked by the users of a search engine and (2) the TREC-8, TREC-9 and TREC-10 questions, for a total of 1,393 questions.

The noisy Excite log was cleaned up with two filters. First, we extracted only those lines containing one of the keywords *Where*, *When*, *What*, *Which*, *Why*, *Who*, *How*, *Why* or *Name*. Next, we eliminated the lines containing the phrase *"find information"* to avoid the bias towards Web searching questions. [1]

From the total of 25,272 Excite *What* questions[2] we have randomly selected a subset of 5,000 questions that were manually analyzed and classified. The decision of what question type to assign to a particular question was

[1] To our knowledge, only one other large scale question analysis is mentioned in the literature (Hovy et al., 2001).

[2] We emphasize the experiments involving *What* questions, since they provide the largest coverage and are considered to be the most ambiguous types of questions. Similar analyses were performed for the other types of questions, but are not reported here due to lack of space.

merely based on the possibility of implementing a procedure that would make use of this question type in the process of finding relevant information. For instance, a question like *What does Acupril treat?* expects a DISEASE as answer, which is doable in the sense that an ontology like WordNet does have a disease node with pointers to a large number of disease names. On the other hand, *What about this Synthyroid class action?* does not require a specific answer, but rather information related to a topic, and therefore no question type is assigned to this question (the type NONE is used instead). For the entire set of 5,000 questions, 361 categories are extracted.

2.1. Quantitative Analysis

To the end of observing the behavior and learning rate associated with question types, subsets of different sizes were created and the number of question types was determined for each subset. The measurements were performed using a 10-fold cross validation scheme on randomly selected samples of data.

Figure 1 plots the distribution of question types with respect to the subset size. It turns out that the number of question types grows sublinearly with the number of questions. Moreover, we noticed a behavior of the curve similar with *Heaps' Law* (Heaps, 1978), which relates the number of words in a text with the text size. *Heaps' Law* states that the size of the vocabulary for a text of size n is $V = Kn^{\beta} = O(n^{\beta})$.

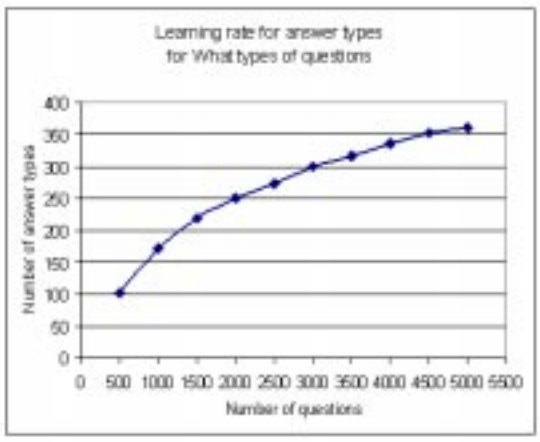

Figure 1: Number of question types vs. number of questions for *What* questions in the Excite log.

Denoting the number of question types with T_q and the number of questions with N_q, it follows:

$$\mathrm{T}_q = K{N_q}^{\beta} \quad (1)$$

The equation is solved by taking the log in both sides. For the Excite *What* set, it results a value of $K = 5.18$, respectively $\beta = 0.50$. The values of the two parameters are changed in the TREC *What* set: $K = 3.89$ and $\beta = 0.54$, which illustrates the difference in question types distribution for the uniform TREC set versus the noisy Excite set.

This is an interesting result, as it defines the behavior of question types with respect to the number of questions. Moreover, it gives us the capability of making estimates on what is the expected number of question types for N_q given questions. For instance, 10,000 questions will result in about 518 question types, 100,000 in about 1,638 question types, and so forth.

2.2. Qualitative Analysis

The qualitative analysis brings evidence for the organization of question types in semantic hierarchies, and supports the idea of incorporating semantics into information retrieval.

An analysis of the questions benchmarks suggested that the majority of question types are found in a general-specific (ISA) relation. This hypothesis is sustained by empirical evidence. We classified the questions into four categories as listed in Table 1[3]. It turns out that on average about 60% of the questions are clear general-specific questions. It is debatable whether or not the DEFINITION types of questions can be classified as general-specific questions or not. It is often the case that a definition requires a more general concept to explain an unknown entity (Prager et al., 2001), and therefore it could be considered as a general-specific information request. Under this hypothesis, it results an average of 80% of information requests being expressed along general-specific lines.

Information type	Frequency
Excite questions	
GENERAL-SPECIFIC	54.6%
DEFINITION	19.6%
NONE	14.8%
OTHER	10.8%
TREC questions	
GENERAL-SPECIFIC	65.0%
DEFINITION	20.9%
NONE	6.6%
OTHER	7.4%

Table 1: Information requests along general-specific lines

Figure 2 shows examples of annotated questions extracted from the Excite log, mapped on an *animal* hierarchy of question types.

The conclusion of these experiments is that the majority of information requests are expressed along general-specific lines, and therefore a semantic based retrieval system that exploits these relations would possibly increase the quality of the information retrieved. This idea was also expressed by (Berners-Lee et al., 2001) in the context of Semantic Web.

3. Conversion of WordNet to DD-encoding

On the one side, we have the users' information need expressed most of the times as a general-specific request.

[3]The OTHER category includes questions that require an answer that cannot be obtained by following a general-specific line. Examples of such question types are CAUSE, EFFECT, QUOTE|ALBUM, QUOTE|MOVIE, WORD-TRANSLATION, etc.

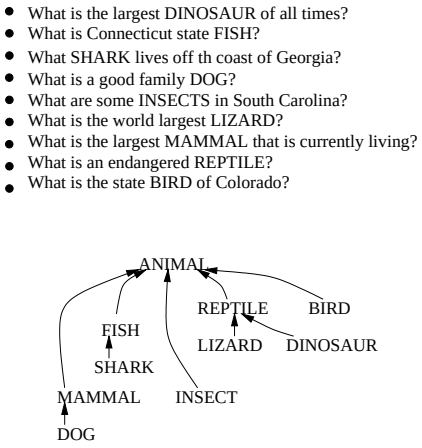

Figure 2: Question types mapped onto the *animal* hierarchy.

On the other side, we have WordNet (Miller, 1995) as the largest general purpose semantic network available today, which encodes about 86,605 general-specific (ISA) relations. We want to exploit as much as possible the semantic network structure of WordNet. To this end, we propose in this section a new encoding to be used for WordNet entries that would enable more efficient semantic searches. The so called *DD-encoding* was inspired by the Dewey Decimal code scheme used by librarians.

