A B S T R A C T

Background: The importance of pigeons as reservoirs and carriers of Cryptococcus neoformans and other species of this genus is well-known; however, less is known about their role as reservoirs and carriers of other yeasts that impact public health.

Aims: The present study was performed on Gran Canaria Island to define yeasts other than Cryptococcus spp. that have been reported to impact public health and which could be carried by pigeons.

Methods: Samples were obtained from 83 pigeon lofts (Columbia livia); moreover, 331 crop samples, 331 cloacal samples and 174 dropping samples were collected. In addition, 17 dropping samples were taken from a total of 17 public squares. Samples were inoculated on Sabouraud dextrose agar with chloramphenicol.

Results: Different yeast species, i.e. Candida guilliermondii (24.36%), Candida kefyr (1.21%), Saccharomyces cerevisiae (2.43%), and Trichosporon asahii (1.21%) were isolated for the first time from the cloaca. The most frequently isolated yeast from the crop, cloaca and dropping samples from lofts was C. guilliermondii (30.46%, 24.36% and 49.37%, respectively). In addition, for the first time, C. kefyr (3.65%), Candida pelliculosa (2.43%), Candida rugosa (1.21%), T. asahii (3.65%), Trichosporon mucoides (3.65%) and Prototheca wickerhamii (1.21%) were obtained from crop samples; Candida pelliculosa (1.20%), T. asahii (9.63%) and T. mucoides (7.22%) were isolated from dropping samples in the lofts. Candida albicans was the most frequently isolated yeast in dropping samples collected in public squares.

Conclusions: It can be assumed that pigeons and their droppings act as carriers and reservoirs of Candida spp. and other zoonotic yeasts.

La paloma y sus excrementos como reservorios de Candida y otras levaduras zoonóticas

R E S U M E N

Antecedentes: Es bien conocido el papel que desempeña la paloma como reservorio y portadora de Cryptococcus neoformans y otras especies del género; sin embargo, se conoce poco sobre el papel que desempeña como reservorio y portadora de otras levaduras que se relacionan en la salud pública.

Objetivos: El presente estudio fue realizado en la isla de Gran Canaria para determinar otras levaduras diferentes del género Cryptococcus que podrían portar las palomas y que repercuten en la salud pública.

Métodos: Se tomaron muestras en 83 palomares (Columbia livia): 331 muestras de buche, 331 cloacales y 174 muestras de excrementos. También se tomaron 17 muestras de excrementos en 17 plazas públicas. Las distintas muestras se sembraron en agar glucosado de Sabouraud con chloramphenicol.

The role of pigeons and other birds as carriers of various important public health pathogens such as protozoa, fungi, bacteria and viruses is well-known. Pigeons and other birds play an important role in public health as carriers of Cryptococcus species, especially *Cryptococcus neoformans*. However, *Cryptococcus* is not the only yeast genus that impacts human public health, as there is currently a boom in pathologies involving other yeasts, especially *Candida* species. In the study, the newly emerging human pathogenic yeast species include *Malassezia furfur*, *Trichosporon asahii*, species of *Rhodotorula*, *Wickerhamomyces anomalus* and different species of *Candida* such as *Candida albicans*. To a lesser extent, *Candida lusitaniae*, *Candida holmii*, *Candida norvegensis*, *Candida valida* and *Candida dubliniensis* appear to be of importance in public health. Similarly, other agents that have previously been considered environmental pollutants or of industrial importance, such as *Candida utilis* and *Candida lipolytica*, are currently identified as agents of fungemia, onychomycosis and systemic disease. For this reason, it is important to study the different yeast strains derived from pigeon samples (crop, cloaca, droppings). The aim of this work was to define which genera of yeasts, other than *Cryptococcus*, could be carried by pigeons and their droppings.

**Materials and methods**

Sampling was performed in 83 pigeon lofts from 17 pigeon-breeding associations distributed throughout Gran Canaria Island (Spain). For this study, 331 samples from the crop and cloaca and 174 samples of pigeon droppings were analyzed. In addition, we also sampled 17 public squares, and a mixture of pigeon droppings from each park was taken.