There are many times when keywords in a query are used with "generic" meanings and they are intended as representatives for entire categories of objects. *Foxes eat hens* is a statement that can be evaluated as a good match for *Animals eat meat*. Unfortunately, with current indexing and retrieval techniques this is not possible, unless both *animal* and *meat* are expanded with their subsumed concepts, which may sometimes become a tedious process. For this particular example, WordNet defines 7,980 concepts underneath *animal*, and there are 199 entries that inherit from *meat*, and therefore we end up with more than 1,500,000 (7,980 x 199) queries to cover the entire range of possibilities. Alternatively, if boolean queries are allowed and the OR operator is available, a query with 8,179 (7,980 + 199) terms can be used. None of these solutions seems acceptable and this is why none of them have been used so far.

We would like to find a way such that *fox* matches *animal* and we propose the employment of matching codes as an elegant solution to accomplish this task.

Finding the means that would allow for this type of matches is a problem of central interest for retrieval applications, as most information requests are expressed along general-specific lines. We want to retrieve documents containing *cat* in return to a search for *animal*, and retrieve *dachshund* and do not retrieve *cat* as the result of a search for *dog*.

To enable this type of general-specific searches and at the same time take advantage of the semantic structure already encoded in WordNet, we propose the employment of a codification scheme similar with the one used in librarian systems, and associate a code to each entry in WordNet.

The role of this code is to make evident to an external tool, such as an indexing or retrieval process, the relation that exists between inter-connected concepts. No information can be drawn from the simple reading of the *animal* and *dog* strings. Things are completely different when we look at *13.1* and *13.1.7*: the *implicit* relation between the two tokens has now been turned into an *explicit* one.

A code is assigned to each WordNet entry such that it replicates its parent code, and adds a unique identifier. For instance, if *animal* has code *13.1*, then *chordate*, which is a directly subsumed concept, has code *13.1.29*, *vertebrate* has code *13.1.29.3*, and so forth. Figure 3 illustrates a snapshot from the noun WordNet hierarchy and shows the *DD-codes* attached to each node. This encoding creates the grounds for matching at semantic levels in a manner similar with the lexical matches already employed by several information retrieval systems.

To our knowledge, this is a completely new approach taken towards the goal of making possible searches at semantic levels. The idea underneath this encoding is very simple but it allows for a powerful operator: the *semantic wildcard*.

3.1. Technical Issues

There are several implementation issues encountered during WordNet transformation, and we shall address them in this section.

Specifically, the new encoding is created using the following algorithm:

---

1. Start with the top of WordNet hierarchies. For each top, load its hyponyms, and for each hyponym go to step 2.
2. Execute the following steps:
2.1. Assign to the current synset the DD-code of its parent plus an unique identifier that is generated as a number in a successive series.
2.2. If the current synset has been already assigned a DD-code, then generate a special link between its parent and the current synset itself.
2.3. Load all hyponyms of current synset and go to step 2.

The algorithm performs a recursive traversal of the entire WordNet hierarchy and generates codes. A code is associated with a synset, and we created a list of pairs containing a synset offset (the current WordNet encoding) and a *DD-code*.

It is worth mentioning the case of multiple inheritance, handled by the Dewey classification system as an addition made for a particular category. For instance, 675+678 means *leather and rubber*. This solution is not satisfactory for our purpose, since it may result in very long codes. Instead, a list of *special links* (generated in step 2b) is created, containing all the links between a *second parent* and a child. For example, if *house* inherits from both *domicile* and *building*, we have the code 1.2.1.32.12.23 for *house*, 1.2.1.32.28.6 for *domicile* and 1.2.1.32.12 for *building*, and in addition a special link is generated to indicate that *domicile* is the parent of *house* even if no direct matching can be performed.

For the entire noun hierarchy in WordNet, 74,488 *DD-codes* were generated. In addition, 4,280 multiple inheritance links were created. The average length of a code is 16 characters. Given the fact that disk space is a cheap re-

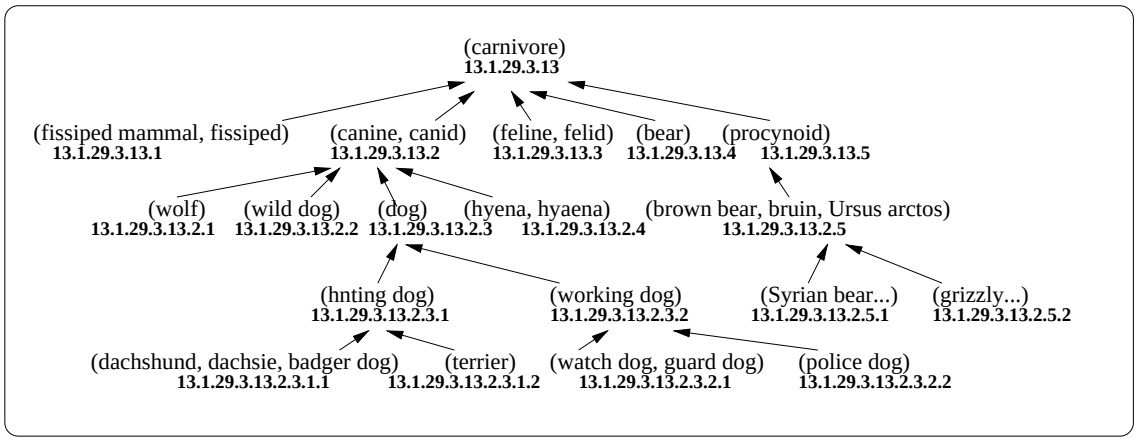

Figure 3: *DD-codes* assigned to a sample of the WordNet hierarchy

source, the length of the codes does not represent a real disadvantage of the proposed approach. Moreover, one should take into consideration that no optimizations were sought in the process of code generation. A simple strategy, like the usage of all 256 ASCII characters instead of using only the 1-9 digits, can shorten significantly the length of the codes (e.g. 1.2.1.32.12.23 changes into 1.2.1.z.b.f). Approaches like Huffman code or other compression methods can be as well exploited for this purpose, but we will not consider these issues here.

4. The IRSLO System

Our improved semantic based information retrieval system comprises the same main components as found in any other retrieval system.

4.1. Question/Query Processing

This stage usually includes a keyword selection process. It may sometimes imply keyword stemming or other processing, and in most cases keywords to be employed in the retrieval stage are selected based on weights, frequencies and stop-words lists.

In IRSLO, we start this stage with a simple tokenization and part of speech tagging using Brill tagger (Brill, 1995). Next, collocations are identified based on WordNet definitions. We also identify the baseform of each word.

Depending on the notation employed by the user, we distinguish three keyword types. (1) Words with a semantic wildcard, denoted with #. (2) Words to be searched by their *DD-code*, denoted with @ (synonymy marker). (3) Words with no special notation, to be sought in the index in their given form. By default, we assume a # assigned to the answer type word, and no other notation for the rest of the words. All words that are denoted with # or @ are passed on to a word sense disambiguation component that solves their semantic ambiguity. Alternatively, this step can be skipped and a default sense of one with respect to WordNet is assigned, with reasonable precision (over 75% as measured on SemCor). The results reported in this paper are based on a simplified implementation that considers the second alternative. Next, *DD-codes* are assigned to words in text and subsequently used in the retrieval process. *DD-codes* are currently assigned only to nouns, considered to be the most informative words. See section 3. for more details regarding *DD-encoding*.

We also face the task of identifying relevant keywords to be included in a query. Extensive analysis of keywords identification was previously reported in (Pasca, 2001). We use a simplified keywords identification procedure, based on the following rules:

1. Use all proper nouns and quoted words.
2. Use all nouns.
3. Use all adjectives in superlative form.
4. Use all numbers (cardinals).
5. If more than 200 documents are returned, use the adjectives modifying the first noun phrase.
6. If no documents are returned, drop the nouns acting as modifiers. Particular attention is paid to abstract nouns, such as type, kind, name, where the importance of the roles played by a head and a modifier in a noun phrase are interchanged.

Any of these keywords may be expressed using its corresponding *DD-code*. The answer type word is also important. It practically denotes the type of information sought, whether is a *country*, an *animal*, a *fish*, etc. We use a simple approach that selects the answer type as the head of the first noun phrase. There are few exceptions from this rule, consisting of the cases where the head is an abstract noun like *name*, *type*, *variety* and so forth, and in such cases we select its modifier. If the answer detected is of a generic type, such as *person*, *location*, *organization*, then we replace it with the corresponding named entity tag. Otherwise, the answer type word is assigned a # semantic wildcard. Notice that the answer type selection process is invoked only if there is no word a priori denoted with #.

After all these processing steps, we end up with a query in IRSLO format. The words that were assigned a semantic wildcard # are now represented as *DD-code**. The words with a synonymy marker are simply replaced with their *DD-code* (thereby allowing for the retrieval of synonym words in addition to the word itself). The other words are replaced with their baseform. See Section 5.4. for representation examples.

4.2. Document Processing

Typically, documents are simply tokenized and terms are extracted, in preparation for the indexing phase. Optionally, stop-words are eliminated and words are stemmed prior to indexing.

In IRSLO, documents are processed following similar steps to question processing. First, the text is tokenized and part of speech tagged. We have an additional component that involves named entity recognition (Lin, 1994). Next, we identify compound words, apply a disambiguation algorithm or, alternatively, assign to each word its default sense from WordNet. Finally we assign to each noun its corresponding *DD-code*.

At this stage, we also identify paragraphs and store them as one paragraph per line. This helps improving efficiency during paragraph retrieval.

4.3. Indexing and Retrieval

The indexing process is not different in any ways with respect to a classic information retrieval system. A TF/IDF weight is assigned to each term. We index complex terms, including the *DD-codes* attached to each noun and the named entity tags, when available. No additional stemming or stop-words elimination is performed. The retrieval system allows for flexible searches, including regular expressions. Based on *DD-codes*, we have the capability of using the *semantic wildcard* operator, in addition to the lexical wildcard. We also have the capability of retrieving named entities of a certain type (e.g. perform a search for *person*). Moreover, we allow for boolean operators and for the new *paragraph operator* for a more focused search. Documents are ranked using the TF/IDF weight associated with each keyword.

5. Experiments with IRSLO

This section focuses on the application of the *semantic wildcard* and *paragraph operator* within the IRSLO system. First, the semantic wildcard enables searches for information along general-specific lines. Second, the paragraph indexing component limits the scope of keywords search to a single paragraph, rather than an entire document.

5.1. Experimental Setup

Several standard text collections are made available through the Information Retrieval community. For our experiments, we have selected the *L.A. Times* collection, which includes a fairly large number of documents. There are more than 130,000 documents adding up to 500MB of text. *L.A. Times* is part of the TREC (Text REtrieval Conference) collections.

The main advantage of standard text collections is the fact that question sets and relevance judgments are usually provided in association with the document collection.

About 1,393 questions have been released during the TREC-8, TREC-9 and TREC-10 Q&A TREC competitions. Relevance judgments are provided for the first two competitions, i.e. for 893 questions. From the 893 questions, we selected only the *What* type of questions, as being the most ambiguous types of questions and the best candidates for the semantic wildcard operator. Subsequently, we identified those questions known to have an answer in the *L.A. Times* collection[4], and out of these 75 questions were randomly selected for further tests.

For this question set, we have the knowledge about the information expected in response to each question (answer patterns provided by the TREC community). We also have a list of *docid*-s pointing to documents containing the answer for each question (list of documents judged to contain a correct answer by TREC assessors). This information helps us measure *precision* and *recall*.

5.2. Evaluating Retrieval Effectiveness

A common methodology in evaluating information retrieval systems consists in measuring *precision* and *recall*. *Precision* is defined as the number of relevant documents retrieved over the total number of documents retrieved. *Recall* is defined as the number of relevant documents retrieved over the total number of relevant documents found in the collection. Additionally, the *F-measure* proposed in (Van Rijsbergen, 1979) provides the means for combining recall and precision into one single formula, using relative weights.

$$F_{measure} = \frac{(\beta^2 + 1.0) * P * R}{(\beta^2 * P) + R}$$

where P is precision, R is recall and β is the relative importance given to recall over precision. During the system evaluations reported here, we considered both precision and recall of equal importance, and therefore β is set to 1.

Moreover, we employ the *success rate* measure (Woods, 1997) as an indicative of how many questions were answered by the system. The *success rate* for a question/query is 1 if relevant documents/answers are found, and 0 otherwise.

Finally, we evaluate IRSLO results using the TREC Q&A score, with a different mark assigned to an answer depending on its position within the final rank. A correct answer on the first position results in a maximum score of 1.00. The second position gets 0.50, the third position is scored with 0.33, the fourth with 0.25 and the fifth and last one acceptable receives 0.20 points.

5.3. Experiments

Three types of experiments were performed, to evaluate the performance of the new *semantic wildcard* and *paragraph operator*.

Experiment 1. Extract the keywords[5] from each question and run the queries formed in this way against a classic index created with the *L.A. Times* collection. The purpose of this experiment is to simulate classic keyword-based retrieval systems. The ranking is provided through a TF/IDF weighting scheme.

Experiment 2. Extract the keywords from each question and run the queries against the paragraph index. In paragraph

[4]The set of 893 questions was devised to ensure an answer in the entire TREC collection, including 2.5GB of text in addition to the *LA Times* collection that we employ in our experiments

[5]See Section 4.1. for the keywords selection procedure

indexing, we use a boolean model that includes the *paragraph operator*, plus a measure that determines the closeness among keywords to rank the paragraphs.

Experiment 3. Again, extract keywords from questions and run them against the paragraph index. Additionally, we allow the *semantic wildcard* (including named entity tags) to be specified in the keywords.

The results of experiments 1 and 2 are compared, to show the power of paragraph indexing. Experiments 2 and 3 provide comparative results to support the use of semantics, specifically the *semantic wildcard*.