Samples of the cloaca and crop were collected from 331 pigeons using sterile cotton swabs in a transport medium (Eurutobo®, Rubi, Barcelona, Spain). The swab was inserted and rotated in the cloaca after cleaning the area with antisepctic iodine solution (10%). For crop sampling, pigeons were restrained and after gently opening the beak of the pigeon, one swab was introduced into the crop. All samples were stored and kept at 4°C until further processing in the laboratory. Dropping samples from public squares and pigeon lofts were collected using sterile wooden spatulas and then kept in sterile vials at 4°C until further processing.

Fecal samples (2 g) were diluted in sterile saline solution (10 ml), homogenized by shaking and allowed to settle for 30 min. Then, 0.5 ml aliquots of each supernatant were used for inoculation on laboratory media agar. All samples (crop, cloaca and feces) were inoculated on Sabouraud dextrose agar and malt agar; chloramphenicol (50 mg/l) was added to the media to prevent bacterial growth. Plates were incubated at 30°C and 37°C (1–7 days) and inspected daily. All colonies with a microscopic morphology consistent with yeast were isolated and identified by auxanogram using API 20C Auxanogram strips and API ID 32C Auxanogram strips (bioMérieux®, Madrid, Spain).

For the strains identified as *Candida* spp., several complementary tests were performed. Pseudohyphae and blastoconidia production was analyzed using corn meal agar (Oxoid Limited, Basingstoke, England) with Tween 80 at a final concentration of 0.02% to reduce surface tension. The identification was performed using the technique described by Koneman et al. and confirmed by using the ChromID® Candida (bioMérieux®) and bird-seed agar.

**Results**

A total of 13 different yeast species belonging to four different genera (*Candida*, *Saccharomyces*, *Trichosporon*, *Rhodotorula*) and a strain of a unicellular alga belonging to the genus *Prototheca* were isolated. The relative incidence of each species detected in crop, cloaca and dropping samples is compiled in Table 1.

*Candida guillermondii* and *Candida albicans* were isolated in a significant percentage in the three sampling locations. *C. guillermondii* was the most frequently isolated yeast both in crop (30.46%) and cloaca (24.36%) samples. Regarding the yeasts isolated in dropping samples, *C. guillermondii* was also isolated the most frequently (49.37%), followed by *C. albicans* (15.66%), *T. asahii* (9.63%), *Rhodotorula mucilaginosa* and *Trichosporon mucoides* (7.22%). In contrast, *Candida kefyr*, *Candida zeylanoides* and *Prototheca wickerhamii* were not isolated from any dropping sample.

*C. albicans* was the most frequently isolated yeast in dropping samples of public squares (29.4%, 5/17), followed by two other yeasts with a significant impact (*Candida krusei* and *Candida inconspicua*, 17.6%, 3/17). The less frequently isolated were *C. guillermondii* and *Candida famata* (11.8%, 2/17), and finally, *C. albicans*. The incidence of yeast species isolated in crop, cloaca and dropping samples from pigeons is presented in Table 1.

C. lusitaniae, Candida glabrata and Candida pelliculosa were detected in only one public square (5.9%).

Discussion

The present study defines the incidence of different yeasts isolated from pigeon lofts. To our knowledge, the results show the first isolation of yeast species other than Cryptococcus spp. in pigeons from three sampling locations (crop, cloaca and droppings samples). These findings show that pigeons are a main reservoir of different species of yeasts, and this fact could be important for public health as there is currently an increase in cases of fungemia in humans.27

Few researchers have isolated fungal species from pigeon cloacas, and for this reason some of these yeast isolates in our study cannot be compared with previous studies in pigeons. Ramirez et al.28 isolated fourteen fungal species from the ilio-cecal-colic conjunction of feral pigeons (including C. albicans), similarly to our study. In 2005, Rosario et al.29 evaluated the prevalence of different yeasts (Cryptococcus genus) in samples from pigeon cloacas. Costa et al.30 reported the isolation of Candida, Trichosporon and R. mucilaginosa from cloaca samples. In the present study, several species (C. guilliermondii, C. albicans, C. kefyr, S. cerevisiae, T. asahii) were isolated for the first time from cloaca samples, although the most frequently isolated yeasts were C. guilliermondii and C. albicans.