The first experiment represents a classic keyword-based information retrieval run, and therefore we evaluate it in terms of *precision*, *recall* and *F-measure*. The second and third experiments are also evaluated in terms of *precision*, *recall* and *F-measure*. Additionally, we use the *success rate* and *TREC score*.

5.4. Walk-through Examples

This section gives several running examples of the IRSLO system, using the *semantic wildcard* and *paragraph operator*.

Example 1. What is the brightest star visible from Earth?
Relevant paragraph. In the year 296036 , Voyager 2 will make its closest approach to Sirius , the brightest star visible from Earth .
Comments. The query formed in this case is star# AND bright AND Earth. Only two answers are found by the system, and the one listed above, which is the correct one, is ranked on the first position. Sirius is defined in WordNet as a star, and consequently was annotated as such in the text.

Example 2. What kind of sports team is the Buffalo Sabres?
Relevant paragraph. Another religious broadcasting company , Tri - State Christian TV Inc. of Marion , Ill. , which was set up with the help of loan guarantees from Trinity , announced recently that it has purchased WNYB Channel 49 in Buffalo , N.Y. , from the Buffalo Sabres hockey team for $2.5 million .
Comments. The query employed is team# AND Buffalo AND Sabres. The original query team# AND sport AND Buffalo AND Sabres did not return any answers, and consequently the back off scheme was invoked and dropped noun modifiers. A total of six paragraphs are found in return to this question, all of them correct.

Example 3. What U.S. Government agency registers trademarks?
Relevant paragraph. After your application arrives at the Patent Office , it is turned over to an attorney who determines whether there is anything " confusingly similar "between your trademark and others [...]
Comments. Patent Office is a type of Government agency, and therefore the query U.S. AND government_agency# AND trademark leads to the correct answer.

Example 4. What cancer is commonly associated with AIDS?
Relevant paragraph. A team of transplant specialists at City of Hope National Medical Center in Duarte is among several groups nationwide that plan to test the experimental procedure on a small number of patients with AIDS - related lymphomas , or tumors of the lymph nodes .
Comments. The query employed is cancer# AND AIDS. The answer was found at rank 4, and it seems that none of the teams in the TREC competition identified this answer, because there is no direct reference in the text to cancer, but only a hidden relation from lymphomas to cancer. Our semantic model has the capacity to detect such non-explicit relations.

5.5. Results

Tests were performed using the benchmark of 75 questions. For each question, we run three experiments, as mentioned earlier. (1) Keyword-based information retrieval using a TF/IDF scheme. (2) Paragraph indexing and retrieval (i.e. enable the paragraph operator). (3) An experiment that involves both paragraph operator and semantic wildcard.

Precision, *recall* and *F-measure* are determined for all these experiments. We have also determined *success rate* and *TREC score*.

Ten sample requests of information are presented below, with their evaluations shown in Table 2. The following notations are used: P = *precision*, R = *recall*, F = *F-measure*, SR = *Success Rate*, TS = *TREC score*.

1. What American composer wrote the music for "West Side Story"?
2. What U.S. Government agency registers trademarks?
3. What U.S. state's motto is "Live free or Die"?
4. What actor first portrayed James Bond?
5. What animal do buffalo wings come from?
6. What cancer is commonly associated with AIDS?
7. What city does McCarren Airport serve?
8. What instrument does Ray Charles play?
9. What is the population of Japan?
10. What is the tallest building in Japan?

Cumulative results for all 75 questions are compared in Table 2. It turns out that the *F-measure* doubles when paragraph indexing is used with respect to document indexing, with increased *precision* and lower *recall*, as expected. The *success rate* is determined for the second and third experiments to evaluate the effect of the *semantic wildcard* over simple paragraph indexing, and an increase of 17% is observed. As of the *TREC score*, the additional use of semantics brings a gain of 34% with respect to simple paragraph indexing.

These results are very encouraging, and in agreement with the suggestions made in (Light et al., 2002) that query expansion and semantic relations are essential for increased performance, for information retrieval in general and Q&A systems in particular.

6. Related Work

Significant work has been performed in the field of semantics applied to information retrieval. The most important directions include: (1) query expansion (Voorhees, 1998), (2) phrase indexing (Strzalkowski et al., 1996), (3) conceptual indexing (Woods, 1997), (4) semantic indexing (Sussna, 1993), (Krovetz, 1997). In addition, the Semantic Web is a new field that considers the use of semantics for Web applications (Berners-Lee et al., 2001).

7. Conclusion

This paper has introduced the *semantic wildcard*, a novel operator that enables the use of semantics in information retrieval applications. The *semantic wildcard*, together with the new *paragraph operator*, were implemented in the IRSLO system. Experiments were performed on a collection of 130,000 documents with 75 *What*-questions extracted from the questions released during TREC competitions. Three experiments were performed. (1) One that

Abstract

Query expansion is considered as one of the most important methods in improving the effectiveness of information retrieval. By combining query expansion with dictionary-based translation and statistics-based disambiguation, in order to overcome query terms ambiguity, information retrieval should become much more efficient. In the present paper, we focus on query terms disambiguation via, a combined statistical method both before and after translation, in order to avoid source language ambiguity as well as incorrect selection of target translations. Query expansion techniques through relevance feedback were performed prior to either the first or the second disambiguation processes. We tested the effectiveness of the proposed combined method, by an application to a French-English Information Retrieval. Experiments involving TREC data collection revealed the proposed disambiguation and expansion methods to be highly effective.

1. Introduction

In recent years, the number of studies concerning Cross-Language Information Retrieval (CLIR) has grown rapidly, due to the increased availability of linguistic resources for research. Cross-Language Information Retrieval consists of providing a query in one language and searching document collections in one or more languages. Therefore, a translation form is required. In the present paper, we focus on query translation, disambiguation and expansion in order to improve the effectiveness of information retrieval through various combinations of these methods. First, we are interested to find retrieval methods that are capable of performing across languages and which do not rely on scarce resources such as parallel corpora. Bilingual Machine Readable-Dictionaries (MRDs), more prevalent than parallel texts, appear to be a good alternative. However, simple translations tend to be ambiguous and yield poor results. A combination that includes a statistical approach for a disambiguation can significantly reduce errors associated with *polysemy*[1] in dictionary translation. In addition, automatic query expansion, which has been known to be among the most important methods in overcoming the word mismatch problem in information retrieval, is also considered. As an assumption to reduce the effect of ambiguity and errors that a dictionary-based method would cause, a combined statistical disambiguation method is performed both prior to and after translation. Although, the proposed information retrieval system is general across languages in information retrieval, we conducted experiments and evaluations concerning French-English information retrieval.

The remainder of the present paper is organized as follows. Section 2 provides a brief overview of related works. Both dictionary-based and the proposed disambiguation methods are described in Section 3. A combination involving query expansion is described in Section 4. Evaluation and discussion of the experiments of the present study are presented in Section 5. Section 6 involves Word Sense Disambiguation and Section 7 describes the conclusion of the present paper.

2. Related Research in CLIR

The potential of knowledge-based technology has led to increasing interest in CLIR. The query translation of an automatic MRD, on its own, has been found to lead to a drop in effectiveness of 40-60 % compared to monolingual retrieval (Hull and Grefenstette, 1996; Ballesteros and Croft, 1997). Previous studies have used MRDs successfully, for query translation and information retrieval (Yamabana et al., 1996; Ballesteros and Croft, 1997; Hull and Grefenstette, 1996). However, two factors limit the performance of this approach. The first is that many words do not have a unique translation and sometimes the alternate translations have very different meanings (*homonymy and polysemy).* The fact that a single word may have more than one sense is called *ambiguity.* Translation ambiguity significantly exacerbates the problem in CLIR (Oard, 1997). Most of the previously proposed disambiguation strategies rely on statistical approaches, but without considering ranking or selection of source query terms, which affect directly the selection of target translations. The second challenge is that dictionary may lack some terms that are essential for a correct interpretation of the query. In the present study, we propose the concept of the combined statistical disambiguation technique, applied prior to and after dictionary translation to solve lexical semantic ambiguity. In addition, a monolingual thesaurus is introduced to overcome bilingual dictionary limitation. Automatic query expansion through relevance feedback, which has been used extensively to improve the effectiveness of an information retrieval (Ballesteros and Croft, 1997; Loupy et al., 1998), is considered. Selection of expansion terms was performed through various means. In the present study, we use a ranking factor to select the best expansion terms-those related to all source query terms, rather than to just one query term.

[1] Polysemy is a word, which has more than one meaning.

3. Translation/Disambiguation in CLIR

There are two types of lexical semantic ambiguity with which a machine translation system must contend: there is ambiguity in the source language where the meaning of a word is not immediately apparent but also ambiguity in the target language when a word is not ambiguous in the source language but it has two or more possible translations (Hutchins and Sommers, 1992). In the present research, query translation/disambiguation phases are performed after a simple *stemming* process of query terms, replacing each term with its inflectional root and each verb with its infinitive form, as well removing most plural word forms, stop words and stop phrases. Three primary tasks are completed using the translation/disambiguation module. First, an *organization of source query terms*, which is considered key to the success of the disambiguation process, will select best pairs of source query terms. Next a *term-by-term translation* using the dictionary-based method (Sadat et al., 2001), where each term or phrase in the query is replaced by a list of its possible translations, is completed. Missing words in the dictionary, which are essential for the correct interpretation of the query. This may occur either because the query deals with a technical topic, which is outside the scope of the dictionary or because the user has entered some form of abbreviations or slang, which is not included in the dictionary (Oard, 1997). To solve this problem, an automatic *compensation* is introduced, via synonym dictionary or existing thesaurus in the concerned language. This case requires an extra step to look up the query term in the thesaurus or synonym dictionary, find equivalent terms or synonyms of the targeted source term, thus performing a query translation. In addition, short queries of one term are concerned by this phase. The third task, *disambiguation of target translations*, selects best translations related to each source query term. Finally, documents are retrieved in target language.

Figure 1 shows thee overall design of the proposed information retrieval system. Query expansion will be applied prior to and/or after the translation/disambiguation process. Among the proposed expansion strategies are, relevance feedback and thesaurus-based expansion, which could be interactive or automatic.

3.1. Organization of Source Query Terms

All possible combinations of source query terms are constructed and ranked depending on their mutual co-occurrence in a training corpus. A type of statistical process called *co-occurrence tendency* (Maeda et al., 2000; Sadat et al., 2001) can be used to accomplish this task. Methods such as Mutual Information MI (Church and Hanks, 1990), the Log-Likelihood Ratio LLR (Dunning, 1993), the Modified Dice Coefficient or Gale's method (Gale and Church, 1991) are all candidates to the co-occurrence tendency.

3.2. Co-occurrence Tendency

If two elements often co-occur in the corpus, then these elements have a high probability of being the best translations among the candidates for the query terms. The selection of pairs of source query terms to translate as well as the disambiguation of translation candidates in order to select target ones, is performed by applying one of the statistical methods based on co-occurrence tendency, as follows:

• *Mutual Information (MI)*

This estimation uses *mutual information* as a metric for significance of word co-occurrence tendency (Church and Hanks, 1990), as follows:

$$MI(w_1, w_2) = \log \frac{Prob(w_1, w_2)}{Prob(w_1)Prob(w_2)}$$

Here, $Prob(w_i)$ is the frequency of occurrence of word w_i divided by the size of the corpus N, and $Prob(w_i, w_j)$ is the frequency of occurrence of both w_i and w_j together in a fixed window size in a training corpus, divided by the size of the corpus N.

• *Log-Likelihood Ratio (LLR)*

The Log-Likelihood Ratio (Dunning, 1993) has been used in many researches. LLR is expressed as follows:

$$-2\log \lambda = K_{11}\log \frac{K_{11}N}{C_1R_1} + K_{12}\log \frac{K_{12}N}{C_1R_2} + K_{21}\log \frac{K_{21}N}{C_2R_1} + K_{22}\log \frac{K_{22}N}{C_2R_2}$$

Where, $C_1 = K_{11} + K_{12}$, $C_2 = K_{21} + K_{22}$, $R_1 = K_{11} + K_{21}$, $R_2 = K_{12} + K_{22}$, $N = K_{11} + K_{12} + K_{21} + K_{22}$,
K_{11} = *frequency of common occurences of word* w_i *and word* w_j , K_{12} = *corpus frequency of word* w_i - K_{11} ,
K_{21} = *corpus frequency of word* w_j - K_{11} , $K_{22} = N - K_{12} - K_{22}$.

3.3. Disambiguation of Target Translations

A word is *polysemous* if it has senses that are different but closely related. As a noun, for example, *right* can mean something that is morally acceptable, something that is factually correct, or one's entitlement. A two-terms disambiguation of translation candidates can be applied (Maeda et al., 2000; Sadat et al., 2001) is required, following a dictionary-based method. All source query terms are generated, weighed, ranked and translated for a disambiguation through co-occurrence tendency. The classical procedure for a *two-term disambiguation*, is described as follows:

1. Construct all possible combinations of pairs of terms, from the translation candidates.
2. Request the disambiguation module to obtain the co-occurrence tendencies. The window size is set to one paragraph of a text document rather than a fixed number of words.
3. Choose the translation, which shows the highest co-occurrence tendency, as the most appropriate.