The isolation of several yeast species from pigeon droppings has been previously reported. Vidotto and Gallo18 confirmed the presence of yeasts in pigeon stool in Turin and found that the fungal load was high. They isolated similar pathogenic yeasts to our study, such as C. guilliermondii, C. albicans, C. lusitaniae, C. parapsilosis, C. rugosa and S. cerevisiae, many of which are considered pathogenic10; therefore, they concluded that the pigeon is an important carrier of pathogens for humans and pets and represents a serious health problem. Gallo et al.13 isolated a total of 25 yeast species, and six of these yeast species were also reported in our study (C. rugosa, R. glutinis, C. parapsilosis, S. cerevisiae, C. albicans and C. guilliermondii). Maldonado et al.15 also identified the following species: C. holmii, C. globosa, C. norvegica, C. lacticola and Lachancea kluyveri (Saccharomyces kluyveri). Finally, R. mucilaginosa1 and Debaryomyces Hansenii var. Hansenii17 have also been isolated from pigeon droppings. In our study, a high number of previously reported yeasts were isolated from fecal samples; however, three yeast-like fungal isolates, T. asahii (9.3%), C. pelliculosa (1.20%) and T. mucoides (7.22%), were recovered for the first time in variable percentages from pigeon droppings.

According to our results, the excreta of pigeons are an ideal environment for Candida and Trichosporon replication. We isolated yeasts from these samples that had not been previously isolated from the crop or cloaca, such as C. parapsilosis and C. lusitaniae. Pigeon feces are an ideal environment for yeast replication with an impact on public health.

In this regard, T. asahii has been isolated from humans and causes a variety of diseases. It has been found in equipment rooms and lavatories, suggesting transmission through toilets. T. asahii has been reported as the most frequently isolated Trichosporon species in human patients, causing invasive trichosporonosis.24 Similarly, T. mucoides, frequently isolated from cases of invasive trichosporonosis, has been identified as being responsible for onychomycosis26 and has also been associated with human fungemia.19 Different studies have confirmed that invasive trichosporonosis has emerged as an opportunistic infectious disease in immunocompromised patients.24 and there are studies associating trichosporonosis in humans with close contact with pigeons.18 Finally, C. pelliculosa was reported as causing an outbreak of fungemia in neonatal intensive care unit14 and was also found in immunocompromised pediatric patients.12,25

Similarly to our study, a high number of yeast species (C. guilliermondii, C. albicans, C. zeylanoides, S. cerevisiae, R. glutinis and R. mucilaginosa) were isolated from crop samples by Hermoso de Mendoza et al.31 Furthermore, in our study different yeast species, such as C. kefyr, C. pelliculosa, C. rugosa, T. asahii and T. mucoides, were isolated from crop samples, and no previous references have reported the isolation of the abovementioned yeasts in pigeons. Prototheca wickerhamii, never previously isolated from pigeons, was also recovered from crop samples, but not from cloaca samples or droppings. Therefore, we can speculate that the isolation of P. wickerhamii from the crop could be due to water contamination. Prototheca wickerhamii rarely causes infection in humans but is capable of producing opportunistic infections of the skin and subcutaneous tissues in humans, especially in AIDS, diabetic or immunocompromised patients.9,11,29,30

It is likely that the emergence and increase of different pathogenic yeasts is due not only to a major incidence of infection among immunocompromised hosts, but also to changes in the pathogenic features of these species of yeasts and increasing resistance to antifungal agents, in particular azoles.32 Malassezia furfur, T. asahii, Rhodotorula, Pichia anomala, C. albicans, C. lusitaniae, C. holmii, C. norvegensis, C. valida and C. dublinensis have been reported as emerging pathogenic yeasts in humans.3 Even yeasts such as C. utilis and C. lipolytica, which are considered to be environmental pollutants and have industrial importance, have been identified as agents of fungemia, onychomycosis and systemic disease.7 The results of the present study show that a large number of yeasts with evident pathogenicity were recovered from both the crop and cloaca and, in addition, C. albicans was the most frequently isolated yeast in drooping samples from public squares. Feral pigeons usually deposit their feces anywhere and nest in the most unlikely places such as air conditioning systems, trees and cornices. These locations could represent a point of dissemination of these pathogens to a large number of sites including hospitals, schools or any place where the prevalence of immunocompromised individuals may be high, as these populations are potentially more sensitive to the effects of such pathogens.

In conclusion, pigeons are an important source of yeasts which could be pathogenic in humans. Pigeon stool is the ideal environment for the replication of T. asahii, T. mucoides and even Candida species, and pigeons are important carriers and reservoirs of C. albicans and C. guilliermondii.

Conflict of interest

The authors declare no conflict of interest.