As illustrated in Figure 2, the disambiguation procedure is used for two-term queries due to the computational cost (Maeda et al., 2000). In addition, the primary problem concerning long queries, involves the selection of pairs of terms, as well as the order for disambiguation. We propose and compare two methods for *n-term disambiguation,* for queries of two or more terms. The first method is based on a ranking of pairs of source query terms before the translation and disambiguation of target translations. The key concept in this step is to maintain the ranking order from the organization phase and perform translation and disambiguation starting from the most informative pair of source terms, i.e. a pair of source query terms having the highest co-occurrence tendency. Co-occurrence tendency is involved in both phases,

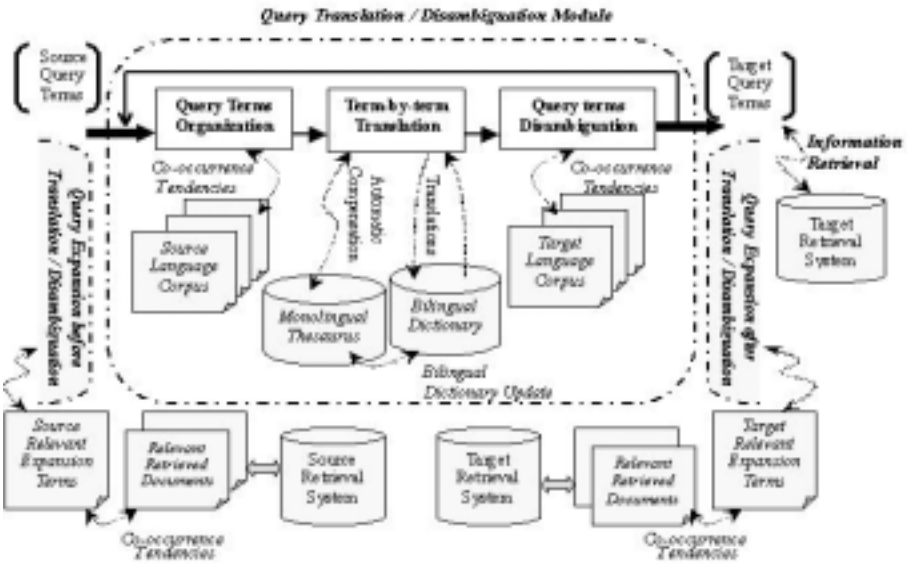

Figure 1: An overview of the Proposed Information Retrieval System
(In this research, source/target languages are French/English)

organization for source language and disambiguation for target language. The second method is based on a ranking of target translation candidates. These methods are described as follows: Suppose, Q represents a source query with n terms $\{s_1, s_2, \ldots, s_n\}$.

First Method: *(Ranking source query terms and disambiguation of target translations)*

1. Construct all possible combinations of terms of one source query: (s_1, s_2), (s_1, s_3), … (s_{n-1}, s_n).
2. Rank all combinations, according to their co-occurrence tendencies[2] toward highest values.
3. Select the combination (s_i, s_j), having the highest co-occurrence tendency, where at least one translation of the source terms has not yet been fixed.
4. Retrieve all related translations to this combination from the bilingual dictionary.
5. Apply a two-term disambiguation process to all possible translation candidates,
6. Fix the best target translations for this combination and discard the other translation candidates.
7. Go to the combination having the next highest co-occurrence tendency, and repeat steps 3 to 7 until every source query term's translation is fixed.

Second Method: *(Ranking and disambiguation of target translations)*

1. Retrieve all possible translation candidates for each source query term s_i, from the bilingual dictionary.
2. Construct sets of translations T_1 , T_2, …, T_n related to each source query term s_1 , s_2, …, s_n, and containing all possible translations for the concerned source term. For example, $T_i = \{t_{i1}, \ldots, t_{in}\}$ is the translation set for term s_i.
3. Construct all possible combinations of elements of different sets of translations. For example, (t_{11}, t_{21}), (t_{11} , t_{22}), …. (t_{ij} , t_{nk}),
4. Select the combination having the highest co-occurrence tendency[2].
5. Fix these target translations, for the related source terms and discard the other translation candidates.
6. Go to the next highest co-occurrence tendency and repeat step 4 through 6, until every source query term's translation is fixed.

Examples using the two proposed disambiguation methods are shown in Figures 3 and 4 for source English queries and target French translations.

4. Query Expansion in CLIR

Following the research reported by (Ballesteros and Croft, 1997) on the use of local feedback, the addition of terms that emphasize query concepts in the pre and post-translation phases improves both precision and recall. In the present study, we have proposed the combined automatic query expansion before and after translation through a relevance feedback. Original queries were modified, using judgments of the relevance of a few highly ranked documents, obtained by an initial retrieval, based on the presumption that those documents are relevant. However, query expansion must be handled very carefully. Simply selecting any expansion term from relevant retrieved documents could be risky. Therefore, our selection is based on the co-occurrence tendency in conjunction with all terms in the original query, rather than with just one query term. Assume that we have a query Q with n terms, $\{term_1 \ldots term_n\}$, then a ranking factor based on the co-occurrence frequency between each term in the query and an expansion term candidate, already extracted from the top retrieved relevant documents, is evaluated as:

$$Rank(expterm) = \sum_{i=1}^{n} co - occur(term_i, exp\ term)$$

[2] Co-occurrence tendency is based on one of the statistical methods: Mutual Information or Log-Likelihood Ratio, …

where, *co-occur(term$_i$, expterm)* represents the co-occurrence tendency between a query term *term$_i$* and the targeted expansion candidate *expterm*. *Co-occur(term$_i$, expterm)* can be evaluated by any estimation technique, such as mutual information or the log-likelihood ratio. All co-occurrence values were computed and then summed for all query terms (*i =1 to n*). An expansion candidate having the highest rank was then selected as an expansion term for the query Q. Note that the highest rank must be related to at least the maximum number of terms in the query, if not all query terms. Such expansion may involve several expansion candidates or just a subset of the expansion candidates.

5. Experiments and Evaluation

Experiments to evaluate the effectiveness of the two proposed disambiguation strategies, as well as the query expansion, were performed using an application of French-English information retrieval, i.e. French queries to retrieve English documents.

5.1. Linguistics Resources

Test Data: In the present study, we used test collection 1 from the TREC[3] data collection. Topics 63-150 were considered as English queries and were composed of several fields. Tags <num>, <dom>, <title>, <desc>, <smry>, <narr> and <con> denote topic number, domain, title, description, summary, narrative and concepts fields, respectively. Key terms contained in the title field <title> and description field <desc>, an average of 5.7 terms per query, were used to generate English queries. Original French queries were constructed by a native speaker, using manual translation.

Monolingual Corpora: The Canadian Hansard corpus (parliament debates) is a bilingual French-English parallel corpus, which contains more than 100 million words of English text as well as the corresponding French translations. In the present study, we used Hansard as a monolingual corpus for both French and English languages.

Bilingual Dictionary: COLLINS French-English dictionary was used for the translation of source queries.

Monolingual Thesaurus: EuroWordNet (Vossen, 1998) a lexical database was used to compensate, for possible limitations in the bilingual dictionary.

Stemmer and Stop Words: Stemming was performed using the English *Porter*[4] *Stemmer*. A special French stemming was developed and used in these experiments.

Retrieval System: The *SMART Information Retrieval System*[5] was used to retrieve both English and French documents. SMART is a vector model, which has been used in several studies concerning Cross-Language Information Retrieval.

5.2. Experiments and Results

A retrieval using original English/French queries was represented by *Mono_Fr/Mono_Eng* methods, respectively. We conducted two types of experiments. Those related to the query translation/disambiguation and those related to the query expansion before and/or after translation. Document retrieval was performed using original and constructed queries by the following methods. *All_Tr* is the result of using all possible translations for each source query term, obtained from the bilingual dictionary. *No_DIS* is the result of no disambiguation, which means selecting the first translation as the target translation for each source query term. We tested and evaluated two methods fulfilling the disambiguation of

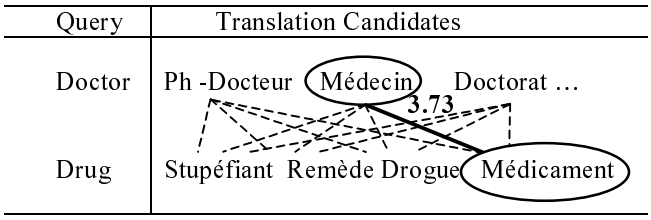

Figure 2: Two-Term Disambiguation Process

Highest co-occurrence tendencies for combinations of target translation candidates are as follows: (médecin, médicament), (médecin, remède), (médecin, drogue) …
Source French query: "doctor drug". Translated query to English: "médecin mèdicament".

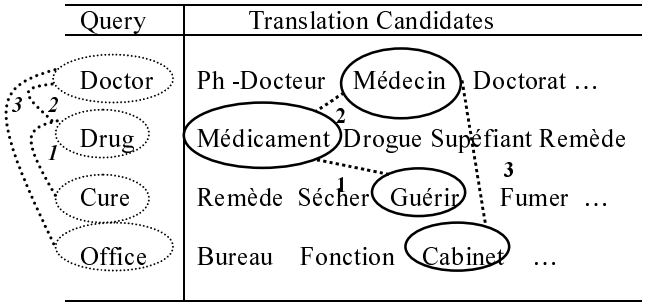

Figure 3: N-Term Disambiguation *(First Method)*: Ranking Source Query Terms and Disambiguation of Target Translations

Highest co-occurrence tendencies related to pairs of source query terms are as follows: (drug, cure), (doctor, drug), (doctor, office), (doctor, cure)…
Source French query:" doctor drug cure office". Translated query to English: "médecin mèdicament guérir cabinet".

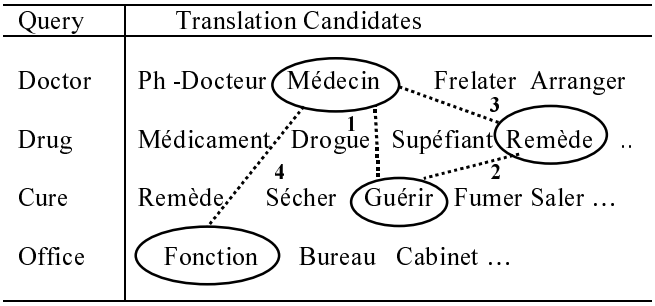

Figure 4: N-Term Disambiguation *(Second Method)*: Ranking and Disambiguation of Target Translations

Highest co-occurrence tendencies related to target translation candidates are as follows: (médecin, guérir), (guérir, remède), (remède, médecin) (médecin, fonction)…
Source French query: "doctor drug cure office". Translated query to English: "médecin remède guérir fonction".

translated queries (after translation) and the organization of source queries (before translation), using the co-occurrence tendency and the following estimations: Log-Likelihood Ratio (LLR) and Mutual Information (MI). LLR was used for *Bi_DIS*, disambiguation of consecutive pairs of source terms, without any ranking or selection (Sadat, 2001), for *LLR_DIS.bef*, the result of the first proposed disambiguation method (ranking source query terms, translation and disambiguation of target translations) and *LLR_DIS.aft*, the result of the second proposed disambiguation method (ranking and selecting target translation). In addition, MI estimation was applied to *MI_DIS.bef* and *MI_DIS.aft*, for the first and second proposed disambiguation methods. Query expansion was completed by the following methods: *Feed.bef_LLR*, which represents the result of adding a number of terms to the original queries and then performing a translation and disambiguation via *LLR_DIS.bef. Feed.aft*, is the result of query translation, disambiguation via *LLR_DIS.bef* method and then expansion. Finally, *Feed.bef_aft*, is the result of combined query expansion both before and after the translation and disambiguation via *LLR_DIS.bef.* In addition, we tested a query expansion before and after the disambiguation method MI_DIS.bef, together with the following methods: Feed.bef_MI, Feed.aft_MI and Feed.bef_aft_MI. Results and performance of these methods are described in Table 1. Figures 5 and 6 show the query translation/disambiguation using LLR and MI. Figures 7 and 8 show the query expansion for different combinations and estimations for the co-occurrence tendency (LLR or MI).

5.3. Discussion

The first column of Table 1 indicates the method. The second column indicates the number of retrieved relevant documents, and the third column indicates the precision averaged at point 0.10 on the Recall/Precision curve. The fourth column is the average precision, which is used as a basis for the evaluation. The fifth column is the R-precision and the sixth column represents the difference in term of average precision of the monolingual counterpart. Compared to the retrieval using original queries (English or French), *All_Tr* and *No_DIS* showed no improvement in term of precision, recall or average precision, whereas the simple two-term disambiguation *Bi_DIS* (disambiguation of consecutive pairs of source query terms) has increased the recall, precision and average precision by +1.71% compared to the simple dictionary translation without any disambiguation. On the other hand, the first proposed disambiguation method (ranking and selecting target translations) *LLR_DIS.aft,* showed a potential precision enhancement, 0.5012 at 0.10 and 90.82% average precision; however, recall was not improved (4131 relevant documents retrieved). The best performance for the disambiguation process was achieved by the second proposed disambiguation method (ranking source query terms and selecting target translations) *LLR_DIS.bef*, in average precision, precision and recall. The average precision was 101.51% of the monolingual counterpart, precision was 0.5144 at 0.10 and 436 relevant documents were retrieved. This suggests that ranking and selecting pairs for source query terms, is very helpful in the disambiguation process to select best target translations, especially for long queries of at least three terms. Results based on mutual information were less efficient compared to those using log-likelihood ratio. However, ranking source query terms before the translation and disambiguation resulted in an improvement in average precision, 100.91% of the monolingual counterpart. Although, query expansion before translation via *Feed.bef_LLR*/*Feed.bef_MI*, gave an improvement in average precision compared to the non-disambiguation method *No_DIS*, a slight drop in precision (0.4507/0.4394) and recall (413/405 relevant retrieved documents) was observed compared to *LLR_DIS.bef* or *MI_DIS.bef.* However, *Feed.aft_LLR/Feed.aft_MI* showed an improvement in average precision, 101.33%/101.25% compared to the monolingual counterpart and improved the precision (0.5153/0.5133 at 0.10) and the recall (433/ 430 retrieved relevant documents). Combined feedbacks both before and after translation yielded the best result, with an improvement in precision (0.5242 at 0.10), recall (434 retrieved relevant documents) and average precision, 102.89% of the monolingual counterpart when using LLR estimation. A disambiguation using MI for co-occurrence tendency yielded a good result, 103.53% of the monolingual counterpart for average precision. These results suggest that combined query expansion both before and after the proposed translation/disambiguation method improves the effectiveness of an information retrieval, when using a co-occurrence tendency based on MI or LLR.

Thus, techniques of primary importance to this successful method can be summarized as follows:

- A statistical disambiguation method based on the co-occurrence tendency was applied first prior to translation, in order to eliminate misleading pairs of terms for translation and disambiguation. Then after translation, the statistical disambiguation method was applied in order to avoid incorrect sense disambiguation and to select best target translations.
- Ranking and careful selection are fundamental to the success of the query translation, when using statistical disambiguation methods.
- A combined statistical disambiguation method before and after translation provides a valuable resource for query translation and thus information retrieval,
- Log-Likelihood Ratio was found to be more efficient for query disambiguation than Mutual Information,
- A co-occurrence frequency to select an expansion term was evaluated using all terms of the original query, rather than using just one query term.
- Each type of query expansion has different characteristics and therefore combining various types of query expansion could provide a valuable resource for use in query expansion. This technique offered the greatest performance in average precision.
- These results showed that CLIR could outperform the monolingual retrieval. The intuition of combining different methods for query disambiguation and expansion, before and after translation, has confirmed that monolingual performance is not necessarily the upper bound for CLIR performance (Gao et al., 2001). One reason is that those methods have completed each other and that the proposed query disambiguation had a positive effect during the translation and thus retrieval. Combination to query expansion had an effect on the translation as well, because related words could be added.

The proposed combined disambiguation method prior to and after translation, was based on a selection of one target translation in order to retrieve documents. Setting a threshold in order to select more than one target translation is possible using weighting scheme for the selected target translations in order to eliminate misleading terms and construct an optimal query to retrieve documents.

6. Word Sense Disambiguation (WSD)

Word sense ambiguity is a pervasive characteristic of natural language and information retrieval. It is considered as one of the major causes of poor performance in Information Retrieval systems. We believe that a relationship between disambiguation, word sense ambiguity and IR, exists (Sanderson, 1994). Our proposed disambiguation method makes use of statistics data based on co-occurrence between words, which can be extracted from large language corpora. The motivation for this type of approach is the assumption that the used data will provide enough information to resolve most of word sense ambiguities encountered in practical applications. The acquisition of statistical data relies on the availability of training corpora, which is easier to acquire than parallel or aligned corpora. This approach could be well incorporated into Word Sense Disambiguation (WSD) when using dictionary-based translation. Moreover, it is easy to implement and cost effective. We believe that resolving word senses is worthwhile and could have a great impact on the recall and precision, especially, when training corpora are related to particular or different subject areas (Krovetz and Croft, 1992).

7. Conclusion

Dictionary-based method is attractive for several reasons. This method is cost effective and easy to perform, resources are readily available and performance is similar to that of other Cross-Language Information Retrieval methods. Ambiguity arising from failure to translate queries is largely responsible for large drops in effectiveness below monolingual performance (Ballesteros and Croft, 1997). The proposed disambiguation approach of using statistical information from language corpora to overcome limitation of simple word-by-word dictionary-based translation has proved its effectiveness, in the context of information retrieval. A co-occurrence tendency based on a log-likelihood ratio has showed to be more efficient than the one based on mutual information. The combination of query expansion techniques, both before and after translation through relevance feedback improves the effectiveness of simple word-by-word dictionary translation. We believe that the proposed disambiguation and expansion methods will be useful for simple and efficient retrieval of information across languages.

Ongoing research includes a search for additional methods that may be used to improve the effectiveness of information retrieval. Such methods may include the combination of different resources and techniques for optimal query expansion across languages. In addition, thesauri and relevance feedbacks will be studied in greater depth. A good word sense disambiguation model will incorporate several types of data source that complete each other, such as a part-of-speech tagger into statistical models. Finally, an approach to learning from documents categorization and classification in order to extract relevant expansion terms will be examined in the future.

Acknowledgments

The present study is supported in part by the Ministry of Education, Culture, Sports, Science and Technology of Japan, under grants 11480088, 12680417 and 12208032, and by the CREST program of the JST Corporation (Japan Science and Technology). We would like to thank Dr Claude de Loupy and all reviewers for their helpful comments on the earlier version of this paper.

Abstract

External linguistic resources have been used for a very long time in information extraction. These methods enrich a document with data that are semantically equivalent, in order to improve recall. For instance, some of these methods use synonym dictionaries. These dictionaries enrich a sentence with words that have a similar meaning. However, these methods present some serious drawbacks, since words are usually synonyms only in restricted contexts. The method we propose here consists of using word sense disambiguation rules (WSD) to restrict the selection of synonyms to only these that match a specific syntactico-semantic context. We show how WSD rules are built and how information extraction techniques can benefit from the application of these rules.

1. Introduction

In today's world, the society of communications is gaining in importance every day. The amount of electronic documents – mainly by Internet, but not only – grows more and more. With this increase, no one is able to read, classify and structure those documents so that the requested information can be reached when it is needed. Therefore we need tools that reach a shallow understanding of the content of these texts to help us to select the requested data.

The process of understanding a document consists in identifying the concepts of the document that correspond to requested information. This operation can be performed with linguistic methods that permit the extraction of various components related to the data that are requested.

Since the beginning of the '90s, several research projects in information extraction from electronic text have been using linguistic tools and resources to identify relevant elements for a request. The first ones, based on domain-specific extraction patterns, use hand-crafted pattern dictionaries (CIRCUS (Lehnert, 1990)). But systems were quickly designed to build extraction pattern dictionaries automatically. Among these systems, AutoSlog (Riloff, 1993; Riloff and Lorenzen, 1999) builds extraction pattern dictionaries for CIRCUS. CRYSTAL (Soderland et al., 1995) creates extraction patterns lists for BADGER, the successor of CIRCUS. These learners use hand-tagged specific corpora to identify structures containing the relevant information. The syntactic structure used by CRYSTAL is more subtle than the one used by AutoSlog. CRYSTAL is able to make the most of semantic classes. WHISK (Soderland, 1999) is one of the most recent information extraction system. WHISK has been designed to learn which data to extract from structured, semi-structured and free text [1]. A parser and a semantic tagger have been implemented for free text. This system is the only one to process all of these three categories of text.
